A
REFERENCE HANDBOOK
OF THE
MEDICAL SCIENCES

EMBRACING THE ENTIRE RANGE OF

SCIENTIFIC AND PRACTICAL MEDICINE
AND
ALLIED SCIENCE

BY VARIOUS WRITERS

ILLUSTRATED BY CHROMOLITHOGRAPHS AND FINE WOOD ENGRAVINGS

EDITED BY ALBERT H. BUCK, M.D.
NEW YORK CITY

VOLUME VIII.

NEW YORK
WILLIAM WOOD & COMPANY

NEW YORK.

PREFACE TO VOLUME VIII.

In bringing the present work to its termination I desire to make full acknowledgment of my indebtedness to various individuals for the aid which they have rendered me in this undertaking. More than three hundred men and women, experts in some particular department of medical knowledge or in one of the kindred sciences, have contributed the actual text of these eight volumes. Their names are appended to the articles which they have written, and the proportionate share which each has taken in building up this reservoir of medical facts and theories, may, therefore, readily be learned upon investigation. While thanking these writers, one and all, for their valuable contributions, I must at the same time call attention to the prompt and willing manner in which many of them have accepted the most laborious tasks. I mention this fact because it reveals the existence among the corps of contributors of a strong sense of professional pride—a desire to do all in their power toward the erection of a structure that might reflect credit upon the entire medical profession of the United States and Canada. Had it not been for this strong and wide-spread professional loyalty, if I may so term it, I am confident that it would have been found necessary either to abandon the Handbook scheme altogether, or else to have made the book a mere compilation or digest of existing treatises.

In the difficult task of selecting suitable topics and writers competent to discuss them authoritatively, I have continued to receive valuable assistance from several of the gentlemen named in the preface to Volume I., and also from the following: Prof. W. T. Councilman, M.D., of the Johns Hopkins University, Baltimore; Prof. Francis J. Shepherd, M.D., of McGill University, Montreal; Dr. A. T. Cabot, of Boston; and Prof. R. A. Witthaus, M.D., Prof. M. Allen Starr, M.D., Dr. Theodore H. Kellogg, and Dr. Leopold Putzel, of this city. To these gentlemen, and to those named in Volume I., I am very largely indebted for whatever degree of credit the editorial part of the undertaking may deserve.

Finally, I owe it to the publishers to say that from the beginning to the end of the work they have done everything that a generous, and when necessary lavish, expenditure of time and money could do to enable me to make the book as complete and as useful as possible to the profession.

The credit for the General Index is entirely due to Dr. Thomas L. Stedman, who from the very beginning of the enterprise has rendered me most valuable assistance.

Albert H. Buck.

LIST OF CONTRIBUTORS TO VOLUME VIII.

W. T. ALEXANDER, M.D.......New York, N. Y.
Physician to the New York Institution for Deaf and Dumb, and to the Colored Orphan Asylum.

CHARLES W. ALLEN, M.D......New York, N. Y.
Visiting Physician, Charity Hospital.

JAMES B. BAIRD, M.D...............Atlanta, Ga.

FRANK BAKER, M.D...........Washington, D. C.
Professor of Anatomy, Medical Department of Georgetown University.

JAMES BELL, M.D............ Montreal, Canada.
Assistant to the Chair of Clinical Surgery, McGill University; Surgeon to the Montreal General Hospital.

ALEXANDER D. BLACKADER, M.D...Montreal, Canada.
Instructor in Diseases of Children, McGill University; Assistant Physician, Montreal General Hospital; Physician to St. Margaret's Nursery, and the Protestant Infants' Home.

W. P. BOLLES, M.D. ....Boston, Mass.
Professor of Materia Medica and Botany, Emeritus, at the Massachusetts College of Pharmacy; Visiting Surgeon, Boston City Hospital.

EDWARD H. BRADFORD, M.D ....Boston, Mass.
Instructor in Clinical Surgery, Harvard Medical School; Surgeon to the Children's Hospital, the Boston City Hospital, and the Samaritan Hospital.

WILLIAM BROWNING, M.D.....Brooklyn, N. Y.

PETER H. BRYCE, M.D........ Toronto, Canada.
Secretary of the Provincial Board of Health of Ontario; Late Professor of Chemistry, Ontario Agricultural College.

SAMUEL C. BUSEY, M.D......Washington, D. C.
Fellow of the American Gynæcological Society; Member of the Association of American Physicians.

J. WELLINGTON BYERS, M.D..Charlotte, N. C.

ARTHUR T. CABOT, M.D...........Boston, Mass.
Clinical Instructor in Genito-urinary Surgery, Harvard University; Surgeon to Massachusetts General Hospital and to the Boston Children's Hospital.

HENRY C. COE, M.D........... New York, N. Y.
Lecturer on Gynæcology, New York Polyclinic; Surgeon to Maternity Hospital; Gynæcologist to the Presbyterian Hospital, Out-door Department.

J. SOLIS COHEN, M.D.........Philadelphia, Pa.

B. FARQUHAR CURTIS, M.D.. New York, N. Y.
Attending Surgeon, St. Luke's Hospital; Assistant Surgeon, New York Cancer Hospital.

EDWARD CURTIS, M.D. ...... New York, N. Y.
Professor Emeritus of Materia Medica and Therapeutics, College of Physicians and Surgeons, New York.

ROBERT H. M. DAWBARN, M.D..... New York, N. Y.
Lecturer on Operative Surgery, New York Polyclinic.

W. S. DENNETT, M.D..........New York, N. Y.
Assistant Surgeon, Ophthalmic Department, New York Eye and Ear Infirmary.

GEORGE T. ELLIOT, M.D......New York, N. Y.
Assistant Physician, New York Skin and Cancer Hospital; Attending Dermatologist, Demilt Dispensary.

GEORGE B. FOWLER, M.D.... New York, N. Y.
Professor of Medical Chemistry and Clinical Medicine, New York Post-graduate Medical School and Hospital; Visiting Physician, Bellevue Hospital, and the New York Infant Asylum.

JAMES M. FRENCH, M.D......... Cincinnati, O.
Lecturer on Morbid Anatomy and Demonstrator of Pathology, Medical College of Ohio; Attending Physician, St. Mary's Hospital.

SIMON HENRY GAGE, Ph.D....... Ithaca, N. Y.
Professor of Physiology, Cornell University.

GEORGE W. GAY, M.D.............Boston, Mass.
Surgeon to the Boston City Hospital.

JAMES R. GOFFE, M.D ....New York, N. Y.
Instructor in Gynæcology, New York Polyclinic; Visiting Physician, Episcopal Orphan Asylum.

FRANK HARTLEY, M.D........New York, N. Y.
Lecturer on Operative Surgery, College of Physicians and Surgeons; Visiting Surgeon, Bellevue Hospital; First Assistant Surgeon, Roosevelt Hospital.

GEORGE HAVEN, M.D............. Boston, Mass.

W. H. HOWELL, M.D.............Baltimore, Md.
Johns Hopkins University.

D. L. HUNTINGTON, M.D....... San Diego, Cal.
Surgeon, United States Army.

GEORGE S. HUNTINGTON, M.D ....New York, N. Y.
Demonstrator of Anatomy, College of Physicians and Surgeons; Chief of Clinic, Surgical Division of Vanderbilt Clinic; Assistant Surgeon, Roosevelt and Bellevue Hospitals.

GEORGE WOODRUFF JOHNSTON, M.D...Washington, D. C.
Professor of Gynæcology, National Medical College; Gynæcologist to the Central Dispensary.

WILLIAM W. KEEN, M.D..... Philadelphia, Pa.
Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College; Attending Surgeon to St. Mary's, St. Agnes', and the Woman's Hospitals.

RUFUS A. KINGMAN, M.D.........Boston, Mass.
Visiting Physician to the Boston Dispensary for Diseases of Women; Visiting Physician to St. Elizabeth's Hospital.

LIST OF CONTRIBUTORS TO VOLUME VIII

CHARLES J. KIPP, M.D. ..... Newark, N. J.
Surgeon to the Newark Charitable Eye and Ear Infirmary; Ophthalmic Surgeon to the Newark General Hospital.

ROBERT W. LOVETT, M.D. ....Boston, Mass.
Assistant Surgeon, Out-patient Department, Boston Children's Hospital.

J. PLAYFAIR McMURRICH, Ph.D. Johns Hopkins, Haverford College, Pa.
Professor of Biology, Haverford College.

JOHN NOLAN MACKENZIE, M.D. Baltimore, Md.
Clinical Professor of Diseases of the Throat and Nose, University of Maryland; Surgeon to the Baltimore Eye, Ear, and Throat Charity Hospital.

HENRY CHILDS MERWIN, LL.B., Boston, Mass.
Attorney and Counsellor at Law.

CHARLES SEDGWICK MINOT, S.D.......Boston, Mass.
Assistant Professor of Histology and Embryology, Harvard Medical School.

SAMUEL NICKLES, M.D. ....Cincinnati, O.
Professor of Materia Medica, Medical College of Ohio.

GEORGE LIVINGSTON PEABODY, M.D ....New York, N. Y.
Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons; Attending Physician, New York and Bellevue Hospitals.

FREDERICK PETERSON, M.D..New York, N. Y.
Chief of Clinic, Department for Diseases of the Nervous System, Vanderbilt Clinic, College of Physicians and Surgeons; Attending Physician, Hospital for Nervous Diseases, Blackwell's Island.

WILLIAM HENRY PORTER, M.D.... New York, N. Y.
Professor of Clinical Medicine and Pathology, New York Post-graduate Medical School and Hospital; Curator to the Presbyterian Hospital.

LEOPOLD PUTZEL, M.D.......New York, N. Y.
Visiting Physician, Randall's Island Hospital.

CHARLES E. QUIMBY, M.D... New York, N. Y.
Assistant Visiting Physician, Bellevue Hospital; Attending Physician, Department of Diseases of the Heart and Lungs, Bellevue and University Dispensaries.

HUNTINGTON RICHARDS, M.D. New York, N. Y.
Aural Surgeon, New York Eye and Ear Infirmary; Chief of Clinic, Department of the Ear, College of Physicians and Surgeons, New York.

E. C. SPITZKA, M.D............New York, N. Y.

M. ALLEN STARR, M.D........New York, N. Y.
Clinical Professor of Diseases of the Nervous System, College of Physicians and Surgeons; Attending Physician, Department of Diseases of the Nervous System, Demilt Dispensary.

THOMAS L. STEDMAN, M.D...New York, N. Y.
Late Attending Surgeon, New York Orthopaedic Dispensary and Hospital.

GEORGE M. STERNBERG, M.D. .... Washington, D. C.
Surgeon, United States Army.

WILLIAM GILMAN THOMPSON, M.D..New York, N. Y.
Professor of Physiology, New York University Medical College; Visiting Physician to the New York and Presbyterian Hospitals.

HENRY S. UPSON, M.D ....Cleveland, O.

ARTHUR VAN HARLINGEN, M.D..Philadelphia, Pa.
Professor of Diseases of the Skin, Philadelphia Polyclinic and College for Graduates in Medicine; Consulting Physician, Dispensary for Skin Diseases.

BURT G. WILDER, M.D..............Ithaca, N.Y.
Professor of Comparative Anatomy and Zoology, Cornell University.

HENRY CRÉCY YARROW, M.D ....Washington, D.C.
Honorary Curator, Department of Reptiles, United States National Museum.

A REFERENCE HANDBOOK
OF THE
MEDICAL SCIENCES.

WORMSEED, AMERICAN (*Chenopodium*, U. S. Ph. ; *Ansérine vermifuge*, Codex Med.). The fruit of *Chenopodium ambrosioides*, var. *anthelminticum* Gray ; Order *Chenopodiaceæ*.

This is a perennial form of *Ch. ambrosioides* Linn., Mexican Tea, Ambrosia, etc., an old-fashioned garden-plant of rather pleasant odor, now rarely cultivated, but frequently growing wild about old country houses. Wormseed grows two or three feet high, has nearly leafless spikes of minute green flowers, and oblong or lanceolate, strongly toothed leaves. All parts of the plant are fragrant and covered with glandular hairs. The flower is minute, consisting of a green, five-toothed calyx, which is persistent, and encloses the fruit ; five stamens, and a single one-ovuled ovary with two styles ; fruit, a little utricle, one or two millimetres ($\frac{1}{12}$ inch) in diameter, enclosing a single, black, shiny seed, embryo coiled in a ring, around the albumen. It is a native of the warmer parts of America, north and south, and has been introduced into the United States and Europe, where it has become naturalized. It is cultivated upon a commercial scale in Maryland, where the oil of the entire plant is distilled. The fruits, generally called "seeds," are "nearly one-twelfth of an inch (2 millimetres) in diameter, depressed, globular, glandular, dull-greenish or brownish, the integuments friable, containing a lenticular, obtusely-edged, glossy, black seed. It has a peculiar, somewhat terebinthinate odor, and a bitterish, pungent taste" (U. S. Ph.).

The fruits contain one or two per cent. of a rather disagreeable, minty, essential oil, which represents it medicinally. This oil is usually distilled from the entire herb. It is a thin, and, when fresh, colorless liquid of aromatic odor and bitterish taste, sp. gr., 0.920.

Like most aromatic herbs, chenopodium, in small doses, is a stomachic tonic ; in large doses it is irritating and nauseating. The property for which it is mostly prized is, however, its poisonous action upon intestinal worms, particularly upon the lumbrici. From five to fifteen drops of the oil in emulsion or on sugar is the usual range of doses.

ALLIED PLANTS.—*Ch. Botrys*, of Europe, in the same fragrant subsection of the genus, is often cultivated for its pleasant odor. Another group of the genus contains the various pigweeds, and related genera furnish beets and spinach. The typical species, *Ch. ambrosioides*, is official in France, "*Ambroisie du Mexique*," as well as *Ch. vulvaria* Linn., "*Vulvaire*," Codex Med.

ALLIED DRUGS.—See Koosso, and the article following this.

W. P. Bolles.

WORMSEED, LEVANT (*Santonica*, U. S. Ph. ; Br. Ph. ; *Flores Cini*, G. Ph. ; *Semen contra*, *Semencine ou Barbotine*, Codex Med., etc.).

These so-called seeds are neither seeds nor fruits, but the unexpanded flower-heads of a variable and not well defined species of *Artemisia :* A. *maritima*, var. *Stechmanniana* Besser ; Order *Compositæ*. *A. maritima* is a very widely scattered species, growing along the sea-coasts of

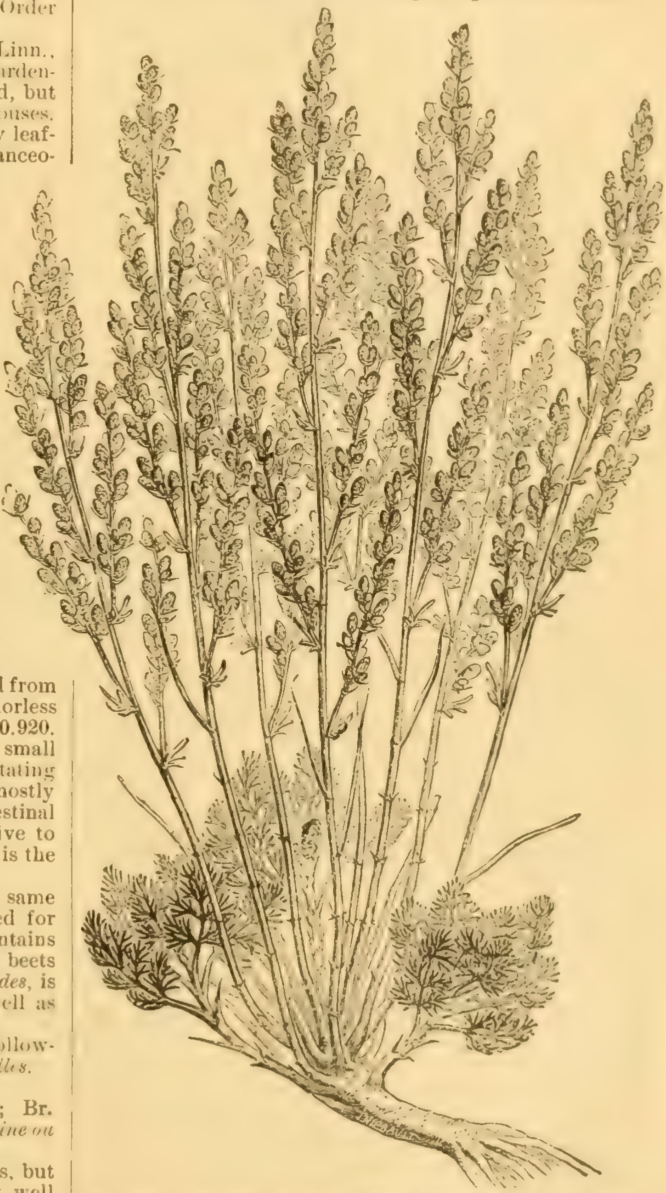

FIG. 4623.—Artemisia Pauciflora. Web. (Baillon.) The plant which, according to Baillon, furnishes the Levant Wormseed of the market.

Great Britain, France, the Mediterranean countries, in the Caspian and Black Sea basins, and elsewhere in Asia. The variety yielding Santonica grows in Southern Russia, Siberia, Asia Minor, Persia, etc., and the drug finds its way westward through St. Petersburg and the other ports of the Levant, whence its distinguishing name. Santonica is an old remedy, and without doubt has been in continuous use from the time of Dioscorides [illegible] down to the present (Pharmacographia).

It consists exclusively of the little unopened flower heads or capitula, picked just before blossoming and dried. They are about two millimetres, 1/12 inch long, ovoid, or narrowly oblong, smooth, of a greenish or brownish-green color, and so light that ninety of them weigh but a grain. They consist of an imbricated involucre of about eighteen oblong, obtuse, glandular scales, and from three to five immature tubular flowerets. No pappus. It has a strong, peculiar, camphoraceous odor, and an aromatic and bitter taste.

Composition.—Wormseed contains [illegible] volatile oil in which are cineol and camphor [illegible], and a very interesting and [illegible] crystalline principle, Santonin, to which it owes its valuable anthelmintic properties. This may be prepared by treating the wormseed with lime and alcohol, whereby the santonin is removed in combination with the lime, from which it is afterward separated, after distilling off the alcohol, by means of some acid. It is then redissolved and purified in the ordinary way. The yield is about two per cent. Santonin (Santoninum, U. S. Ph., [illegible]) is in colorless, shining, flat, rhombic prismatic crystals, not altered by exposure to air, but turning yellow on exposure to light; odorless and nearly tasteless when first placed in the mouth, but afterward bitter, and leaving a [illegible] taste. Nearly insoluble in cold water. Soluble in 250 parts of boiling water, in 40 parts of alcohol at 15° C. (59° F.), and in 8 parts of boiling alcohol; also soluble in 140 parts of ether, in 4 parts of chloroform, and in solutions of the alkalies. The alcoholic and ethereal solutions have an intensely bitter taste. By heating with various bases several santoninic acids are produced.

Action and Use.—Santonin is a pretty active substance, causing depression of the pulse, slowing of the breathing, trembling, sometimes severe tremors and convulsions, and in death. Pallor and cold sweats are also present. Most of the cases of poisoning by it have naturally been in children, and probably due to idiosyncrasy, as the doses were not very much larger than are frequently given. Yellow vision, in which all objects appear as if seen through a yellow glass, is a pathognomonic symptom of the absorption of santonin. It is a rather late-appearing phenomenon, and may last some days. Santonin is eliminated in alkaline combination in the urine, to which it also gives a deep orange color. It is not, however, with the hope of its physiological effects that either santonica or its active principle are given, but as a poison for intestinal worms, especially lumbrici. For this purpose it is an efficient one, on account of its comparative tastelessness and small bulk, a very convenient means, and is extensively employed, both by the profession and also in domestic practice, in the form of one or another of the popular "worm lozenges." The official troches of Santonin (Trochisci Santonini, U. S. Ph.) consist of one grain of santonin, a [illegible] of sugar, and half a grain of tragacanth each. One troche is a dose for a child five or six years of age. It is hardly safe to give santonin to very young children—two grains have caused death in one instance, and three or four grains have frequently produced dangerous symptoms in children.

Allied Plants.—Barbary wormseed is from another species of Artemisia. It is larger than Levant Wormseed, and [illegible] woolly. A. Absinthium is the Wormwood of the next article, and several other Artemisias are either called wormwoods or are used as such: [illegible]. They are all bitters like wormwood. For the order, see Chamomile.

Allied Drugs.—See Kousso.

W. P. Bolles.

WORMWOOD

WORMWOOD (*Absinthium*, U. S. Ph.; *Herba Absinthii*, Ph. G.; *Absinthe grande* ou *Aluyne*, Codex Med.).

Artemisia Absinthium Linn. Order, *Compositæ*. A European perennial, cultivated and naturalized in the United States. The [illegible] stems send up numerous slender, suffrutescent stems, about two feet high, with twice or thrice pinnate, silky, hoary leaves, and small panicles of nodding, hemispherical heads of yellowish flowers. Odor of crushed leaves, aromatic and fragrant; taste intensely bitter. The leaves and tops collected at the time of flowering are official. The Pharmacopœial description is as follows: "Leaves about [illegible] long, hoary, silky-pubescent, petiolate, roundish-triangular in outline, pinnately two or three cleft, with the segments lanceolate, the terminal one spatulate; heads [illegible] hemispherical, with numerous small, pale yellow florets, all tubular and without pappus; odor aromatic; taste persistently bitter."

The medicinal properties of wormwood are due to an essential oil of a dark green color, burning taste, and to some [illegible] of [illegible], and an incompletely crystalline neutral bitter principle, *Absinthin*. Wormwood has the [illegible] and aromatic properties that pervade many [illegible] in this great order, e.g., [illegible], chamomile, etc., and like them it is an agreeable stomachic. In large doses it is a disturber of the digestive apparatus and produces vomiting, diarrhœa, etc. It is also a convulsant of [illegible] power to [illegible] in use. It is not often prescribed at the present day by physicians.

Wormwood may be given in infusion like chamomile tea, or the essential oil may be given in small doses of from three to ten drops. It is an ingredient of a nearly obsolete liniment. [illegible] constitutes one per cent.

Allied Plants.—See Chamomile, and the preceding article.

Allied Drugs.—Most aromatic bitters.

W. P. Bolles.

WOUNDS, DRAINAGE OF.

WOUNDS, DRAINAGE OF. All wounds of healthy tissues are followed, after hemorrhage has been arrested, by an exudation of serous fluid varying in quantity according to the extent of the wound and the nature of the tissues injured. The amount and character of this fluid are also modified by extraneous circumstances, notably by the subsequent treatment of the wound. In subcutaneous and aseptic wounds, for example, the quantity is much less than in wounds which are not aseptic, where in the latter the clear serum soon becomes turbid, and is rapidly replaced by pus. On the other hand, wounds involving tissues which are already in a condition of inflammation are followed by a greater flow of serum, which in its turn is also more prone to become purulent; and finally, wounds involving tissues which are already in a state of suppuration are bathed in pus from the outset. All wounds, therefore, contain a fluid (serum or pus) which, if retained by the closure of the wound by sutures or otherwise, produces the surgical condition described as tension. Tension in its turn, by its gradually increasing pressure from within outward, produces venous and capillary stasis, pain from nerve pressure, fever, and other symptoms which warn the surgeon that all is not right. Briefly, the results which follow, proportionate to the amount and intensity of the condition—death of tissue, infection, suppuration, or perhaps merely reopening of the wound in whole or in part, but always more or less interference with the normal physiological process of repair. But when the wound secretions are allowed to flow off as rapidly as they form, a most important, if not the most important, aid to repair is thus secured. Hence arose the surgical law now almost universally adopted, that all wounds of any magnitude must be provided with drainage from the outset. Exceptions to this rule are subcutaneous wounds, superficial wounds which are allowed to remain open to heal by granulation, intra-peritoneal wounds when aseptic, wounds which are closed by buried sutures from the bottom by the [illegible], and sometimes wounds which are allowed to fill with an organizing blood-clot, as now recommended by Schede, of Hamburg.

Suppurating wounds are always drained. This, however, may be called secondary drainage, and differs entirely in its objects and results from the drainage of fresh aseptic wounds.

Materials Used for Securing Drainage.—Tubes of india-rubber, decalcified bone, glass, and metal, as well as skeins of silk, catgut, or horse-hair, are employed for this purpose. The introduction of india-rubber tubes into surgical practice is credited to Chassaignac, for although it seems tolerably clear that they had been used before his time in isolated cases, there is no doubt but that his practice and teaching were the causes of their general adoption. For a long time, however, their use was limited almost entirely, if not altogether, to suppurating wounds, and the next great impetus which the use of the drainage-tube received was from Lister, who in his antiseptic teachings showed that thorough drainage was an important factor in maintaining wounds in an aseptic condition. With the march of surgical progress, however, came the system of dry and infrequent dressing of wounds, and consequently an objection arose to the use of the rubber tube; for while a large wound could be healed under a single dressing, the sinuses left after the removal of the rubber tubes required further treatment. This led to the introduction of decalcified bone tubes for wound drainage. These are of two kinds: *a.* "Neuber's bone drains," introduced by Neuber, of Kiel, and prepared from beef bones by boring and turning with a lathe. They are then decalcified in a weak solution of hydrochloric acid, and preserved in an antiseptic solution. *b.* The long bones of fowls (chickens, turkeys, etc.), which are first boiled and scraped to remove the muscular and ligamentous attachments. They are next partially decalcified in a weak solution of hydrochloric acid, the articular ends cut off, and the periosteum removed by scraping. The contents of the medullary cavity with the endosteum must now be removed. This is easily done by detaching the endosteum at one end, and pushing the contents through with a small file, as in pithing a piece of green stem. Decalcification is then completed, and the bones are preserved in an antiseptic solution. The advantages of bone drains are that they are rapidly absorbed in wounds and require no removal, the sinus closing in upon the tube and healing as it is absorbed. The length of time required for the absorption of bone drains depends upon the size of the bone, and whether it has been completely decalcified or not. The writer has seen turkey-bone drains which were not completely absorbed at the end of six weeks in a wound of the knee-joint, and in other cases, in which a tube of the same size had been employed in a similar wound, complete absorption and healing of the wounds had occurred at the end of four weeks.

Choice of Tubes.—In ordinary aseptic operations or accidental wounds, bone drains are to be preferred for the reasons already given; but it must be borne in mind that, if for any reason drainage is likely to be required for a longer period than ten days or two weeks, the bone drain cannot be relied upon, as within the time mentioned it becomes so far absorbed as to collapse and become, therefore, inefficient or useless.

There is only one objection to the rubber drain, the necessity for its removal; otherwise it is the most reliable and the most universally applicable of all forms of drainage-tubes. Rubber tubing should, however, be thoroughly cleansed and preserved in an antiseptic solution for some time before being used. The use of the glass drain is practically limited to the drainage of the peritoneal cavity after abdominal operations—especially those upon the pelvic organs. Metallic tubes have been recommended for the drainage of wounds, but are seldom or never employed except for the drainage of the pleural cavity, where a tube of yielding material would soon become compressed between the ribs by the contraction of the chest-wall. A number of strands of catgut, silk, or horse-hair laid in the bottom of a wound, form a very efficient means of drainage for comparatively superficial wounds, and especially for wounds of the scalp, where a tube can usually only be retained with some difficulty and at the expense of some stretching of the sutures. It has been claimed that these substances secure drainage by capillary attraction, but it is very doubtful if this principle ever comes into operation under such circumstances. A number of threads or hairs placed in the bottom of a wound, simply form a conduit along which the wound secretions find their way by virtue of gravitation or pressure applied to the walls of the sinus or cavity. Fine catgut is by far the best material for such drainage, as it is rapidly absorbed, and is indeed the counterpart of the bone drain in larger wounds. Silk retains the secretions in its meshes, where they are liable to decompose and render the wound septic, and as it does not become absorbed, the dressings must be removed for its withdrawal. Horse-hair possesses the same disadvantages as silk, together with this extra one, that, owing to the imbricated arrangement of each hair, it is quite impossible to thoroughly cleanse it for use.

Influence of Dressings upon Drainage.—The dressings applied to wounds materially aid or interfere with their drainage. A properly applied dry dressing of soft absorbent material greatly facilitates drainage. But in the use of such dressings, if good judgment be not exercised, it is also possible to completely frustrate this end and prevent drainage. For example, in a small wound such as the operation-wound left after the amputation of a finger, or a moderately large scalp wound, the first serous discharges being moderate in quantity, are liable to dry up immediately over the face of the wound from contact with the dry material of the dressing and the dry air, and thus seal it up completely. It is necessary, therefore, in the great majority of wounds, to exclude the air from too direct contact with the discharges, either by the use of rubber cloth or gutta-percha tissue over the dressing, or in larger wounds by an external bandage of sized muslin, or muslin charged with plaster of Paris.

Drainage-tubes should always be introduced at the most dependent parts of the wound cavity, and a greater number of short tubes should be used in preference to a lesser number of long ones. The size, length, and number of tubes employed must be regulated by the extent of the wound and by other circumstances influencing the amount of secretion to be removed. In short, the removal of the fluid secretions of wounds must be conducted on ordinary hydraulic principles. For example, in the operation-wound left after the removal of a breast with the contents of the axilla, or after an amputation of the thigh, it is usually better to drain through incisions in the lower flap, when the original incision may be closed.

James Bell.

WOUNDS INCIDENT TO WARFARE. The consideration of wounds incident to warfare, aside from the practical view of treatment, affords an interesting and valuable study to the civil and military surgeon, especially when large numbers of wounds can be made available for the purpose.

In this article, it is proposed to make use of the large experience gained in the late civil war, and to present to the profession generally, in a succinct manner, the results attained from a careful study of the data collected by the Government, and presented at length in the third Surgical Volume of the Medical and Surgical History of the War of the Rebellion.

This material is generally illustrative of facts of general interest, and of statistical value, relating to wounds; of the nature, peculiarities, and effects of missiles and projectiles used in warfare; of the conditions affecting the course and result of wounds with especial reference to the graver complications of secondary hæmorrhage, erysipelas, pyæmia, gangrene, and tetanus, with a brief comparative reference to the subject of conservation, excision, and amputation.

During the late war there were treated 246,712 cases of wounds caused by weapons of war. Of these, 245,790 were shot wounds, and 992 were bayonet and sabre wounds.

Sabre and Bayonet Wounds.—In comparison with the large number of shot wounds, the number of sabre and bayonet wounds were insignificant, indicating the advance of modern military science in the general adoption of long-range repeating firearms, and showing that the sabre and bayonet are rapidly falling into disuse, and that the time is not far distant when these old and honored weapons will become obsolete, and when wounds from these sources will be regarded rather as incidents of warfare than as the results of regular tactical manœuvres.

Of the wounds of this nature grouped together in the following table a large proportion had their origin in private quarrels and brawls, or were inflicted by sentinels in the discharge of their duty.

Summary of Nine Hundred and Twenty-two Sabre and Bayonet Wounds Recorded during the American Civil War, 1861-65.

The fatality of these wounds, as indicated in the table, is small, perhaps exceedingly so, when it is considered that the injuries derive their importance from their tendency to excite inflammatory action in deep-seated tissues and cavities, with the danger of formation and confinement of pus, from the chances of injury to blood-vessels, nerves, and viscera, and from the possibility of pyæmia, gangrene, and tetanus.

As might be anticipated, wounds by the sabre involve, chiefly, such parts of the body as are especially exposed to blows in the ordinary use of this weapon; thus, injuries of the head and upper extremities are more largely represented, while wounds from the bayonet show a decided preponderance in the lower extremities.

Wounds from sabre blows were not of a grave character, except in cases involving the cranial cavity, where the mortality attained its highest percentage, though several cases were reported resulting in primary or secondary amputation.

Epilepsy, insanity, loss of vision and hearing, and impairment of the mental faculties, seem to have been among the remote effects of injuries to the cranium from this cause.

The fatality of bayonet wounds exceeds that of sabre wounds by 2.7 per cent., and is chiefly due to injuries of viscera and large blood-vessels.

The heart, lungs, diaphragm, liver, stomach, jejunum, and spleen are noted as having been punctured; and of the blood-vessels, the common iliac, femoral, internal pudic, and brachial were involved.

The fatal cases of bayonet wounds of the lower extremities resulted from gangrene in three cases, and from primary hæmorrhage and pyæmia in one instance each. The median and sciatic nerves were lacerated in two cases, and the psoas punctured in one. No case of tetanus is reported as following a bayonet wound.

Cavalry engagements were not common; in almost every case the cavalry was dismounted and fought as infantry with carbine and pistol.

The troops were almost entirely uninstructed in the use of the sabre, and this weapon was rarely sharpened.

Arrow Wounds.—During the prevalence of Indian hostilities on our frontier, in years past, arrow wounds were of frequent occurrence. Since the general adoption of firearms by all the tribes, and since the practical solution of the Indian question, they are rarely seen, but possess sufficient interest for passing remark.

The arrow used in warfare by savage Indians consists of a head and shaft. The former is roughly wrought by hand from schist, flint, obsidian, or iron, is from three-fourths of an inch to one inch and a half in length, triangular in shape, barbed at the inferior angles, acutely pointed and sharpened upon the edges. In later years thin hoop-iron, which is readily obtained and easily worked, has been generally substituted for other materials for arrow-heads, and makes a formidable missile. The head is fastened to the shaft by a neck, and secured in place by thongs of sinew or the tough filaments of the yucca plant, covered with gum or resin. The shaft is a wooden rod or cane, varying in length, notched at the end to admit the bow-string, and feathered for several inches from the notched end to secure steadiness and precision of flight.

The arrow, when thrown from a powerful bow, has a high initial velocity, and a force sufficient to pierce any animal tissue. Instances are cited of arrows passing entirely through the body of a man, or even of the larger animals. The collection of the Army Medical Museum, at Washington, D. C., contains specimens in which arrow-heads have perforated the thick dense ribs of a buffalo, and also the human cranial bones.

The effective range of an arrow is generally within seventy-five yards, but severe injuries may be caused at much greater distances. The Indian in warfare endeavors to bring his victim within the smallest range possible by ambush, or by creeping upon him stealthily.

Arrow wounds are punctured, lacerated, or incised, or may combine these several qualities.

When coming into contact with bony structure an arrow may penetrate or perforate; the injury to the bone may be a simple incision, as when a well-sharpened iron head is used; or it may be accompanied by fissuring, as when the blunter stone head is used, acting with wedge-like force.

Injuries to muscular tissue are generally in the form of deep penetrations, with more or less laceration. If the arrow glances, or penetrates at an oblique angle, the wound may show a cleanly cut incision, not unlike the cut or thrust of a small sword or dagger.

Arrow wounds are necessarily serious in their nature; copious hæmorrhage generally attends them: nerve-trunks are severed, and wounds of the internal organs are usually fatal; wounds involving bony structures are not uncommonly followed by periostitis, osteitis, and osteomyelitis; and even in muscular tissue, simple wounds are liable to result badly from inflammation, suppuration, and other surgical complications, owing to the fact that the arrow-head is easily detached from its shaft by the solvent action of the moist tissues upon the gum and resin attachments, and becomes a foreign body, difficult of extraction or removal.

There is a very common belief that poisoned arrows are used in Indian warfare. In one sense it is probable that this may be true. When war is determined upon, certain religious rites are observed, one of these being the preparation of the war arrows, by dipping them in a mixture of putrid animal offal, combined with the juices of certain plants considered to be death-bearing, and gathered from burial places and sacred soil. Wounds inflicted by arrows so prepared may excite severe inflammation, or even induce fatal septicæmia; but whether the use of absolute poison is common is doubtful. It is claimed that the poison of the rattlesnake is used for this purpose, but it is probable that only the putrid flesh of the reptile is employed, as above alluded to.

Spear Wounds.—Many of the Indian tribes formerly used spears in warfare. These weapons consisted of a blade of iron or sharpened flint, or obsidian, mounted on a staff; they are at present but little used. Wounds from this weapon differ but little in their character from bayonet, sabre, or sword wounds.

Shot Wounds.—The cases of shot wounds recorded during the war number 245,790. Undoubtedly this number falls far short of the actual truth. Lists and records of wounded are especially imperfect during the early part of the war, when each regiment, and often each detachment of troops, before the organization and establishment of base and general hospitals, continued to find shelter for its more seriously wounded men in tents or buildings temporarily occupied, which afforded no facilities for keeping records, and when both officers and men were allowed to proceed to their homes for treatment by their family physicians.

For convenience these wounds have been grouped in five tables, the first containing shot wounds of the head and face, the second of the neck, the third and fourth of the trunk, and the fifth those of the extremities.

Tabular Statement of the Shot Wounds of the Head and Face Recorded during the American Civil War.

Nature and seat of injury.	Totals.	Results.			Percentage of fatality.
		Recoveries.	Deaths.	Undeterm'd results.	
Shot injuries of the head:

Wounds injuring pharynx and larynx	2	...	2	....	100.0
Total shot injuries of the neck	4,895	3,496	618	781	15.0

Aside from flesh wounds of the scalp and hip, and slighter forms of contusion and fracture, shot wounds of the head were of very fatal character, the ratio of mortality following closely upon the degree of injury inflicted upon the brain and its appendages.

Fractures of the inner table of the cranial bones were of difficult diagnosis, and could in general be substantiated only after *post-mortem* inspection.

Perforating gave slightly more favorable results than penetrating fractures; this may have been due to the fact that less vital portions were involved, or that these wounds were more satisfactorily treated, being freed from the complications attending the lodgement of foreign bodies.

The results of shot injuries of the face confirm the opinion that these wounds commonly do well, notwithstanding the amount of destruction apparent at the time of injury.

The high mortality of shot wounds of the neck is almost necessarily to be expected from the lesions of these parts of great vital importance, placed in close relation with the great nervous and vascular trunks found in this region.

Tabular Statement of the Shot Wounds of the Spine and Chest Recorded during the American Civil War.

Nature and seat of injury.	Totals.	Results.			Percentage of fatality.
		Recoveries.	Deaths.	Undetermined results.	
Shot wounds of the spine:					
Fractures of cervical vertebræ	91	27	63	1	70.0

The great fatality of unqualified shot penetrations of the abdomen is apparent in the preceding table; of the [illegible] determined instances of such lesions, [illegible] had a fatal termination, a mortality rate of [illegible] per cent, exceeding that of the shot fractures of the cranium with penetration of the brain, which was [illegible] per cent. Even the large fatality of shot fractures of the hip, [illegible] per cent, in the succeeding table, is in some measure due to complications with injuries of the viscera of the abdominal cavity.

With two exceptions, the generally accepted rule in fractures of the extremities, that the ratio of fatality diminishes with increased distance of the injury from the trunk, is verified in the table.

In the upper extremities the fractures of the wrist had a greater fatality than those of the forearm (12.9 and 9.4 per cent, respectively); and in the lower extremities the results of injuries of the knee joint were slightly less favorable than those of the femur, the mortality rate being 53.8 per cent in the former and 53.1 in the latter, although the difference, 0.7 per cent, is very trifling.

Although the wounds of the joints indicate injuries of a more serious nature than those of the long bones immediately above them, the percentages of fatality do not seem to have been proportionally increased.

But wounds of the joints were more frequently followed by excision and amputation, and it would seem, therefore, that the increased ratio of operations had tended to reduce the percentage of fatality.

Measurements of the Pythian Apollo and Farnesian Hercules cited by Longmore in his work on gunshot injuries, as to the relative amounts of superficial area presented by the principal divisions of the human body, give as a mean the following percentage of the whole target area of the body: for the head, face, and neck, 8.51 per cent; for the trunk, 28.91; for the upper extremities, 21.14; for the lower extremities, 41.41 per cent.

If battles were fought and decided on level and unobstructed ground we might find that the percentages of the injuries inflicted on the various sections of the human body would correspond with the proportional percentage of the area; but it is evident that the nature of the field of operations, whether fortified places or the open plain, or rolling wooded districts, must necessarily affect the relative regional frequency of injuries.

Of the wounds treated in the late civil war, as shown by the following table, 10.77 per cent. were injuries of the head, face, and neck; 18.37 of the trunk; 37.71 of the upper extremities, and 35.15 of the lower extremities.

Table indicating Percentage of Fatality and Relative Frequency of Shot Wounds Recorded during the War of the Rebellion.

Seat of injury.	Total cases.	Results.			Percentage of fatality.	Relative frequency.	
		Recoveries.	Deaths.	Undetermined results.			
Shot injuries of the head	12,089	6,573	2,676	2,840	28.9		14.91
Shot injuries of the face	9,416	7,406	462	1,548	5.8	10.77	3.87
Shot injuries of the neck	4,895	3,196	618	781	15.0		1.99
Shot injuries of the spine	642	279	349	14	55.5		0.26
Shot injuries of the chest	20,264	13,921	5,373	970	27.8		8.24
Shot injuries of the abdomen	8,438	3,455	3,293	1,690	48.7	18.37	3.43
Shot injuries of the pelvis	3,159	2,194	930	35	29.7		1.28
Shot flesh wounds of the back	12,681	10,883	800	998	6.9		5.16
Shot injuries of the upper extremities	87,793	80,090	5,608	2,095	6.5		35.71
Shot injuries of the lower extremities	86,413	73,665	11,813	935	13.8		35.15
Aggregates	245,790	201,962	31,922	11,906	13.6		00.00

According to this tabular statement, the injuries of the extremities form 70.86 per cent. of the total number of wounds, and the proportion of the wounds of these parts would therefore appear disproportionally large.

But it must be borne in mind that these figures constitute only a portion of the injuries received, as the large number of killed are not included in these calculations.

According to the report of the Adjutant-General of the Army, the total number of killed was not less than 44,238.

The records of the Surgeon-General's office give the seat of injury in only 1,173 cases of soldiers killed on the battle-field. Of these, 487 were of the head and neck, 603 of the trunk, 30 of the upper extremities, and 53 of the lower extremities.

Applying the above proportions of the 1,173 cases to the total of 44,238 killed, we would have 18,367 killed from injuries of the head, 22,741 from wounds of the trunk, 1,131 from wounds of the upper extremities, and 1,999 from casualties of the lower extremities.

Adding to these the cases of wounded according to the above table, viz., 26,400 of the head, 45,184 of the trunk, 87,793 of the upper extremities, and 86,413 of the lower extremities, we have a total of injuries, according to regions of the body, including killed and wounded, of 44,767 head, 67,925 trunk, 88,924 upper extremities, and 88,412 lower extremities; or, according to percentages, 15.44 per cent. injuries of the head, 23.42 per cent. injuries of the trunk, 30.66 per cent. injuries of the upper extremities, and 30.48 per cent. injuries of the lower extremities, making a total of 61.14 per cent. of injuries of the extremities.

Whether we take into consideration the percentage of the injuries of the upper extremities derived from the total number of wounded and killed, 30.66 per cent., or that obtained from the number of soldiers treated for wounds only, 35.71 per cent., the regional proportion of these injuries is very large.

But the protection afforded to the lower extremities and the trunk in the many siege operations, by parapets, and in the field by trenches, ditches, trees, etc., saved these parts largely from injury, while the head and upper extremities were continually exposed to the practised eye of a vigilant foe.

The percentage of regional injuries, compiled from the most reliable accounts of European and other campaigns is illustrated in the following table, and closely approximates the percentage derived from a study of the injuries of the American civil war.

Tabular Statement of the Relative Frequency of Shot Wounds of the Different Regions of the Body.

The excessively large percentage of wounds of the hands and fingers, frequently noticed by writers on military surgery, was also observed in the late war.

It is possible that this large percentage is due to the increased exposure of the hand from constant movement over a considerable area, thus increasing the chances of intercepting missiles in their flight.

Definition of Shot Injuries.—All injuries caused directly or indirectly by missiles and projectiles, impelled by the force of gunpowder or other explosive, have been included in the term "shot" injuries.

They differ from the accidents common to ordinary life, not so much in their essential character, as in the peculiarities of the conditions and circumstances attending them, and on this account invite especial attention to the producing causes, to the dangers and complications liable to arise in their course, and to their management and treatment under conditions generally

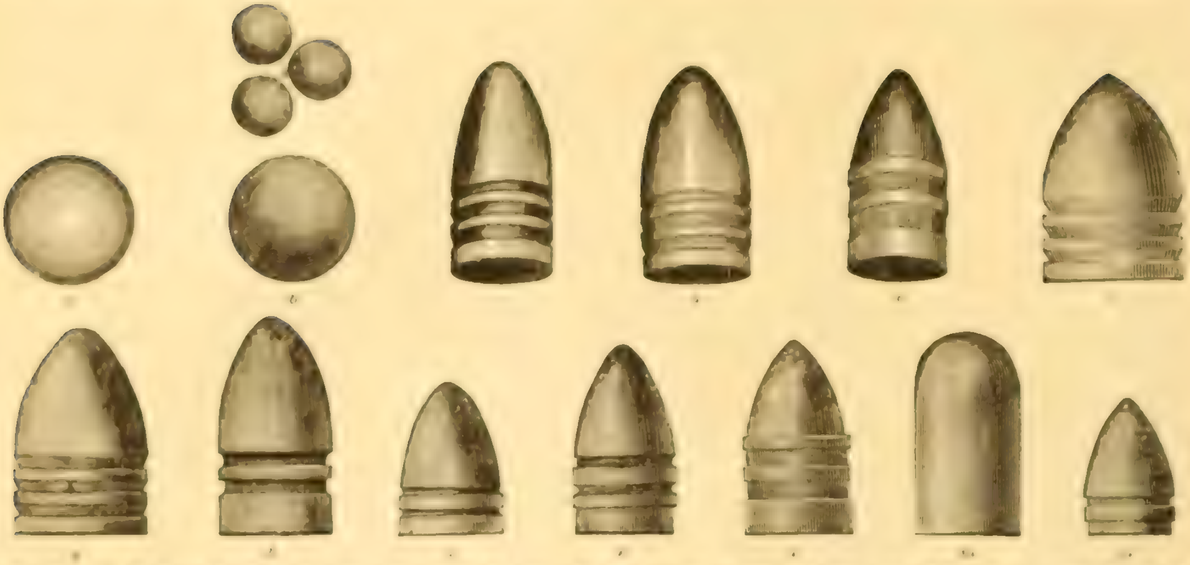

FIG. 4624.—a, U. S. round musket-ball, calibre .69, weight 412 grains; b, buck and ball cartridge, [illegible]

less favorable than are found in the practice of civil surgery.

A gunshot wound is essentially a contused wound, yet the character of the missile and the circumstances surrounding the individual at the time of injury may impose upon it the additional features belonging to incised, lacerated, and penetrating wounds.

In degree it may range from trivial simplicity to all the terrible gravity of injuries seen upon the battle-field; yet in all its phases, simple or complicated, the application of the sound principles of general surgery forms the basis of treatment and marks the advance of surgical science in the present day.

The great superiority of the rifled arm and cylindro-conoidal projectile as compared with the smooth-bore musket and round ball, had been fully established by the experience of foreign nations in the great wars of Europe between the years 1848 and 1860, and had opened to the military surgeon an interesting field of inquiry regarding the modification of the nature of wounds resulting from the use of the improved firearms.

FIREARMS AND THEIR PROJECTILES.—Projectiles common in warfare may be divided into those used with small arms, as rifles, muskets, pistols, etc.; those discharged from heavy ordnance, as cannon, both rifled and smooth-bore, mortars, torpedoes, etc.; those which act indirectly in the causation of injury, as splinters, stones, and fragments detached or set in motion by projectiles in their flight; and missiles of an unusual or eccentric character. By far the greater number of shot injuries in warfare are inflicted by missiles from small arms.

In the late war the nature of the missile was ascertained in [illegible] cases, of which [illegible], or [illegible] per cent., were caused by missiles from small arms.

The projectiles or missiles used with small arms are either spherical balls, usually discharged from smooth-bore muskets, or those of an elongated form adapted to rifled arms; the latter are conical, cylindro-conoidal, or ovoid, varying in size, weight, and volume.

The material composing small-arm missiles is usually lead hardened by an alloy of tin or antimony.

The superiority of the elongated missile thrown from the rifled barrel over the spherical ball, rests upon the fact that the elongated bullets have usually an expansive base, [illegible] which by the explosion of the charge is intended to fill the grooves of the rifle, and give the projectile, as it is driven forward, rotation on its long axis, thus increasing its range and precision.

The cuts appended (Fig. 4624) are designed to illustrate the general appearance of the more common and typical varieties of small-arm missiles used during the late war by both parties.

The large projectiles used with ordnance may also be classified under the headings spherical and elongated, the former being generally used with smooth-bore, the latter with rifled guns.

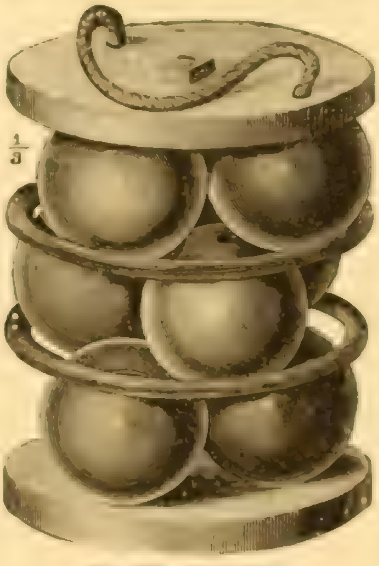

FIG. 4625.—Grape-shot.[1]

Round shot are solid spheres of cast iron varying in weight and size.

A grape-shot (Fig. 4625) is composed of a number of cast-iron balls (in the U. S. service generally nine) arranged in layers of three each, and kept together by a central rod secured by nuts on each end. These missiles vary in calibre to fit guns of different sizes. Upon discharge the several parts become separated, and each part acts as a distinct projectile. They have considerable range.

A canister shot is a projectile made by enclosing a large number of iron or leaden balls, of less size than grape, in a cylinder of tin, which is torn asunder at the discharge of the gun; the contents are scattered, assuming in their onward course something of the area and shape of a cone. When used against bodies of troops and at short range, the canister shot is very destructive.

Shrapnel-shots are spherical or elongated, according to the character of the gun in which they are used, and when adapted to smooth bores they are designated spherical case-shot. They are shells of considerable thickness, filled with musket-balls consolidated into mass by a composition of resin and sulphur, and are exploded by a charge of powder fitted into their interior, which is ignited by a time or percussion fuse. (Figs. 4626, 4627, and 4628.)

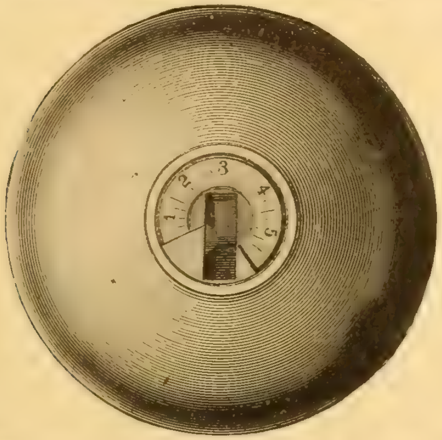

FIG. 4626.—A Twelve-pound Spherical Case-shot, outer and upper view.[1]

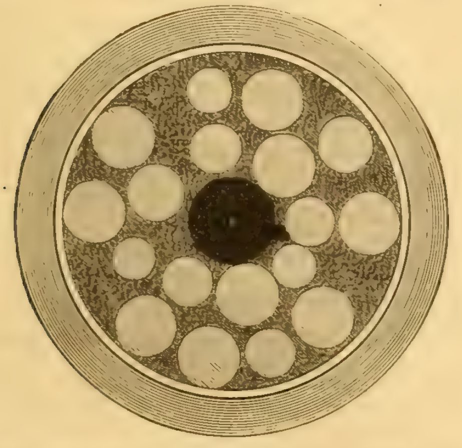

FIG. 4627.—The Same Sawn in Half, Showing the Bullets and Composition.[1]

They have a long effective range and are calculated to inflict serious injury by the great number of fragments set loose at their explosion.

The projectiles used in rifled guns exclusively, combine with the properties and character of the projectiles just described those which pertain particularly to guns constructed on the rifled principle; they vary greatly in size and weight; their velocity varies with the calibre from 1,100 to 1,550 feet per second, and in more recent guns a much higher velocity has been obtained, as well as increased power and range.

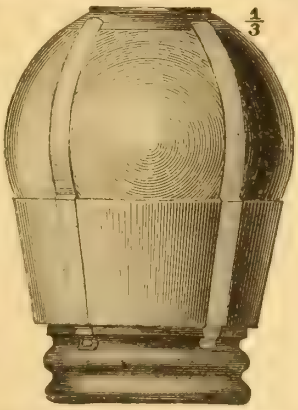

FIG. 4628.—A Spherical Case-shot Strapped for Howitzer or Gun.[1]

The ten-pounder percussion Parrott case-shot, much used in the late war (Fig. 4629), is a missile of this nature.

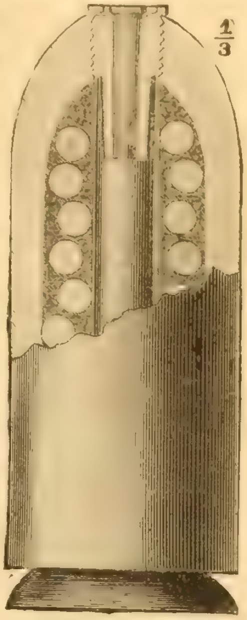

FIG. 4629.—A Ten-pound Percussion Parrott Case-shot.[1]

By the explosion the shell is rent into many fragments, small and large; these fragments are driven in all directions with great force, and inflict injuries of the gravest character.

Rifled projectiles are also cast solid, and are used for breaching or battering purposes.

Bolts, so called, are solid metal projectiles of elongated form, with surfaces cut to fit corresponding surfaces in the barrel of the gun; they are made to fit with great exactness, so that a greater proportional effect is attained with a smaller charge of explosive.

The Whitworth projectile, used to some extent in the late war, may be taken as a type of this class.

Shells thrown from mortars differ little, if any, from ordinary spherical shells, except in size and in the manner of projection. Their use is generally restricted to siege purposes. Solid shot heated in furnaces designed for the purpose, are sometimes used in warfare, but with the intent of destroying property rather than human life.

Hand-grenades are small iron shells filled with powder and discharged by percussion; they are commonly used in sieges and assaults at close quarters; injuries result from the fragments of the exploded shell. As their name indicates, they are thrown by hand.

Torpedoes were largely used during the late war as a means of defence, and were commonly large shells arranged with levers connecting with a percussion fuse. They were sunk below the level of the earth and concealed by dirt and brush. The pressure of the foot was sufficient to explode them, with effects similar to the bursting of a like projectile under ordinary circumstances.

In a third division of missiles and projectiles are included such as cause wounds and injuries indirectly; splinters, stones, foreign bodies set in motion or driven by the force of projectiles in their course, and which, by their action or lodgement frequently complicate direct shot wounds, and are themselves sources of danger.

The most common examples of this class are fragments of stone and splinters of wood, torn from the earth or from trees, and structures forming defensive works, scraps of iron or metal from ordnance, firearms, or from articles of equipment; or indeed from any object with which a projectile may come in contact.

The ordinary "buck and ball," a compound missile, was extensively used in the earlier years of the war; it consisted simply of the ordinary round ball, calibre .69, and three buck-shot enclosed in the same cartridge. These missiles were very effective at close range.

Slugs and fowling-piece ammunition were not infrequently used.

The subject of the employment of explosive bullets in small arms in warfare between civilized nations has been largely discussed from an ethical point of view, particularly since the civil war in the United States. While their use is acknowledged to savor of barbaric warfare, there is still a manifest reluctance to place them entirely beyond the pale of legitimate employment.

One hundred and thirty cases of wounds attributed to explosive bullets were recorded among the casualties of the late war; the injury from these missiles is greater and more severe than that from a simple ball; bony structones are more extensively shattered, and the area of destruction of soft parts is larger; hæmorrhage, both primary and secondary, is more common; extensive sloughing follows, and the course of repair is slow and tedious.

The Gardner explosive bullet or "musket-shell" (Fig. 4630), used in the civil war, is a cylindro-conoidal projectile of lead, made in two sizes—the larger of calibre .58, weighing 451 grains, the smaller of calibre .54, weighing 363 grains. Within the interior is placed an accurately-fitting cup-shaped chamber filled with percussion powder, and communicating with a time-fuse which is exposed to the charge at the rear of the missile; the fuse is ignited by the discharge of the piece. The bursting charge is sufficient to rend the bullet and transform it into a dangerous jagged missile. Should it have penetrated the body before exploding, its effects are most disastrous. It is claimed that other forms of projectiles of this nature were used, provided with percussion caps intended to explode upon contact with even soft tissues.

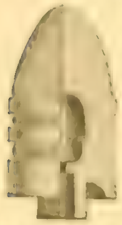

FIG. 4630.—Gardner's Explosive Ball.

Surgeon H. R. Tilton, U. S. Army, mentions in correspondence upon this subject the fact that explosive bullets were found among ammunition captured from the Nez Percés Indians during the late war with that tribe.

The appearance of an exploded musket-shell extracted from the thigh of a soldier is shown in Fig. 4631. The wound resulting was a flesh wound of the muscles of the thigh, and the bullet was removed by enlarging the opening of entrance.

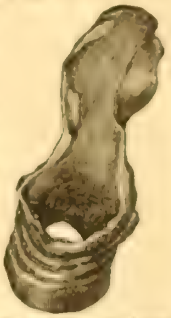

FIG. 4631.—Exploded Bullet Extracted from Thigh.

EFFECTS OF LARGE PROJECTILES.—The injuries caused by large projectiles depend upon their weight, size, and momentum. At high velocities they virtually encounter no resistance from a single human body, and their force is but slowly expended on masses of soldiery. Their form is of little importance, as similar results follow the use of spherical and elongated shot and shells; their impact is followed by instant death or by wounds of great severity.

When the injury is not immediately fatal, as when a limb is carried away by a projectile of considerable size striking directly, the surface of the stump will be found to be somewhat cleanly cut, the skin and muscular tissue contused and dark, with little retraction; the bone fractured with not much splintering or comminution above the seat of injury; the arteries retracted, and the hæmorrhage generally slight.

If the projectile strikes obliquely and with diminished force, the resulting wound shows a deeply grooved furrow, corresponding to the size of the projectile and influenced by its direction; the skin, fascia, and soft parts are extensively contused and lacerated, or removed entirely; the surface is covered with blood-clots and shreds of connective, muscular, and areolar tissue; arteries and nerves are often seen stretched and hanging in the open wound. Hæmorrhage is commonly slight or ceases after a first gush.

If the projectile penetrates cavities, disorganization and destruction of parts will follow, resulting in death, either immediately or in a very short time.

A solid shot whose velocity is so greatly diminished as to seem harmless is still capable of doing great damage through its acquired momentum. It may not possess the force necessary to carry away any part of the body, but a contusion or wound resulting from its impact is generally serious, and not infrequently fatal.

It may be that no outward evidences of injury are manifest beyond some discoloration, but subsequent symptoms indicate the existence of grave internal lesions; rupture of the viscera, concussion of the brain or spinal cord, and often fractures of bones with extensive comminution and disorganization of the surrounding soft parts.

Slighter contusions generally impair or destroy the vitality of the skin and soft parts, and result in extensive sloughing and in slow repair.

The occurrence of simple fracture and dislocation are sometimes noticed, but are infrequent.

Probably the largest class of injuries attributable to heavy projectiles is that resulting from fragments of exploded shell.

The character of these wounds depends largely upon the weight, form, and velocity of the fragments. Pieces of great weight and size, moving with high velocity, inflict wounds similar to, and not less severe than, those caused by the larger projectiles already mentioned. As their velocity diminishes, which is rapidly the case, owing to the great resistance offered by the air to the passage of irregularly shaped bodies, as well as to gravitation and modification of the original impetus, the factor of weight alone assumes importance, as even with slow motion the momentum of such masses is almost irresistible.

The form of the projectile may determine the severity of a wound, especially when the fragment is of small size, the sharply outlined edges becoming sources of danger to blood-vessels, nerves, and viscera.

Wounds from large shell fragments are attended with great laceration and destruction.

When the force is insufficient to carry away a portion of the trunk or an extremity, the resulting wound is deeply contused, with jagged and irregular edges; there may be a loss of more or less of substance; bony structures exposed to the force of a blow are shattered and comminuted; not infrequently the fragment will be found lodged in the wound.

In some cases a large fragment will pierce the skin without destroying its vitality, and sink deep into the cavities or soft parts, the skin retracting so as to present so small an opening as to obscure the diagnosis, until subsequent symptoms disclose the true nature of the injury.

As in cases of solid shot, contusions of little or no outward significance beyond apparently slight bruising, but attended with extreme internal disorganization, are frequently met with.

A curious case of lodgement may be referred to as occurring during the late war, in the case of a soldier from whose left gluteal region an operating surgeon removed a twelve-pound round shell, the patient surviving the injury some forty-eight hours. The missile was entirely concealed behind the gluteal muscles.

Wounds from grape-shot partake of the general nature of injuries from cannon-balls. The velocity of these projectiles is, however, generally lower and their weight less, so that their destructive power is somewhat limited.

Case and canister shot, as well as small fragments of shell, produce effects not materially differing from those of small-arm missiles.

The effects resulting from the explosion of torpedoes, though somewhat dependent upon their size, nature, and proximity, are extremely terrible.

Not only is the violent action of fragments, splinters, stones, and foreign bodies, hurled at great velocity, to be considered, but also the consequences of exposure to the flame and gas of the exploding charge. Should life be not immediately extinguished, fearful mangling and mutilation result, while the presence of burns and the effects of the inhalation of heated gases serve to complicate the condition.

Although the reports of alleged effects from the "wind of balls" do not seem to merit serious consideration, it would appear, by the number of reports of cases of this character during the war, that there is still a lingering belief that injuries from this source are not of infrequent occurrence.

After a careful examination and consideration of these reports, the evidence unmistakably points to effects produced by actual contact of the missile, causing severe concussion, or to the accident known as the "brush of a ball," in which the missile passes so near as to actually touch the clothing or skin without tearing the one or the other, yet producing severe results, among which may be cited swelling, inflammation, and sloughing, and even paralysis.

The several theories of vacuum, of foreign bodies carried along with the ball, and of electricity, which have, from time to time, been suggested to support the idea of injuries from the "windage" of balls, have all been disproved, and it is now conceded by modern surgeons that, without actual contact of a projectile, injuries cannot occur; but it is admitted that slight contact from the "grazing" or "brushing" of a projectile, or the rolling motion of a cannon-ball over the surface of the body, may, by weight and momentum, aided by the elasticity of the skin, effect most serious results, while little or no external evidence of such contact is left.

Instances of injuries attributable to the explosion of shells near at hand, without wound or contusion, are numerous and generally well authenticated. They are for the most part cases of partial or complete paralysis, deafness, blindness, loss of voice, rupture of superficial vessels, and mental prostration.

The proportion of cases of deafness among artillery officers and cannoniers has been, since the late war, a frequent subject of remark, and the frequency of rupture of the membrane of the tympanum from propinquity to artillery fire has been specially noted.

EFFECTS OF MISSILES AND PROJECTILES FROM SMALL ARMS.—In the great aggregate of shot wounds reported during the civil war, by far the greatest number was due to missiles from small arms.

In considering the effects of large projectiles, size, weight, and velocity constituted the principal factors; in the case of missiles from small arms, form, both original and that acquired by accidental causes, assumes importance, as well as the relation of the individual injured to the impinging projectile, the direction of the ball, position, structure, and power of resistance of the parts, and the course of the missile through the tissues.

With reference to the projectile itself, form and velocity are of principal importance; size, weight, and volume modify the character and extent of the wound, while the remaining factors have an especial subjective relation.

Aside from the influence which the improvements in modern small arms may have had in increasing the general effectiveness of projectiles, the adaptation of the conoidal missile to the rifled barrel has unquestionably wrought a change in the surgical relations of wounds, the opinion being generally expressed by surgeons that wounds caused by elongated missiles are more severe and dangerous than those resulting from spherical balls.

The cylindro-conoidal missile attains a great range with effective power, it opposes less frontage to the resistance of the air, and its velocity suffers more gradual retardation than that of a round ball.

Rotation upon its long axis tends to give it a steadier flight and a more direct course.

Its pointed apex, aided by its rotation, gives it the mechanical advantages of the wedge and screw, enabling it to pierce more easily the structure of opposing bodies, while it suffers a proportionally less diminution of force; adding the factor velocity, we have a missile endued with tremendous force, maintaining for a long time and over great distances a steady flight, not easily deflected, piercing and rending opposing obstacles, and preserving, even at immense range, a momentum sufficient to render it deadly in its effects.

It is probably true that at very close quarters the effects of the round ball are hardly less destructive than those of the elongated missile; but, as the peculiar power of the rifled bullet mainly lies in its destructive effects at long range, the change of military tactics based upon this fact has compelled the general use of weapons of greater power, and has lessened the opportunities for comparison on any extended scale.

The size and weight of small-arm missiles vary within such narrow limits as to make practically but little difference in the effects produced by them; though in the question of the extraction of a ball between bones or joints, dimension may be of importance, as well as in the consideration of the gravity of penetrating wounds of the chest.

Missiles from carbines, pistols, and fowling-pieces, when used as weapons of war, produce injuries very analogous to those of the ordinarily used small arms, but being of smaller size and impelled with less force, their wounding power is generally less.

Even the small buck-shot, one of the constituents of the "buck and ball," have sufficient force to place one or more men, temporarily at least, *hors de combat*.

The accidental forms and distortions which leaden projectiles are liable to assume by contact with opposing obstacles, both within and without the body, form a curious and interesting feature in the study of missiles and their effects. These distortions are of all imaginable forms, and their course through the tissues is frequently no less erratic.

ENTRANCE AND EXIT WOUNDS.—Small missiles impinging upon the human body and penetrating the skin, inflict what is known as the wound of entrance; if preserving sufficient force to perforate, the opening last made is called the wound of exit.

Wounds of entrance and exit have for years been the subject of lengthy discussion by surgical writers, and are supposed to possess certain diagnostic value, as indicating in a general way the form and variety of missile, its velocity, its probable course through tissues, and, to some extent, the nature and character of the wound.

Under the force of ever-varying conditions, they are very diverse in appearances and extent, and their significance is largely dependent upon the experience and acuteness of the observer.

In general, a bullet preserving its integrity, impinging at ordinary range and at a right angle upon a portion of the body well covered with soft tissue, and not unnaturally put upon the stretch, leaves, as it passes through the skin, an opening more or less regularly rounded in form, often perhaps a little less in diameter than the missile, with the edges inverted and livid in hue, due partly to the contusion and partly to the discoloration from the burned powder carried upon the missile. In the case of a spherical ball there is usually some loss of substance, a portion of the integument being carried away before its obtuse surface. A cylindro-conoidal missile will generally cause a more irregularly outlined opening, either stellate or slit-like, with serrated or ragged edges.

The wound of exit may closely resemble that of entrance, but is commonly larger and more irregular, with everted edges, bearing fewer evidences of contusion, but often showing a greater loss of substance.

From these simple, uncomplicated forms of wound we find an almost infinite variation, dependent upon the peculiar circumstances which impress their characteristics upon each case.

If the missile has carried before it a foreign body, or has become distorted, or has suffered a diminution of velocity and force, the wound of entrance will be modified accordingly, showing greater irregularity of outline, and presenting greater laceration of tissue.

The resistance offered by the tissues to the passage of a missile through any part of the body, will largely influence the character of both entrance and exit wounds.

Obliquity of the course of a missile to the plane of the surface of the body may result in merely a superficial grazing or furrowing, or in penetration and perforation; in which cases the appearance of the wounds of entrance and exit will depend on the angle of impact.

Fragments of shell produce irregularly-shaped wounds, with contusion and considerable loss of substance; should their force be sufficient to perforate a part, the wound of exit is lacerated and ragged, with portions of muscular and connective tissue thrust out of the opening.

The differential diagnosis between these and bullet wounds is usually not difficult.

A single wound of entrance may have two or more wounds of exit; as, for example, when a missile is divided upon a bone.

A bullet may be split into fragments before striking the body, in which case the fragments may each enter and leave separately, or one or more of the fragments may lodge.

Multiple wounds of entrance and exit are common, resulting from a missile perforating two or more parts of the body successively, as two arms, two legs, the body and one or more extremities, or parts of the same extremity when flexed. Cases are recorded in which the missile has entered and made its exit by the same opening.

EFFECTS OF MISSILES ON MUSCULAR TISSUE AND FASCIÆ.—The differences of structure and density of the muscular and tendinous tissues of the body, encountered by a bullet in its passage, are found to influence the direction of its course, unless the velocity, and consequently the momentum, is sufficiently great to overcome the resistance offered, as in the case of a conoidal ball at high velocity, the course of which is generally direct.

Round balls presenting an obtuse frontage part more easily with their force, and are readily deflected by fasciæ and aponeurotic expansions, pursuing curious and devious courses until they either find exit or make lodgement.

The effects of missiles of different character upon muscular structure are not dissimilar; the track of a small conoidal bullet passing swiftly through a muscle is generally more cleanly cut than that made by a large or round ball; but in all shot wounds there is usually found an irregular channel, with contused and lacerated walls, more or less devitalized by contact with the missile, the area of injury gradually shading off by concentric layers until lost in healthy tissue.

There is always more or less loss of substance dependent somewhat on muscular tension and relaxation, also upon the rotation of the missile in its passage, whether upon its long or short axis.

Fasciæ and aponeurotic tissue are torn and lacerated, or simply perforated, according to their condition of tension at the time; their openings seldom correspond with the openings in muscular tissue, owing to the ever-constant change in the position of parts due to movement and muscular action; hence it is frequently difficult to follow the course of a missile with accuracy; when for the purpose of accurate diagnosis it becomes necessary to do so, the relation of the individual to the impinging missile becomes of great importance.

Contusions of muscular tissue are often found as the result of impact of "spent" balls, or when the force of the missile has been lessened by contact with some obstacle, as parts of equipment, books, money, buttons, etc.

The contusions may present all degrees of severity from simple ecchymosis to loss of vitality of the part struck; this may be limited to the skin, in which case an eschar of rounded form and of about the size of the missile is thrown off; or it may affect deeper structures, as the contents of the great cavities.

A soldier found an iron breastplate, which he wore into action; he was struck by a Minié bullet upon the breastplate, over the region of the third rib, and was seriously contused, expectorating a considerable quantity of blood; a rounded excavation of about the size of a musket-ball sloughed at the point where he was hit, laying bare the rib; he recovered, but a companion who wore the same breastplate in a subsequent action was not so fortunate; a conoidal ball struck the plate near its lower border and passed through it, carrying before it fragments of the plate, which entered the abdomen, causing death.

Contusions seem to more frequently follow the impact of round than conoidal missiles.

Wounds by conoidal bullets, by fragments of shell, or by foreign bodies, are more destructive in their nature than those resulting from lesser missiles; the irregularity of a bullet track, due to the causes mentioned, constitutes one great source of danger in flesh wounds; the cavities and irregular pouches found along the track give lodgement to foreign matter driven in with the missile, as shreds of clothing, etc., causing irritation, inflammation, and abscesses, with the retention and burrowing of purulent accumulations, and exposing the patient to the danger of septicæmia, or at least prolonging convalescence.

Many cases attended with extensive destruction of skin, connective tissue, tendons, and ligaments, result in serious disability from contraction and rigidity of parts, and from the formation of extensive cicatrices, impeding motion and becoming the seat of pain and hyperæsthesia.

After shot wounds of the soft parts of the lower extremities particularly, and when there has been great laceration or complications by lodgement of foreign bodies, cases are not infrequently noted in which missiles, without immediately injuring osseous articular surfaces, so injure the surrounding ligaments and soft parts, in some instances even the synovial membrane, as to light up immediate or consecutive inflammation in the capsular cavity, or to induce, through the formation of cicatricial bridles or by other deformities, a diminution or even abolition of the movements of the joint. These injuries are known as periarticular wounds.

Gangrene, tetanus, and pyæmia are not infrequent complications of lesions of the muscles, and, when affecting the extremities, life may at times only be preserved by recourse to amputation.

A few instances of repair of shot wounds by first intention were recorded during the late war, but they were very rare and must presuppose a cleanly cut wound, a sound constitution, and a temperate habit of life.

EFFECTS OF MISSILES AND PROJECTILES IN BONY STRUCTURES.—Gunshot injuries of bones may be classified as contusions, simple fractures, partial fractures, penetrations, perforations, and complete fractures, with varying degrees of comminution and destruction of substance.

Nearly every form of missile and projectile used in warfare is liable to cause these various injuries.

The properties inherent to the missile, as velocity, size, form, weight, and the conditions pertaining to the individual at the time, as posture, part wounded, etc., will determine the nature, extent, and severity of the injury.

Slight forms of injury may result from the impact of a solid shot, a fragment of shell, or from a leaden bullet; injuries of the gravest character may equally be inflicted by these agents.

Contusions of bone more commonly result from the impact of missiles under low velocities, as a spent bullet or fragment of shell, or when the force of the missile has been nearly expended in overcoming the resistance of overlying tissues, or when the line of direction has been oblique to the bone, causing a grazing or glancing blow.

Round balls parting rapidly with their force after their initial velocity is diminished, will generally contuse rather than fracture. The same is true of shell fragments, unless their weight is sufficient to cause fracture by crushing.

Contusions of bone may be followed by no very serious results, as instances of this nature have been reported. In many cases the contusion was at first unrecognized until tardy and faulty cicatrization and discharge of bone proved the presence of caries and necrosis.

Unhappily, a very considerable percentage of cases of contusion of bone prove to be far from innocent, and are followed by a train of most serious complications.

Surgeon John A. Lidell, U. S. V., in an excellent article upon shot contusions of bone, enumerates the consequences of this injury as follows: Ecchymoses of the osseous tissue, ecchymoses of the medullary tissue, osteomyelitis of a simple character, necrotic osteitis, and suppurative osteomyelitis, and says: "Any injury of bone of the nature of a bruise, however trivial it may appear at the time of infliction, may be followed by serious consequences, which it is the duty of the surgeon to anticipate and ward off if possible."

After a bone contusion without fracture, the periosteum is injured and destroyed, if the injury is a serious one, or if proper treatment is neglected and necrosis of the bone sets in.

In crowded hospitals and under unfavorable conditions, such injuries, especially in the long bones, cause suppuration of the medullary canal, which extending itself, finally results in septicæmia through the admission of pus into the neighboring veins.

The experience of the late war seems to favor the opinion that, owing to their better blood-supply and consequent greater vitality, shot contusions of the upper portions of the body give more favorable results than similar lesions of the lower extremities.

The tabulated results from official records are given below:

Numerical Statement of Shot Contusions of the Bones of the Head, Trunk, and Extremities.

Seat of Injury.	Cases.				Percentage of fatality.	Treated by conservation.			Treated by excision.		Treated by amputation.	
	Total.	Recovery.	Fatal.	Unknown.		Recovery.	Fatal.	Unknown.	Recovery.	Fatal.	Recovery.	Fatal.
Shot contusions of the bones of the skull	328	273	55	..	16.7	261	51	.	12	4	..	..
Shot contusions of the pelvic bones.....	30	25	3	2	10.7	25	3	2	..	..	..	..
Shot contusions of the humerus........	22	18	4	..	18.1	18	4	..	..	..	..	..
Shot contusions of the forearm.........	10	8	2	..	20.0	7	1	..	1	..	..	1
Shot contusions of the femur and knee.	205	144	61	..	29.7	140	46	..	..	..	4	15
Shot contusions of the leg and ankle...	194	165	29	..	17.5	157	15	..	..	..	8	14

Aggregates..........................	816	659	155	2	19.0	634	121	2	13	4	12	30

Structure has undoubtedly a great influence in determining the severity of the effects of contusion.

Such lesions in the spongy bones or cancellated portions of long bones, attended with extravasation of blood, are very likely to result in extensive and dangerous necrosis, inasmuch as the blood confined within an unyielding structure interferes by compression with the nutrient blood-vessels, or, acting as a foreign body, destroys the vitality of the bone by setting up inflammatory action.

The following case of simple osteomyelitis affords a typical and instructive illustration of one of the frequent and grave results of bone contusions observed during the late war. A soldier aged thirty years was wounded at Cold Harbor, June 6, 1864; he was admitted to hospital for a gunshot wound of the left thigh, in the upper third, inflicted by a conoidal ball which penetrated the front of the limb at the inner side of the femoral vessels, and passing backward and outward through the limb, lodged beneath the skin. It was extracted by an incision behind, and the wound was regarded as one of the soft parts only. His general condition was fair, or rather below par, at the time; for several days the wound did well; about July 1st, it was observed that the patient was failing in strength and emaciating; stimulants, tonics, and a supporting treatment were ordered, but he sank into a typhoid condition, with warm skin but without sweating; the pulse was frequent and feeble, the tongue red and dry, and there was almost entire loss of appetite. He became somnolent and was roused only with difficulty. The discharge from the wound was at no time large, but the leg remained swelled and inflamed. He died July 18th; at the autopsy it was found that the bullet had struck the shaft of the femur on its postero-inner side, two or three inches below the trochanter, *grazing and bruising it.* The aperture of exit had healed; there was an abscess about the place of injury of the bone as large as an orange, and pus had burrowed among the muscles of the thigh; there was a large deposit of new bone about the contused portion of the femur. On making a longitudinal section of the bone, new osseous tissue was found deposited in the medullary canal; the marrow presented the "red inflammatory" appearance described by Virchow; there was no thrombosis nor any lesion of the arteries and veins. The body was much emaciated. No lesions of the intestines or internal organs were found.

Many other cases were not as simple in their course, but were complicated with erysipelas, phlebitis, and pyæmia.

Not a few cases were reported in which no permanent injury was sustained.

One soldier was struck by a conoidal bullet which entered the region of the groin and flattened itself upon the pubic bone. He lay upon the field all night in an unconscious condition, but after having been placed in hospital he did well, and was detailed to duty as a clerk.

Another soldier was struck by a large leaden bullet on the spine of the right tibia, between the middle and lower third; the ball was split to within a few lines of its base, overlapping the bone. A portion of the bone subsequently came away, leaving a depression, but no serious consequences followed.

Instances are also adduced in which missiles were split upon the bones of the forearm, and on the zygoma, but in each case little permanent injury seems to have resulted. In many cases balls were found wedged between bones without doing serious harm.

Simple fractures following shot injuries are infrequent, and generally result from the impact of projectiles of the larger class, as solid shot, grape-shot, or shell fragments, the momentum of which is nearly expended.

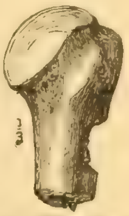

FIG. 4632.—Head and One and a-half inch of Left Humerus, showing Partial Fracture.

An examination of many cases of shot injuries of the bones of the extremities has confirmed the opinion that shot fractures of long bones, without injury of soft parts, are more infrequent than visceral ruptures without external wounds.

Hamilton, in his "Military Surgery," observes: "When the bones of a limb are broken by a solid shot and the integuments are not torn, the fracture is seldom simple, but almost always the comminution is excessive." The cases of simple fractures reported during the war bear out this opinion.

Partial Fractures.—Instances of partial fractures of bone in which a portion of the substance has been cut out without a complete solution of continuity, are occasionally met with. This lesion is more commonly seen in spongy bones, or in the parts of long bones well supplied with cancellated structures. Figs. 4632, 4633, and 4634, from the "Medical and Surgical History of the War of the Rebellion," represent fractures of this kind, and are generally serious from the excessive suppuration and consequent exhaustion. Amputation or excision has commonly to be resorted to for the purpose of saving life. Small missiles, as bullets and small shell fragments, often penetrate a bone and remain fixed with little splintering and fissuring. Instances

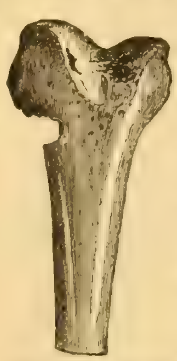

FIG. 4633.—Lower Third of Right Femur, showing Partial Fracture.

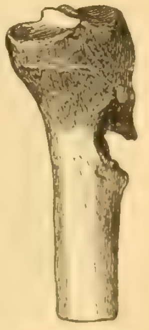

FIG. 4634.—Upper Portion of Left Tibia, showing Partial Fracture.

[illegible] of this nature are [illegible] in spongy bones or in the cancellated structure of long bones. A unique illustration of such an injury is shown in Fig. 4635. An excavation at the base of the great tuberosity of the humerus, the shape and a little greater than the size of a conoidal ball, one inch deep, extends into the head of the bone; the walls of the cavity are perfectly smooth, as if made by design, and there is no fissuring or comminution connected with the injury.

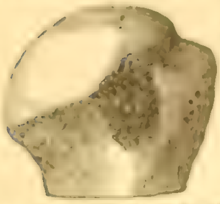

Fig. 4635.—Head of [illegible] Humerus [illegible]

Figs. 4636 and 4637 show the result of penetration of a missile lodged in the cancellated structure of the femur without splintering.

More frequently penetration is accompanied by fissuring and splintering, as represented in Fig. 4638, where a conoidal ball is shown to be imbedded in the lower third of the femur, just above the patella. A fissure extends upward three and a half inches, and another and independent one traverses the outer surface. This patient was wounded by a Minié ball, which perforated the quadriceps femoris close above the left patella, and lodged one inch above the articular surface of the knee joint; recovery followed amputation.

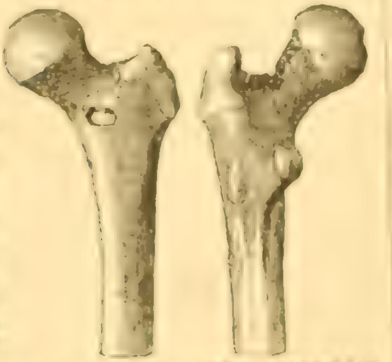

Fig. 4636.—[illegible] Femur. [illegible] by a Missile.

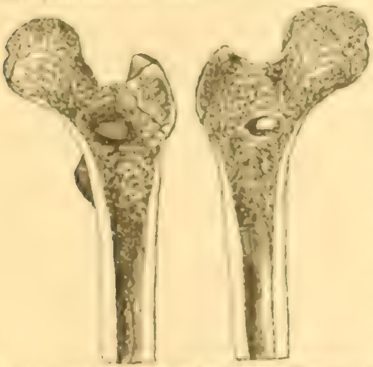

Fig. 4637.—View of Fig. 4636 [illegible] Specimen.

Fig. 4639 shows the upper third of a right femur with a conoidal ball imbedded, point downward, in the anterior aspect, just above the articulation; a fissure extends upward the length of the specimen. The limb was amputated at the lower third of the thigh, the patient dying in a few hours from exhaustion from loss of blood.

Figs. 4640 and 4641 represent specimens received at the Army Medical Museum without histories; they were taken from the battle-fields of the Wilderness and from the front of Petersburg. The fissures do not extend into the knee joint, although the point of impact was close to the articulation.

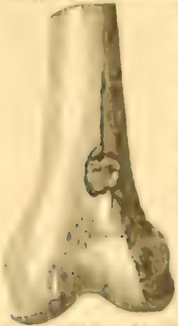

Fig. 4640.—Lower Third of Left Femur. [illegible] by a Musket.

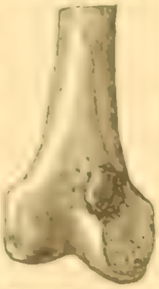

Fig. 4641.—Femur [illegible] Lower Third [illegible] of a Musket.

Perforations of Bone.—When shafts of long bones are perforated there is commonly much splintering, as is illustrated by Fig. 4642. A Colt's revolver ball passed through the upper third of the femur from behind forward, comminuting the bone; death occurred three hours after amputation. In Fig. 4643 the tibia had been perforated below the head, causing longitudinal fissures. Figs. 4644 and 4645 represent a perforation of the lower third of the femur by a musket ball; two longitudinal fissures extend upward, and a slight one enters the joint.

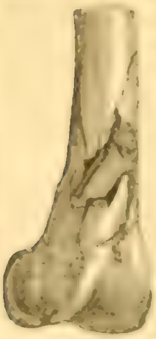

Fig. 4642.—[illegible] by a Missile.

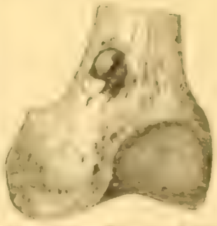

Fig. [illegible].—Fissure of the Lower Extremity of Left Femur by a Musket.

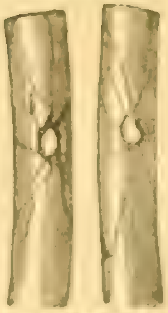

Fig. [illegible].—Section of Left Femur Perforated.

In Figs. 4646 and 4647 the shaft of the femur is perforated, with a longitudinal fissure on the anterior surface extending into the joint and for four inches upward, ending in a slight transverse fissure; on the posterior surface an oblique fracture runs upward for nearly four inches. The condyles are also separated by a fissure. The fracture was made by a round musket ball.

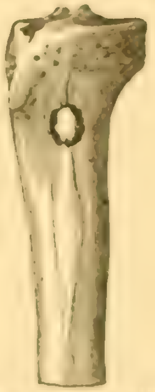

Fig. [illegible].—Upper Third of Left Tibia Perforated.

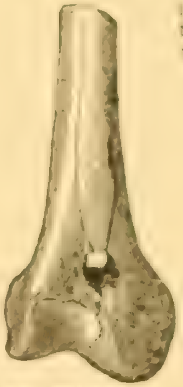

Fig. 4646.—Lower Third of Left Femur Perforated.

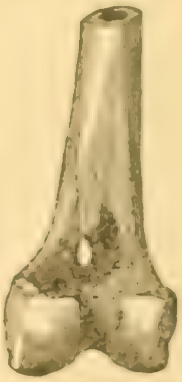

Fig. 4647.—Posterior View of the Specimen shown in Fig. 4646.

Complete Fractures.—In by far the greater number of shot fractures of bones the solution of continuity is complete, the degree of comminution depending upon the attending circumstances.

In rare instances fractures, transverse or oblique, but simple or rarely comminuted, occur. They are commonly due to the impact of nearly spent missiles or to grazing or glancing balls.

Fig. 4648 shows an oblique fracture of the upper third of the left femur, with a minute fissure extending to the lesser trochanter, and a small portion chipped from the anterior face of the

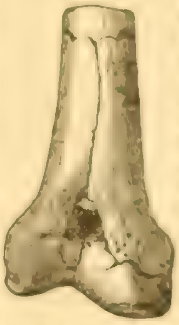

Fig. 4648.—[illegible]

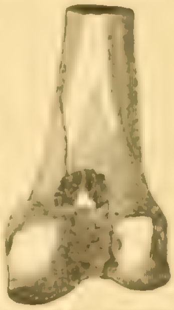

Fig. 4649.—[illegible]

point of impact. Another illustration of this rare fracture is given in Fig. 4649, showing the lower half of the right humerus, apparently amputated because of a nearly transverse fracture through both condyles. In these cases the missile is generally found in close apposition to the fracture.

A form of injury has been noted in which the bones are fractured and comminuted, though less than usual, at the point where the ball impinged, while at a short distance above or below this point an oblique or transverse fracture is produced. When the point of impact is above the middle of the bone, the fracture is below; when below the middle, the fracture is above; Fig. 4650 shows a nearly transverse fracture in the middle of the left tibia, communicating with the point of impact by a longitudinal fissure. Fig. 4651 exhibits the lower portion of the left femur amputated in the middle third, for a perforation with oblique fracture above the seat of injury.

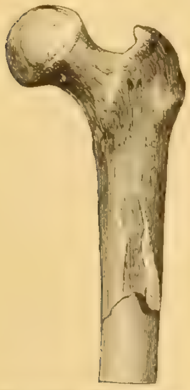

Fig. 4648.—Transverse Fracture of Upper Third of Femur by Conoidal Ball.[1]

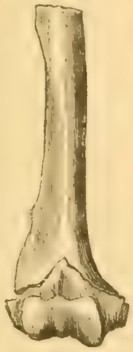

Fig. 4649.—Transverse Fracture in Lower Third of Humerus.[1]

Fig. 4652 represents an extensive longitudinal fracture, implicating the joint, and complicated with an oblique fracture of the lower third.

Fractures of this nature are usually found in the long bones of the extremities, and are probably the result of the direct impact of a missile at high velocity, upon bones somewhat firmly fixed by the weight of the body.

Commonly a bone is broken into many fragments, some of which are entirely detached and driven into the surrounding tissues, while others remain connected with one or another of the fragments by shreds of periosteum.

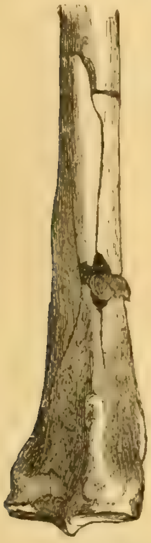

Fig. 4650.—Tibia, Representing Transverse Fracture.[1]

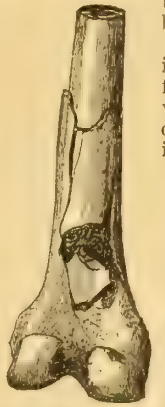

Fig. 4651.—Lower Half of Femur, Showing Transverse Fracture.[1]

Over and above this shattering and comminution, effects common to all forms and varieties of missiles, the extensive splintering and destruction so often found is unquestionably due to the wedge-like form and great force of the conoidal bullet.

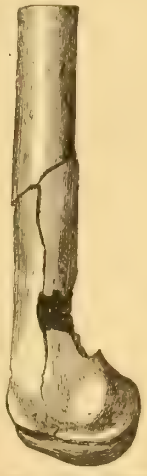

Fig. 4652.—Lower Half of Femur with Transverse Fracture.[1]

When the shaft of a long bone is fractured about equidistant from the epiphyses, the fissures extend upward and downward in about equal proportion; but as the point of fracture approaches the ends, the tendency is to split in the direction of the longer fragment. This is particularly noticeable in fracture of the humerus near the head, when the general tendency of fissuring is downward.

Fig. 4653 represents the excised portion of a left humerus, including the head and four inches of the shaft. The fracture is at the surgical neck and extends with comminution obliquely down the shaft. Fig. 4654 shows the upper half of a right femur; the missile struck the anterior face of the bone a little below the trochanter minor, and shattered and fissured the femur downward. In Fig. 4655 the comminution is represented as extending upward and downward in about equal proportion. The weapon causing this wound was discharged at very close range; a soldier, becoming enraged from some cause, threw his musket from him, causing its discharge; the missile, a Minié ball, entered the right thigh, greatly lacerating the soft parts and comminuting the bone as shown by the figure. The specimen is a fair illustration of the effects of a conoidal ball at short range.

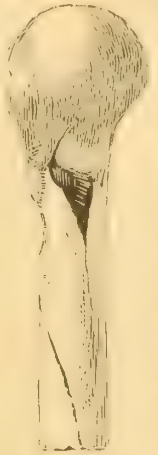

Fig. 4653.—Humerus, Showing Downward Tendency of Fissure.[1]

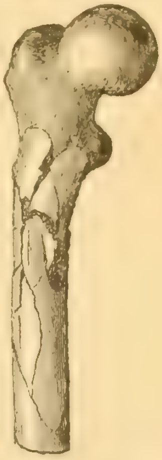

Fig. 4654.—Femur, Showing Extensive Comminution.[1]

From a careful examination of a large number of specimens of long bones in the collection of the Army Medical Museum, it would seem that the statement made by Esmarch is correct, that "in comminution of a long bone the fissures almost never extend into the epiphyses; in the same manner, injuries of the epiphyses, only in some rare cases, extend into the shaft, unless the bullet strikes the adjoining border of both parts, in which case both head and shaft are more or less comminuted."

This is probably due, as Esmarch says, "to the soldier being generally young, and the parts not consolidated." The Army Medical Museum possesses several specimens showing this kind of injury, some of which have been illustrated above (see Figs. 4650 and 4651).

The few exceptions to this rule seem to be in cases in which consolidation is complete, or in which the direction of the missile was such as necessarily to cause this effect, as in Fig. 4656, where fissures extend through the head and into the shaft.

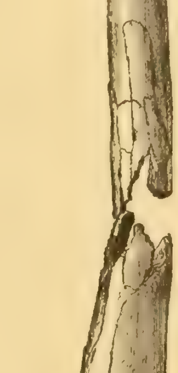

Fig. 4655.—Femur, Showing Extensive Shattering by Conoidal Ball.[1]

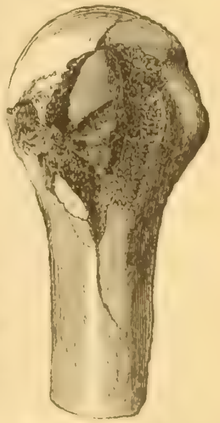

Fig. 4656.—Humerus, Showing Fracture at the Epiphysis.[1]

It has been shown that cases of penetration and perforation of bones may occur without complete fracture; but this is contrary to the more general rule, and even in spongy bones, where we would naturally look for such lesions. It will usually be found that complete destruction of the bone results.

EFFECTS OF MISSILES AND PROJECTILES ON NERVES.—Shot wounds and injuries of nerves afforded a wide field for observation and study during the late war.

Wounds of this class, not implicating the great nerve centres, and not complicated by severe lesions of other tissues and parts, show a very small percentage of mortality, but comprise a class of injuries which result too often in great and permanent disability, attended with intense suffering and misery, and are often but little amenable to treatment.

Early in the late war a hospital for the reception and treatment of this class of injuries was established by the Government in Philadelphia, Pa. Acting Assistant Surgeons S. Weir Mitchell, George R. Morehouse, and W. W. Keen, Jr., United States Army, were placed in charge, and to the experience of these gentlemen in the study and treatment of the large number of cases in their care we are indebted for the most valuable contribution to the literature of a much neglected subject.

With reference to the above hospital, the surgeons in charge remark as follows: "Among the cases were representatives of every conceivable form of nerve injury—from shot and shell, from sabre cuts, contusions, and dislocations. So complete was the field of study that it was not uncommon to find at one time in the wards four or five cases of gunshot injury of any large nerve. It thus happened that phenomena, which one day seemed rare and curious, were seen again in other cases the next day, and grew commonplace as our patients became numerous."

The immediate effects of shot injuries of nerves were pain—not generally felt locally, but at some point in the distribution of the nerve; when a nerve was completely divided, total loss of sensation in the parts supplied by it; shock more or less profound, proportionate to the reflex disturbance; and paralysis of motion and sensation, complete or partial.

Of forty-eight cases of severe shot injuries of nerves, selected with a reference to the study of the immediate effects of injuries, Drs. Mitchell, Morehouse, and Keen found that "by far the greater number felt, when shot, as though some one had struck them sharply with a stick," and that "about one-third experienced no pain nor local shock when the ball entered. More rarely, the pain of the wound was dagger-like and intense, while a few, one in ten, were convinced for a moment that the injured limb had been shot away; in two instances of neck wounds the pain at the moment of wounding was intense, and was referred to the insertion of the deltoid muscle."

In a case of shot wound of the leg, it is reported that the patient felt no pain, but had so vivid an "impression" of a wound in the other leg, that he found it difficult to get rid of the erroneous idea.

With reference to the shock from wounds of nerves, the same authorities say: "Every case of wound of nerve trunks in the legs fell instantly, and not one of the twelve so wounded lost consciousness; yet, in gravity and in the size of nerves injured, these were among our worst cases. Of the remaining thirty-one, seven fell instantly, unconscious; one only of these bled very largely. Of the seven, all were wounded in the neck, face, or arms.

"Of the total number of arm cases, eighteen in all, two were of the class described above as falling senseless; of the remainder, two only fell, but with entire consciousness and in full possession of their senses. Fourteen continued standing or walked away. Of the wounds of the lower neck and axilla, brachial plexus or axillary nerves, one fell senseless, four fell conscious, and the remaining eight suffered no immediate fall. If, then, we regard the fall with loss of consciousness as the most marked expression of the condition known as shock, we shall have some right to infer that it is most likely to be felt severely in wounds about the upper third of the body."

In paralysis of nerves, motion is more frequently impaired than sensation. While it would naturally be supposed that both motor and sensory fibres would suffer equal damage by a missile striking or contusing a nerve, it is found that practically the motor fibres suffer most seriously; and this is true of all stages of such cases. Lesions of motion are always the least readily relieved, and the last to improve.

Of the forty-eight cases above alluded to as having been studied by the authorities named, five were reported as being wounds affecting nerves of single function; of the remaining forty-three, thirty-two exhibited total loss of motion with defective sensation, or entire loss of that function. In the remaining eleven there was partial loss of motion, and usually slight loss of sensation. In defining total loss of motion it must be understood that the whole limb became powerless at once.

Of injuries caused by shot wounds of the great nerve centres, it may be stated in general terms that the greater percentage of such injuries proved fatal at once, or within a very short period. Those that survived the original injury most generally became the victims of insanity, epilepsy, or chorea.

When the spinal cord is severed or seriously involved, a fatal issue ensues more or less remotely.

Aside from these graver injuries are found innumerable cases of shot lesions in which it is evident that damage is done to the nervous centres by concussion, compression, or contusion, or in which are presented the phenomena of reflex paralysis.

The following cases, taken from the records of the war, will serve to illustrate these lesions and injuries of the spine:

In the case of a soldier wounded at Gettysburg, July 1, 1863, a Minié ball entered the back at the angle of the right shoulder blade, passed across, and was extracted three inches below the left shoulder blade, escaping the [illegible]. The patient complained of numbness and loss of power in the legs; no displacement or tenderness of the spinal column was apparent. He was discharged the service in January, 1864, on account of partial paralysis of the lower extremities, the result of his wound, and was pensioned.

The last report received by the Pension Office in his case, September, 1877, states that the pensioner has only partial control of his bladder and rectum. This is not an uncommon result of what are at first considered trivial wounds.

Lieutenant J. F. M. was wounded June 27, 1863, by a Minié ball, which struck him two inches to the left of the spinal column, opposite the first lumbar vertebra, and followed up the spinal column until it reached the spinous process of the first cervical vertebra, where it turned to the left, and was cut out from beneath the skin over the middle third of the sterno-cleido-mastoideus muscle. The lower half of his body was paralyzed; his symptoms continued to grow worse and he died July 12, 1863.

A color-sergeant was wounded at Vicksburg, May 19, 1863, and was discharged the service for shot wound of the spine, with fracture of the spinous and transverse processes of the ninth, tenth, and eleventh dorsal vertebræ; the ball struck the crest of the left ilium three inches back of the anterior spinous process, passed through near the sacrum and lumbar vertebral articulation, and was cut out two inches to the right. A year later he is reported as a complete paraplegic; the wound of entrance is discharging, and an opening over the spine gives vent to pus and pieces of the vertebræ. In 1874 the pensioner is reported as wearing an apparatus to support the upper part of the body, without which he has no power to sit erect; the legs are entirely useless, and he requires the services of a personal attendant continually.

In some cases it happens that the spine itself escapes direct injury, but the lodgment of a missile in close proximity to the nerve centres causes compression of the adjacent branches.

The following case illustrates what is known as concussion or "commotion" of the spine; it is not supposed that any large nerve could have been touched : The patient, a soldier, was accidentally shot, while sitting upon a fence rail, by a pistol-ball ; it entered at the median line, exactly over the interspace between the spinous processes of the sixth and seventh cervical vertebræ, and was cut out on the left side of the neck one inch below the angle of the jaw. No bone escaped at the time, and the surgeon who examined him felt assured that there was no fracture. The patient thinks he was looking to the left when shot ; if he be correct as to his position, the ball could have come near to no part of importance except the spine, and in any case, it would be difficult to assert that it could have wounded the cervical, and still less the brachial, plexus. He fell senseless, and was conveyed to a hospital tent, but recovered his senses within two hours. He then found that he had neither motion nor feeling in any of his limbs—the trunk was equally powerless, and he was unable to feel the bed upon which he rested. Gradually, sensation first, and then the power of voluntary motion, returned to the whole right side. Within a month the left side improved, with the exception of the left arm. Five months after the injury his condition is reported as follows : General loss of flesh, left arm markedly atrophied ; no notable difference in legs ; the left shoulder much atrophied, especially the deltoid ; the left hand is congested and swollen, with burning pains in the palm ; the left leg is weaker than the right, and his gait is awkward from his swinging his right leg outward and forward.

Cases of reflex paralysis are met with as a result of shot wounds of nerves, and among those recorded may be mentioned those in which paralysis of some remote part or organ has been occasioned by the injury done to some large nerve, or to some portion of the body which is richly supplied with nerve branches of even secondary size and importance.

These injuries are rare ; of sixty or more studied by Mitchell, Morehouse, and Keen, only seven cases of reflex paralysis of remote parts or organs were met with in which the influence was severe or prolonged. In the majority of the cases reflex effects are slight and transient, and could perhaps be better observed on the battlefield, was not the attention of surgeons taxed to the utmost by the more palpable wounds thrust upon them.

Among the reflex effects alluded to may be classed the cases of syncope, arrest or disturbance of the heart's action, the great pallor, weakness, and depression attendant upon shock after injury ; and among the more severe and prolonged effects, paralysis of sensation and motion, and of special senses.

But few cases of injuries of nerves of special sense caused by missiles are recorded as having occurred during the late war. Among these are noted two cases involving the whole or branches of the sympathetic nerve ; two cases of shot wounds of the portio dura of the seventh pair, and one of injury of the facial nerve resulting in facial paralysis and great distortion ; this latter patient also suffered loss of sight in the left eye, and of hearing in the left ear.

Nerve-trunks may be completely severed by a missile, or they may be partially divided and lacerated ; they may be contused by the near passage of a missile which has insufficient power to divide or lacerate, or which has expended its force on neighboring tissues. As in the case of arteries, their position and surroundings tend to protect them, and it is probable that their mobility and form may enable them to slip aside and escape damage from a passing missile.

Mitchell, Morehouse, and Keen add to the above more common forms of shot injury, those from cicatricial pressure, and those from the extension of diseased processes from wounded nerves to those which are healthy. The same authors consider injuries from concussion of a nerve to be those "most apt to be permanent and serious." The persistence and severity of the symptoms—such as shock, pain, and partial or complete loss of motion and sensation—and the extent of loss of function, seem to indicate, in some degree, the remote effects generally to be expected.

Instances of immediate death from injuries of nerve-trunks are probably rare, though it is not difficult to conceive of such disturbance of central ganglia as may induce a fatal result, and actual cases of this kind are not wanting in the records.

The important labors of Mitchell, Morehouse, and Keen in the vast field presented by the organization of a hospital for diseases and injuries of nerves, cannot be better appreciated than in their clinical observations upon the remote effects of nerve injuries.

"Most of the cases presented phenomena which are rarely seen, and which were naturally foreign to the observation even of those surgeons whose experience was the most extensive and complete. Nowhere were these cases described at length in text-books, and their treatment was passed over in silence. In the great monographs on military surgery this defect is still so complete that wounds of nerves are there related rather as curiosities and as matters for despair, than with any view to their full clinical study and systematic treatment."

In cases of nerve injury, immediate symptoms, when not severe, may pass away, leaving the patient uninjured, but by far the more common result is that, while there may be a temporary improvement, there is a permanency of certain symptoms, especially those of paralysis of movement and sensation. As time progresses, others are added which give the case a hopeless aspect, viz., altered nutrition, changes in calorification, persistent pain, and other sensory phenomena.

Atrophy of muscles certainly follows complete division of nerves, when there is no subsequent repair. The muscles waste, the areolar tissue shrinks, vessels fade from view, and the pulse becomes feeble and small. These processes go on with certainty until nothing is left but bone and degenerated areolar tissue, covered with skin altered in its appearance and functions.

Among the forms of altered nutrition, that of the skin, noticed by Paget, is not infrequently seen ; reference is made to the "glossy fingers ;" in well-marked cases the fingers which are affected—and it may be confined to one or two of them—are usually tapering, smooth, hairless, devoid of wrinkles, glossy pink or ruddy, or blotched as if with permanent chilblains ; they are commonly very painful, especially on motion, the pain extending up the arm. In most of the cases this condition of the fingers is attended with very distinct neuralgia, both in them and in the arm. Out of fifty partial nerve lesions under treatment in the hospital for nervous diseases and injuries, this condition existed in nineteen, and the description of the symptoms agrees well with that of Paget.

Eczematous eruptions are a frequent accompaniment of this condition of the skin.

In many cases of altered nutrition, the hair disappears from the affected region, and a remarkable alteration in the nails is noticed, consisting in longitudinal curving, and an extreme arching, with, generally, a thickening of the cutis beneath its extremity ; distressing ulceration is apt to occur at the angles of the nails of the toes, when they are affected, which is inveterate, despite every care and attention.

Acute, painful swelling of joints is often a sequence of nerve injuries ; it is distinct from swelling due to inflammatory action about the wound, but is more permanent and persistent ; when the acute stage passes, the tissues about the articulations become hardened, and partial anchylosis results; so that, in many cases, the only final cause of loss of motion is due to this state of the joints. Of all agencies which impede movement, it is the most difficult to relieve.

After complete division of nerves the secretions of the skin are generally absent, while incomplete division results in a variable condition of this function ; in some cases there is excessive sweating, limited to the area of the surface affected. Cases of perverted secretion, acid sweating, and perspiration of a disgusting odor have been noted after incomplete division of nerves.

Lesions of sensation are always present in some degree. Hyperæsthesia and anæsthesia are very comrently observed. Neuralgia is of great frequency and persistence, stubbornly resisting treatment. Its favorite seats seem to be the hand and foot; other portions of the body are less frequently attacked. Severe neuralgia may, in some instances, be due to the presence of foreign bodies, as fragments of lead from a bullet, splinters of wood, bone, or bone pressing upon or imbedded in a nerve-trunk. The pain in such cases is always acute and persistent. Not infrequently neuralgia assumes such an intensity as to react upon the whole economy, leading to nervous prostration and break-down.

Paralysis of the motor nerves from shot injuries varies in all degrees of intensity and completeness. The following case presents interest on account of the motor lesion, and also as presenting well marked reflex effects:

A sergeant, engaged in scouting, was wounded by three bullets (slugs), one striking the right hip, another the right arm, and the third lodging in the left shoulder. The wounds of the hip and arm gave no subsequent trouble; the wound in the shoulder was deep and painful.

The slug entered just over the third left rib, about in a line with the middle of the clavicle, and passed upward and backward, lodging in the deep muscles. The pain was sharp and tingling, accompanied by a buzzing or throbbing sound in the left ear, and the eyes became very sensitive to light; all these symptoms gradually disappeared, and he rejoined his command. In about a year his eyesight had failed to such a degree as to require positive glasses, and he suffered attacks of neuralgia of the cardiac region.

This situation remained unchanged for nearly twenty years, when he fell down a flight of stairs, striking upon the left shoulder. The day after the fall, while writing, he suddenly lost the power over the fingers of the left hand, and soon after the whole left arm became powerless. He could not rise from his chair on account of weakness of the left leg, and soon paralysis of the whole left side ensued. His general condition improved in a few days, leaving the left arm and hand useless.

Feeling that the slug in the shoulder was probably the cause of the trouble, he had it removed; it was about the calibre of a lead pencil, three-fourths of an inch long, and flattened at both ends; it weighed one hundred and twenty-seven grains. After the removal of the slug the numbness gradually disappeared from the hand and arm, and in six weeks these members had recovered, with the exception of a slight weakness. The eyesight, which for nearly twenty years had compelled the use of glasses, improved to the extent that they were no longer needed or used. There was also great diminution of the cardiac neuralgia from which he had long suffered.

The prognosis of motor injuries is uncertain, and is largely dependent on whether the loss of function is complete or incomplete; if a muscle responds to the will after the injury, there is a reasonable hope of increasing gain and restoration of power; early loss of tone, rapid shrinking of muscular tissue, and contraction, when not merely spastic, are bad indications. They show loss of nutritive fibre, and result in deformity and permanent loss of power.

As results of motor paralysis are found loss of motion from [illegible] joints, contracted muscles, spasmodic affections, and tremors.

Drs. Mitchell, Morehouse, and Keen made a series of carefully conducted experiments on the condition of calorification in injuries of the nerves. The results of a number of grave cases are summed up as follows: "It was observed that the member the nerves of which were affected, was nearly always colder than the other, whether the nerve lesion was extensive or trifling. In two cases there was no difference. One of these was an instance of total motor palsy below the knee, with good tactile feeling preserved, and without [illegible]. The other was a wound of the portio dura of the seventh nerve; the motor palsy complete, sensation perfect. Five cases had a higher temperature in the wounded limb than in the normal member. At the time of the observations we had no wound in which complete division of all of the nerves of a part had occurred; and in fact this is a rare accident. The sole exceptions were wounds of the seventh pair. One of these we examined as to temperature, but with no notable result: there was no difference between the two sides."

EFFECTS OF MISSILES AND PROJECTILES ON BLOOD-VESSELS.—Wounds of blood-vessels by missiles and projectiles were few in comparison with the total number of shot wounds received during the late war. In the general consideration of these injuries, the question as to the particular character of the missile does not appear to possess much practical importance. In fact, it is difficult to distinguish the effects of injuries inflicted by one or the other of the more common forms of bullets.

It is probable, from the general conditions pertaining to missiles, that a round ball will more frequently contuse than divide a blood-vessel, while the contrary may be expected to result from an injury by a conoidal bullet; but perforations by round balls have been observed.

Distorted balls, pieces of shell, fragments of stone and iron, and splinters follow the general rule common to all missiles, by contusion, cutting, and punctuating blood-vessels.

The graver lesions due to the impact of large projectiles are so manifest in their character as to need no comment.

The position of the larger trunks of the principal blood-vessels tends to give them immunity from accident.

They are deeply placed, sheltered by bony framework, protected by soft parts and by fasciæ capable of deflecting the course of a missile; their investing sheaths are strong and tough, having a certain degree of freedom of motion; they are able to slip aside and elude a passing missile; their tubular form and easily compressed fluid contents are also elements of safety.

All of these conditions may have their influence in contributing to the many fortunate escapes from severe, perhaps fatal, injury common to the experience of every military surgeon.

The following are cases in point:

A soldier was wounded while on picket by a ball, whether round or conoidal is not known, which entered the right thigh near the lower angle of Scarpa's space, crowded or pushed aside the femoral vessels, passed upward, and escaped posteriorly. Very little hemorrhage followed, though he walked a considerable distance. No bad symptoms developed, and he made a rapid recovery.

In another case, a musket ball lodged between the carotid artery and jugular vein, pressing the vein forward to such an extent that the vessel was collapsed and little or no blood passed through it.

In still another case, a musket ball passed on a level with the pomum Adami between the jugular vein and carotid artery, without injuring either vessel.

Aside from the injury of large trunks which are immediately fatal, it would appear that the number of cases of wounds of important blood-vessels is small. It is stated that in the campaign of the Army of the Potomac from the Rapidan to the James in May, June, and July, 1864, of a total of [illegible] gunshot wounds, only [illegible] belonged to this category.

Dr. Longmore ("Gunshot Injuries," [illegible]) says: "Out of [illegible] wounds detailed in the British returns of the Crimean War, only 17 wounds of arteries were registered."

Surgeon Goldsmith, U. S. V., desiring to know whether external primary hemorrhage often occurs as the instant result of shot wounds, placed himself near the line of battle and observed only one case, a soldier struck in the neck, the ball severing the carotid, and resulting fatally before he could reach him.

In the following case almost instant death ensued from the perforation of the carotid artery. Lieutenant-Colonel F. A. K. was shot at Suffolk, Va., at about 4 A.M., April 12, 1863. He uttered a brief ejaculation after he was shot and died instantly. At the autopsy made upon the body it was found that the common carotid was absolutely perforated from before backward, there being a roundish opening in the anterior, and a somewhat longitudinal one in the posterior wall, the two lateral portions being entire; the par vagum and jugular vein were uninjured. The missile was a conical pistol-ball, and quite a size larger than the diameter of the artery.

The passage of a missile through any part of the body will necessarily divide and lacerate many small blood-vessels, but serious hæmorrhages seldom follow, as permanent retraction of the wounded vessels takes place at once.

When an artery of some size is completely divided by the impact of a large or small projectile at high velocity there may be a gush of blood; but the immediate retraction of the inner and middle coats, and the formation of a coagulum, will generally prevent further hæmorrhage, and secure the patient for the time, at least.

In 84 of 118 cases of complete division of the large arteries no primary bleeding was observed, while in 34 cases, or 28.8 per cent., the injury was followed by primary hæmorrhage.

Summary of One Hundred and Eighteen Cases of Complete Division of the Larger Blood-vessels, Indicating the Number of Cases in which Primary Bleeding Occurred.

The proportion of primary bleedings to the number of cases in which the vessels were completely divided is rather larger than that observed by Dr. Lidell, who found that in twenty cases the bleeding ceased spontaneously in all but three.

In some cases, in which the division of the blood-vessel is followed by primary hæmorrhage, it is possible that some foreign body may be thrust into the open lumen of the artery which will prevent retraction, while insufficient to act as a plug; or that there may have been paralysis of the nerves of the arterial coats, preventing their retraction.

Cases of partial division of vessels more frequently come under the observation of the surgeon. In these cases it is usually found that only a portion of the calibre of the vessel is carried away, or that perforation has taken place.

Under such circumstances the retraction of the vessel is rendered impossible, and hæmorrhage ensues proportionally to the size of the artery and of the wound. A case of shot perforation of the carotid has been cited above; and a perforation of the right primitive iliac is shown in Fig. 4657. The injured man died in twelve minutes. If a wounded artery is large the hæmorrhage will be profuse and attended with speedily fatal results, unless help is at once at hand, as in the case of an officer who was wounded by a partially spent rifle-bullet in the front of the left thigh. Profuse hæmorrhage ensued, followed by syncope. Several surgeons were close at hand and promptly arrested the bleeding with a tourniquet; later the wound was enlarged and the femoral artery ligated above and below the injured point. The wound was situated about four inches below Poupart's ligament, and about an inch below the profunda. On the eighteenth day there was a second hæmorrhage of about eight ounces; it ceased with compression and quiet, and there was no return. Had not this officer received instant help, a fatal issue could hardly have been averted.

In the case of a soldier whose femoral artery had been perforated there was copious, instant hæmorrhage, which was arrested by the prompt application of a tourniquet. Bleeding recurred on the sixth day, and was again arrested by pressure; the wound became unhealthy, and the patient died on the tenth day after the injury. Prompt operative interference would have afforded a chance of life.

Sometimes hæmorrhage will continue, though it may be retarded by the formation of a coagulum in the track of the wound; but the tendency is to form a diffuse traumatic aneurism, which, untreated, will exhaust the patient by frequently recurring hæmorrhages.

In the greater number of cases injury to blood-vessels was caused by contusion.

Missiles with low velocities, or those whose force is partially expended previous to contact with the artery, seldom divide or penetrate the vessel, but contuse the arterial coats, destroying or impairing their vitality, and establishing inflammatory action which results in the removal of a slough at definite periods, accompanied by profuse secondary hæmorrhage. In some cases the resulting inflammation, or the injury to the vasa vasorum, effects a partial or complete occlusion of the arterial tube; if the collateral circulation becomes well established, recovery may take place; but fatal gangrene of the extremity, deprived of its blood-supply, very commonly supervenes.

This condition is well illustrated by the case of a soldier who was wounded in the superior portion of the left thigh, and posterior part of the neck of the left femur. After considerable exposure upon the battle-field, the left leg and foot of the patient were found to be cold and insensible; shortly after, a line of demarcation appeared encircling the ankle at the malleoli; amputation at the union of the middle and lower third of the leg was performed, but the man died on the forty-eighth day after the injury. An autopsy showed the course of the ball to have been posterior to the femoral artery, impinging upon its sheath, for the wall of the artery was thickened at this point and was of a brownish color, and the calibre of the vessel was diminished one half; a fine coagulum filled the sheath for a distance of one inch below the track of the ball. The gangrene in this case was clearly due to the diminution of the calibre of the artery, assisted probably by the exposure to cold and wet which the soldier had suffered.

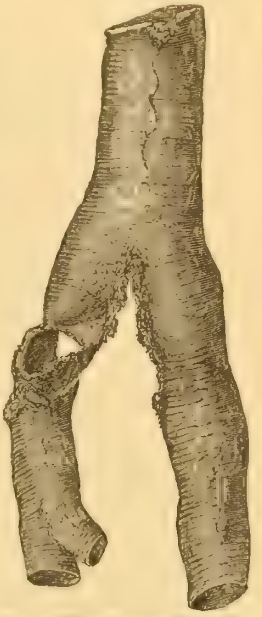

FIG. 4657.—Showing Shot Perforation of Right Primitive Iliac Artery.[1]

Not infrequently, spicula of bone, driven before a missile, puncture vessels, and although they may not be productive of immediate trouble, set up inflammatory action, followed by ulceration and sloughing with secondary hæmorrhage.

A soldier received a compound fracture of the lower third of the femur, by a conoidal ball, necessitating a secondary amputation at the middle third of the thigh. The femur was found to be much shattered, and the popliteal artery ruptured by a spiculum of bone.

Wounds closely resembling incised wounds are caused by sharp-edged shell fragments flying with great velocity; but a certain amount of contusion and laceration, always present, separates them from the class of purely incised wounds.

Missiles and foreign bodies lodging sometimes act as plugs, controlling for a time hemorrhage from a wounded blood-vessel. An interesting case of occlusion of the common carotid is reported by Surgeon John A. Lidell. A soldier died of secondary hemorrhage, who had been wounded by a round ball, nearly spent, which had struck the lower eye-lid, forward, and had been deflected downward, backward, and a little forward in such a manner as to pass obliquely through the left carotid artery and to lodge in the sheath of that vessel underneath the omohyoid muscle, pressing somewhat upon the par vagum, and occluding completely the proximal end of the divided artery. The hemorrhage occurred fourteen days after the injury. It came on suddenly and was very profuse, causing death in a few hours. At the autopsy it was found *that the divided carotid artery was still occluded on the side of the wound toward the heart by the impacted ball; that the hemorrhage occurred from rupture or spontaneous sloughing of a small fresh coagulum which had formed on the distal extremity of the wounded artery; that the hemorrhage was evidently but recurrent in character; and that it would not have been arrested without the application of a ligature to the vessel on the distal side of the wound.* A remarkable and unique feature of this case is that the traumatic aneurism had formed on the distal end of the divided common carotid artery, the occurrence of which seems to have been favored by the free anastomosis which exists between the terminal branches of both the external and internal carotids of the two sides of the body.

In another case an autopsy revealed the presence of a ball resting upon the right vertebral artery, which had been extensively lacerated at the point where it passes through the foramen of the transverse process of the atlas, and had probably acted as a plug in preventing hemorrhage from that artery, as no clots of blood were discovered at the seat of injury. Death in this case was the result of repeated secondary hemorrhages from a traumatic aneurism of the right internal carotid artery, which had been wounded by the missile in its course.

LODGMENT OF MISSILES AND PROJECTILES.—Cases of lodgment of missiles, projectiles, and foreign bodies in the persons of the wounded in battle are common, and many such are noted during the late war.

Round balls are more prone to lodge than those of a conoidal form, as would naturally be inferred from the rapidity with which the former lose their initial velocity, and the resistance offered to their passage through the tissues of the body.

Conoidal balls at ordinary range preserve sufficient force to perforate the body; but at long range or with velocity diminished by contact with intervening objects before reaching the body, or when the position is such as to compel a long course through the tissues, lodgment very commonly occurs. As a general rule, the lodgment of conoidal missiles is deeper than that of round balls.

The collection of the Army Medical Museum at Washington, D. C., furnishes many specimens, not only of missiles and projectiles proper, removed from the persons of soldiers, but also of foreign bodies, as coins, buttons, pieces of pocket-knives, shreds of clothing, portions of the accoutrements of the soldier, and fragments from objects carried by the force of missiles, as iron wire from the bail of a tin bucket, a portion of a ramrod, a tompion nearly entire, etc.

Not infrequently, pieces of bone or teeth from a wounded comrade, driven before a missile, become themselves wounding missiles.

Splinters of wood and iron, stones, and débris from artillery caissons and carriages, from breastworks and defences, act in a similar manner.

All parts of the body share the liability to lodgment.

The direct effects of lodgment are those common to the presence of foreign bodies generally in the tissues of the human structure; they become the centres and sources of irritation, liable to be followed by symptoms of every degree of severity in nature's efforts to rid herself of the offending matter.

The symptoms largely depend upon the size, nature, and form of the intruding body; also upon the region of the body involved. The most serious results follow the lodgment of missiles and foreign bodies in joints and cavities of the body, or in organs necessary to life; even small missiles, with qualities the most irritating, may be the source of great mischief by the production of tetanus and hemorrhage, when lodged where they may cause pressure upon nerves and blood-vessels.

Passing from the more immediate or primary effects of irritation and inflammation resulting from the lodgment of foreign bodies, we find that the usual tendency of their continued presence is to prevent or retard the process of healing. Cicatrization is thus said to be interfered with by such aggravation of the primary irritation; the wound takes on a condition of chronic inflammation, sinuses form with purulent discharges, sapping and undermining the strength and vigor of the patient, and opening the way for the invasion of any of the surgical complications.

Especially does this seem to be true of substances of organic nature, as shreds of wool or cotton, or splinters of wood.

Until such substances are removed, by nature or art, the progress of the case is usually held in abeyance.

Foreign bodies of a metallic nature, particularly those with smooth surfaces, seem to rest more quietly, frequently permitting the closure of the wound; but if their location is such as to subject them to frequent movements, the wound is liable to reopen; this process will be repeated until the offending body is removed or discharged.

Lodged missiles tend to move or change their position. Slowly and gradually the substance will work to the surface of the body, where it will form an abscess and be discharged; or it may tend toward the internal surfaces of the great cavities, where its presence may be productive of harm; or, on the other hand, it may be harmlessly ejected from the body. Thus balls lodged in or about the abdominal region, and of which the exact position had not been ascertained, have finally been passed at stool *per vias naturales*.

Scraps of iron and lead have been known to work their way through the coats of the bladder, where they became the nuclei of vesical calculi, which were subsequently removed by lithotomy. The collection of the Army Medical Museum contains several fine specimens of this nature; also of portions of bullets and shell fragments which had been similarly lodged in the bladder and removed by operation.

The least harmful effects of lodgment are seen in the cases of balls lodged in the muscular or cellular tissues of the body, and in regions of little vital importance.

Musket balls have remained encysted for years, causing little or no inconvenience. It is not uncommon to find old soldiers who have carried encysted bullets in their person for years. The writer has in mind the cases of two soldiers, one wounded in the lower maxillary region during the Mexican war, the other in the gluteal region during the late war, in both of whom the balls are firmly encysted; the missiles give so little trouble that the suggestion of removal is not received with favor.

A most remarkable instance of the encysting of a ball, is that of an officer of the late war, who carried for fifteen years a full-sized conoidal bullet in the cancellated structure of the condyles of the femur, experiencing but little trouble from its presence.

PRIMARY SYMPTOMS COMMON TO GUNSHOT WOUNDS.—The immediate symptoms common to shot injuries are pain, shock, and hemorrhage.

To be duly appreciated they must be seen early, as they are speedily evanescent, fatal, or merge themselves into conditions pertaining to the later stages of shot injuries.

Shock.—Severe shot injuries, particularly those involving the larger bones and the more important cavities, are followed by a train of phenomena known as "shock," or a general perturbation of the reflex nervous system. Upon the reception of such injuries the recipients suddenly turn pallid, tremble, and may fall to the ground;

the surface of the body is cool and bathed in profuse perspiration ; the features often indicate anxiety and distress, the respiration is labored and sighing ; the circulation is feeble ; there may be loss of consciousness to a greater or less degree ; the mind is often agitated as with fear, or there may be an entire loss of self-control ; finally, shock may result in death without reaction.

The degree of shock seems to bear some relation to temperament, to physical condition, and to the region of body affected. Equal degrees of injury affect individuals differently ; while some are apparently overwhelmed, others maintain their self-control and composure ; in some shock seems to heighten the excitement under which the individual is laboring during a battle ; in others the effect is to produce timidity and panic. As a rule, the more severe the injury the greater will be the degree of shock.

Injuries caused by the larger projectiles, as the loss of a limb near the trunk, are generally followed by depressing shock, and this independently of any loss of blood.

Shock is more profound and persistent in grave wounds of the abdomen than in wounds of any other part of the body. Profound and fatal shock has been the occasional consequence of shot contusion of the abdominal parietes.

Wounds producing great splintering and comminution of long bones are generally followed by a severe degree of shock.

The duration of shock is very variable, sometimes lasting but a few minutes, at other times showing great persistence and continuing for hours or days ; here, too, individual temperament and idiosyncrasy seem to exert a great influence. When shock is very persistent the prognosis must be very guarded, as its persistence may depend upon some severe or fatal injury not recognizable at the time ; as was probably the case in the instance of a soldier who was struck by a Minié ball under the left shoulder : the blow caused him to fall across a railroad track, upon his left hip. He complained of this more than of the wound ; suffered intensely from pains in hip, back, and leg ; his urine had to be drawn by catheter ; all the nervous symptoms increased in intensity, and he never recovered from the shock of the fall, and died eleven days after the reception of the injury. Of twenty-seven fatal cases of shock recorded, fourteen were found to be shot wounds of the abdomen, and eight of the femur. Longmore ("Gunshot Injuries," etc.) found that out of twenty-two deaths from shock, only eight were caused by bullets, and in all of these the cavity of the abdomen had been penetrated by the missile. In the remainder the injuries were from gunshot, shell, or grape.

Pain.—Pain, as a primary symptom of shot injury, is rarely absent. In degree it may be slight or severe, according to the locality of the wound, its nature, and the mental condition of the individual. In simple flesh wounds it is commonly described as stinging or cutting, as from a blow by a cane ; it is sometimes likened to the passage of a hot wire thrust through the part ; by others it is described as dull, like a blow from a heavy body.

When nerves are injured or contused the pain is generally severe, and is commonly referred to parts supplied by the nerve.

In severe wounds, generally, the pain which accompanies them is lost in the anæsthesia of the shock which soon follows.

Pain following shot contusions of bone is often severe and widespread, especially if the injury is insufficient to cause unconsciousness,

Under the stimulus of great excitement, as that prevailing during an active engagement, men may receive wounds without being aware of the fact, until their attention is drawn to the blood flowing from the wound, or until they are affected by faintness from the loss of blood.

The white races, as a rule, seem to be more susceptible to pain, and to suffer more acutely.

The negro soldiers engaged in the late civil war bore their sufferings with great fortitude and patience ; but it is questionable if the actual degree of suffering was as great as that of the white soldiers.

The nervous and sanguine temperaments show a greater capacity for suffering than the lymphatic or lethargic temperaments.

Primary Hæmorrhage.—Primary hæmorrhage, or the loss of blood immediately upon the receipt of an injury severing or wounding a blood-vessel, has been alluded to as causing speedily fatal results, or as ceasing spontaneously by the retraction of the coats of the bleeding vessels, or as being so retarded upon the occurrence of syncope as to allow assistance to reach the wounded man, rendering him secure for the time, at least. As a result of the experience of the late war it may be stated that primary hæmorrhage, within the bounds of possible succor, was infrequent ; yet, without doubt, many wounded men perished through lack of self-possession, want of coolness, or of sufficient knowledge to save themselves.

It is probable that a large percentage of the "killed in battle" were cases where primary hæmorrhage followed the division of important vessels, death ensuing instantly, or before help could be procured.

Surgeon John A. Lidell, U. S. V., observes that a large proportion of the persons killed in battle perish directly from loss of blood. He examined the bodies of 43 dead soldiers, lying where they had fallen on the field of battle. Of these, 23 were wounded in the cranium, 15 in the thorax, and 5 in the abdomen. The blanched and exsanguinated appearance of the bodies wounded in the abdomen, showed clearly that death had been produced by hæmorrhage, and the extreme rapidity with which death had ensued implied that some large blood-vessel had been severed. In the cases wounded in the thorax the bodies also presented the same blanched appearance. There was much blood in the clothing and on the ground in most of the cases wounded in the trunk, showing that the fatal hæmorrhage had taken place externally. There were, however, some cases wherein death had been caused by internal hæmorrhage ; there was but little blood in their clothing or on the ground, but they presented the pallid, wax-like appearance common to death by bleeding. All the wounds appeared to have been inflicted by cylindro-conoidal bullets.

Primary hæmorrhage from wounded veins is generally regarded as of less imminent importance than that from wounded arteries ; but primary hæmorrhage from large trunk-veins lying in cavities and beyond the reach of ligation appears to be as fatal as that from arteries. Primary hæmorrhage from the jugular and femoral veins would appear to be less amenable to treatment than that from others which yield to pressure or cease spontaneously.

Early in the late war it was recommended that each soldier should have in his possession some simple form of tourniquet, and in many regiments the recommendation was carried out ; how far they were of use is not known, as no cases were reported of life having been saved by them ; but it is probable that they were little used, and it is very doubtful if, in the excitement and confusion of battle, they could have been applied with any efficacy. Later in the war, experience taught the older and more seasoned troops to do all that could be done in cases of emergency.

Of the many complications of shot wounds perhaps no one plays a more important part than hæmorrhage.

Injuries apparently trivial prove fatal in the most unexpected manner, as the lesion of the artery causes at first little or no disturbance ; or hæmorrhages occur in cases in which, judging from the course of the ball, no injury to a blood-vessel could have been surmised. Thus the prognosis of a shot wound becomes exceedingly problematical, and the surgeon, not infrequently, is suddenly roused from a feeling of security and brought face to face with an unexpected and serious complication, which, under the peculiar necessities of war, is of difficult treatment ; and the results thus far have been by no means so satisfactory as could be wished.

Too often the surgeon is induced to await developments rather than to resort to prompt action.

ARTERIES.—The number of arterial hæmorrhages found on the records of general and field hospitals, as having occurred during the late war, is 3,245. Of these bleedings 1,049 occurred in the lower extremities; 878 in the upper extremities; 291 were hæmorrhages of the head, face, and neck; and 497 of the trunk.

Of the 3,245 cases recorded the blood-vessels involved were not named in 1,010 instances; and as the details of these cases are not as complete as those of the remaining 2,235, in which the bleeding vessels were definitely ascertained, the former will be dropped in the further discussion of the subject.

The following table shows, first, the bleedings of the ramifications of the ascending aorta in the chest, neck, head, and upper extremities; next, those of the descending aorta in the abdomen, pelvis, and lower extremities; and lastly, the few cases of pulmonary hæmorrhages. The table also indicates the number of cases in which pyæmia, erysipelas, tetanus, and gangrene are reported as complications; the number of cases in which death was ascribed directly to hæmorrhage; and the proportion of cases in which primary injury to vessels and primary bleedings were observed.

Summary of Two Thousand Two Hundred and Thirty-five Cases of Arterial Hæmorrhages of the Head, Neck, Chest, Trunk, and Upper and Lower Extremities, in which the Bleeding Vessels were Indicated by Name.

The number of cases of primary lesions of blood vessels is quite large, comprising 485, or nearly one-fourth of the number under discussion. Of these 110 were immediately followed by hæmorrhage.

To what extent the injuries to arteries influenced the mortality-rate among the wounded will be seen from the fact that, of the 2,235 instances in which bleedings formed an important element, 1,380, or 61.7 per cent., proved fatal; while of the total number of shot wounds (245,790, see table supra) only 13.6 per cent. ended in death. Nor can this high mortality be attributed to the presence of other complications, as pyæmia, gangrene, tetanus, and erysipelas, as the fatality of the cases in which these diseases occurred comprised only 20.5 per cent. of the whole number of deaths; while in 653 instances, or 47.3 per cent., death was ascribed directly to hæmorrhages, and in 22.2 per cent. to exhaustion following severe or continuous loss of blood.

It will be found most convenient, in dealing with the cases of hæmorrhage, to classify them simply as primary and secondary. While, undoubtedly, some of these bleedings occurred a short time after the injury and before the period of suppuration had commenced, it is found impossible to eliminate these cases with certainty and accuracy; and inasmuch as such hæmorrhages partake more or less of a primary or secondary character, they have been assigned to one or the other of these groups.

The following table indicates the days on which hæmorrhage first occurred:

Table Indicating the Days on which the First Hæmorrhage Occurred.

Day after injury on which the hæmorrhage occurred.	Cases.	Head, chest, and upper extremities.	Abdomen, pelvis, and lower extremities.
1st day	153	68	85
2d day	17	5	12

The number of bleedings on the first day was 153, of which 110 were hæmorrhages immediately following the injury (strictly primary), while 43 occurred at some period within the first twenty-four hours succeeding the injury. If deemed desirable to make a group of intermediary cases, these forty-three cases, with those occurring on the second and third days, should probably be so classified. Those of the first day undoubtedly partook of the nature of primary hæmorrhage and were results of reaction; as to those of the second and third days, the data are insufficient to determine their proper classification. By the fourth day sufficient time had elapsed to allow such changes as result from inflammatory action, and which are recognized as productive of secondary hæmorrhage; and it will be noticed that from this day the bleedings perceptibly increase until the tenth and eleventh days, when the greatest number of hæmorrhages occurred. From this point their frequency gradually and somewhat regularly diminishes, until the thirtieth day; after this time they lose their regularity and occur at various intervals, subject to infectious diseases or other peculiar conditions attending each case. Examples of long-deferred hæmorrhage were not rare. In one recorded case it did not occur until the two hundred and sixty-fourth day; in another the first bleeding occurred on the one hundred and twenty-second day. In another instance—a case of sloughing after gunshot fracture of the humerus—it did not occur until the one hundred and twenty-ninth day, necessitating, at that late period, amputation of the arm.

Not infrequently the hæmorrhage following immediately upon the injury ceases spontaneously, only to return at a later period, generally in the evening or during the night, at times when the reactionary process is most pronounced. A soldier was wounded May 12, 1864; the ball entered right side of chest in front, near the armpit, fracturing in its course the right shoulder-blade at the middle. Secondary hæmorrhage occurred May 27th, to the extent of eight ounces, from the axillary artery. The fractured lower angle of the scapula was removed; the subscapular artery was found intact; an operation to ligate the axillary artery was therefore commenced, but the patient died before the operation was finished. His comrade said that hæmorrhage to the amount of a gallon or more occurred immediately after the reception of the wound, but that it had ceased spontaneously.

In several instances one or more slight bleedings—"warning bleedings"—preceded the actual hæmorrhage. A soldier of a South Carolina regiment was wounded in the upper part of the right femur, July 28, 1864; he was captured and taken to hospital at City Point. The fracture was high up and the femur was badly shattered; the limb was placed on an inclined plane and the fragments brought as nearly in apposition as possible; slight hæmorrhages took place on September 4th and 7th, which yielded readily to pressure; on September 8th a severe hæmorrhage occurred, exhausting in amount, and from which the patient sank rapidly and died the next day.

Instances of hæmorrhage from the distal end of arteries after ligation of the cardiac end are reported; there were also a few cases in which the bleeding occurred from the distal extremity of a wounded blood-vessel, as either primary or secondary hæmorrhage, before operative interference.

The form of hæmorrhage known as capillary or parenchymatous was occasionally seen, and was marked by a steady leakage of blood from the capillary vessels, often great in amount, and frequently resulting in syncope or exhaustion. The discharge had neither the bright scarlet of arterial, nor the darker hue of venous blood; it flowed without jets and was difficult to arrest. When observed as a primary condition, or after a primary operation, it was generally the result of what is known as the hæmorrhagic diathesis. In other cases it was due to paralysis of the capillary vessels from inflammatory action. It was most frequently noticed as an accompaniment of pyæmia and osteomyelitis, and was caused by interrupted venous circulation, assisted by the leucocythæmic condition of the blood in such cases.

Fifteen cases of this form of hæmorrhage are reported. In the cases of recovery the bleeding was comparatively slight and easily controlled by cold, compression, or styptics. Of the nine fatal cases, death occurred either as a direct result of the bleeding, or from the complications which probably gave rise to it, as pyæmia, gangrene, erysipelas, and diarrhœa. Of the fifteen cases capillary hæmorrhage followed amputation in seven instances—with three recoveries and four deaths; and ex-ration in six cases, with one recovery and five deaths. Four cases of secondary hæmorrhage are noted. Two, occurring from maxillary arteries of [illegible], were controlled by [illegible]. One appears to have been a case of recurring hæmorrhage from the medullary artery of the tibia of a patient whose [illegible] finally recovered. The fourth was a case of osteomyelitis of the tibia, and finally, complicated by diarrhœa, ultimately [illegible] in recovery.

Traumatic Aneurism.—In 74 cases the injuries were followed by traumatic aneurism. Twenty-three cases terminated in recovery and 51 in death, a mortality-rate of 68.9 per cent. Thirty-four, or nearly one-half of all the cases, were aneurisms of the femoral or axillary arteries—20 of the former and 14 of the latter.

The aneurisms were either diffused or circumscribed, and in one case time had been given for anastomotic communication. In one case recorded ligation of the subclavian had been performed for aneurism of the axillary artery; an aneurism again developed after his discharge from the service. The man is a pensioner, and the last report of his condition states that he now has aneurism involving the innominate artery; the thrill is very distinct, radial pulse cannot be felt, he suffers pain in the chest and is incapacitated for all labor.

Forty-two of the 74 cases were treated by ligation; of these, 13 recovered and 29 died. In one case of shot wound of the axillary region, unattended by fracture, an aneurism appeared three months after the injury, which increased very rapidly; the subclavian was ligated, but on opening the sac the tissues were found infiltrated with blood and disorganized, and the arm was amputated at the shoulder joint. The patient died in a few days from exhaustion.

Causes of Hæmorrhage.—The earlier cases of hæmorrhages are due to the force of the blood-current in the returning circulation during reaction; to commencing inflammatory action in which the swelling has been sufficient to force out the protecting coagulum; to weakened arterial walls, or finally to a depraved condition of the blood in persons suffering from exhausting or depressing diseases.

Not infrequently the hæmorrhage of the earlier days has its source in the injury of some vessel of considerable size, unnoticed in the primary examination of the wound. Cases are cited in which no excessive hæmorrhage had been noticed until attempts were made to effect the removal of a lodged missile or foreign body, which had prevented bleeding by acting as a plug or tampon.

Regarding secondary hæmorrhage in its usual acceptation, as embracing all cases of bleeding from wounded vessels occurring after the establishment of suppuration, including cases of rupture of the sacs of traumatic aneurisms, we find that by far the greater number is due to the separation of a slough, the result of a contusion of the walls of a vessel, and the inflammatory action consequent upon it.

The time required for this process varies within very wide limits, and appears to be dependent upon the size of the artery, the contusion, and somewhat upon its proximity to the heart. Ulcerative action extending from neighboring parts may attack a vessel, with similar results.

Scorbutic diathesis, fevers, gangrene, pyæmia, osteomyelitis, and all conditions which lower the vital forces or alter the elements of the blood, as well as the general condition of the patient and his physical health, largely influence this complication.

Hygienic surroundings must also be taken into consideration as playing an important part in the maintenance of good physical status and enabling the wounded man to successfully resist the insidious attacks of disease.

Thrombosis of veins will cause pressure on the arteries of wounded parts and reopen vessels temporarily closed.

Diseases of the coats of the arteries, as atheroma, etc., will hasten hæmorrhage, and in such cases the conditions will render operative interference doubtful and uncertain.

Transportation of the wounded during the process of suppuration has been mentioned as a cause of hæmorrhage by surgical writers, and cases recorded during the late war justify its enumeration as an exciting cause. A soldier suffering from a gunshot, compound fracture of the right knee-joint, after doing well for three weeks, was removed from hospital on the evacuation of the place; while being lifted into an ambulance wagon a sudden and uncontrollable hæmorrhage took place, which proved almost immediately fatal.

Accidental causes will be found to be not uncommon, as falling out of bed, the pulling away of ligatures during delirium, falling upon stumps, and spasmodic twitching of muscles.

Hæmorrhages subsequent to ligation may be due to the engorged condition of the vessels in the neighborhood of the injury, which were cut or injured during such operation.

Treatment.—Of the 2,235 cases of hæmorrhage, 294 were followed by amputation; 786 were treated by compression, styptics, etc., or ceased spontaneously; and in 1,155 cases the bleeding vessels were ligated.

Summary of Two Thousand Two Hundred and Thirty-five Cases of Hæmorrhage, Indicating Mode of Treatment.

Treatment.	Cases.	Recovered.	Died.	Percentage of fatality.
Hæmorrhage followed by amputation	294	122	172	58.5
Hæmorrhage ceased spontaneously, or was arrested by compression and styptics	786	[illegible]	[illegible]	[illegible]
Hæmorrhage treated by ligation	[illegible]	[illegible]	[illegible]	[illegible]
Hæmorrhage followed by ligation and subsequent amputation	[illegible]	[illegible]	[illegible]	[illegible]
Hæmorrhage from stump after amputation (ligated)	[illegible]	[illegible]	[illegible]	[illegible]
Aggregate	2,235	[illegible]	[illegible]	[illegible]

Amputation was resorted to for the purpose of saving life in cases of uncontrollable hæmorrhage, both primary and secondary. In primary bleeding, where the original injury was so far destructive to the parts as to render ligation unavailing; in secondary bleeding, in cases of traumatic aneurism, with great infiltration of tissue; in gangrene following division or ligation of the principal arteries; and in cases where ligation had failed to arrest bleeding, and where more radical measures were demanded to prevent a further loss of blood. Of 294 cases thus treated by amputation, 122 recovered, and 172 died, a fatality of 58.5 per cent.

Of the remaining 1,941 cases of hæmorrhage, 786 were treated by compression, styptics, etc. The fatality of these cases was large, exceeding that of ligation by 12.2, and that of ligation and subsequent amputation by 5.7 per cent.

In a number of cases digital compression was employed as a temporary measure, and in a few instances steadily continued compression appears to have been rewarded with favorable results. Generally the tourniquet was carefully and judiciously used, although, in a few instances, a resort to operative procedure would have been much better for the patient.

Cases of troublesome bleeding from the posterior auricular, occipital, or temporal arteries or their branches are reported to have been controlled by means of compression by a clamp, tourniquet, bandage and compress, or by a metallic disk acting as a compress. In one such instance transverse division of the wounded artery was sufficient to secure complete retraction of the ends.

No cases of acupressure, after the method of Sir James Y. Simpson, appear in the records, though it would seem probable that many wounds must have prosented themselves in which this measure would have been found convenient, speedy, and effectual.

Torsion was employed in a few recorded cases, and in one case the actual cautery was used to arrest troublesome bleeding.

Two cases of transfusion of blood are reported, one successful, the other unsuccessful.

Styptics were very commonly used, and were to be found in every knapsack and pannier; while it is possible that in many cases their use may have been ill-advised, and while it may be admitted that, in the hands of the timid or ignorant surgeon, they may furnish an excuse for procrastination or non-action in imperative cases, still, the evidence of their usefulness during the late war is not altogether unfavorable. The use of ice and cold was very general, and was very favorably regarded. Internal hæmostatics were used to some extent, but little can be said decisively in their favor from the records of cases in which they were used. Tannic and gallic acid and ergot were most generally used; these remedies were especially employed in cases where the vital powers were much depressed, and where the coagulative elements of the blood were deficient.

Ligations.—Of the 2,235 cases of hæmorrhage in which the bleeding vessels were specified, 1,155 were followed by ligation, embracing nearly all the principal arterial trunks and their branches. Of these, 471 recovered and 684 died. The fatality in these cases, as well as in the cases of hæmorrhage followed by amputation, was principally due to exhaustion following excessive loss of blood previous to the operation, to recurring hæmorrhages after operations, or to complications, such as gangrene, erysipelas, and especially pyæmia.

Five hundred and forty-one of these operations, with 292 recoveries, and 249 deaths, a mortality of 46.0 per cent., were performed in the upper circulatory system, and 614, with 435 deaths, a fatality of 70.8 per cent., in the lower circulation, thus confirming the general opinion that proximity to the centre of circulation favorably influences the final issue.

Three hundred and forty-eight were ligations after amputations; of these, 157, with 52 recoveries and 105 deaths, were ligations in the continuity of the stump, and 191, with 134 deaths, ligations on the face of the stump.

It is probable that the ligation in continuity was frequently the only alternative, and perhaps a greater saving of life would have resulted had the operation been more generally performed in the continuity, as bleedings from the stump were generally found in patients of low vitality, and where but little was to be expected from any operation in the immediate proximity to diseased tissue.

Of the remaining 807 cases, 236 were ligations in the wound, 5 ligations above and below the wound, and 413 ligations in continuity; in 153 instances the mode of ligation was not indicated.

It is probable that the large majority of ligations of the last group were operations in continuity.

The various modes of ligation, with their respective mortalities, are indicated in the following table:

Table Indicating the Various Modes of Ligation and their Fatality.

The fatality after ligations in continuity was 66.4 per cent.; after ligations in the wound, 39.9 per cent. The propriety of ligating both ends of a wounded artery was shown in numerous instances, and cannot be too strongly insisted upon.

Out of 410 ligations in continuity, 261 had fatal terminations, a mortality-rate of 64.1 per cent., largely exceeding the fatality of ligations in the wound; but it will be observed that, with the exception of the femoral, the larger vessels, as the carotid, subclavian, axillary, iliac, and popliteal arteries were, as a rule, tied in continuity. It is to be regretted that ligations of both ends in the wound had not been more generally practised.

Lidell records, as his personal observation after several severe battles, that he had not met with a single case of primary hemorrhage which required a surgical operation, such as the application of a ligature, for its suppression.

Neudörfer and Richter, experienced European military surgeons, have never been called upon to control primary hemorrhage after injuries of blood-vessels by ligation on the field of battle, at the first place of dressing; but a number of such operations were performed during the War of the Rebellion, and the result of these operations seems to have been quite successful. Thus, for instance, of thirteen ligations of the femoral performed on the battle-field, seven proved successful; of ten ligations of the tibial arteries, seven terminated in recovery; and of fourteen ligations of the brachial, only one had a fatal termination, although several of these cases were complicated by fractures.

VEINS.—Hemorrhage from wounded veins is generally regarded as of less practical importance than that from wounded arteries.

The record shows five instances of ligation of veins.

From the number of venous vessels, and from the fact that they are less liable to evade a missile than arteries, it would seem that injuries of veins should have been more frequently noted.

Statistics on the relative frequency of injuries of the arteries and veins are nowhere found in treatises on military surgery. Richter suspects that many soldiers perish on the battle-field from injuries of these vessels.

It remains a fact, however, that hemorrhages from veins came far more rarely under the observation of the surgeon than those of arteries; but that their fatality is equally as great, if not greater, than that of arteries, is clearly proven by the above tabular statement.

Secondary hemorrhage from veins occurred at irregular periods of from one to seventy days; in one instance the bleeding did not take place until the one hundred and thirty-second day; and in another, a case of shot wound of the buttock, uncontrollable venous hemorrhage occurred from a persistent fistula, three years after the injury.

Two cases of death are ascribed to the sudden entrance of air into veins; in a third case the subclavian vein was accidentally cut while searching for the axillary artery; the entrance of air caused syncope, and death ensued in less than ten minutes.

TETANUS.—Considering the number of injuries recorded during the late civil war, the proportion of cases of tetanus is not large: of the 246,712 injuries by weapons of war, 505 (0.2 per cent., or a little over two in a thousand) were followed by tetanus.

In the cases in which this complication was observed, the seat of injury was: in the head, face, and neck in 21 instances; in the trunk in 45; in the upper extremities in 147; and in the lower extremities in 292 instances.

The preponderating frequency of tetanus in the lower extremities, observed by Beck and others, was very marked, over one-half of all the cases having occurred after injuries in this portion of the human structure, due undoubtedly to the massive layers of muscles and soft tissue, which prevent the surgeon frequently from clearing the track of the wound of foreign bodies and other obnoxious influences.

Of the 292 cases of tetanus in the lower extremities, the injuries were in the hip in 2 instances, in the thigh in 99, in the knee in 17, in the leg in 95, in the ankle in 22, and in the foot in 57 instances; of the 147 cases in the upper extremities, the injuries were in the hand in 47, in the arm in 34, in the shoulder in 31, in the forearm in 24, in the elbow in 7, and in the wrist in 4 instances.

The belief that shot wounds of the hand and feet are particularly apt to cause tetanus is not confirmed by this summary. In 131 instances tetanus followed closely upon operations in the extremities, viz.: in 116 cases after amputation, and in 15 cases after excision.

The rarity of tetanus as a complication of chest wounds was especially marked.

The recoveries after tetanus appear to have chiefly occurred in cases of slighter or localized forms, or in those in which the disease took a chronic course; and it is possible that the early application of powerful narcotics interrupted the progress of the malady in a few acute cases.

It may be considered that the later the occurrence of the disease after an injury, the better is the chance of recovery ; and also, that the longer the duration of the affection after its inception, the greater is the chance of life.

In the following table are indicated the days after the injury or after amputation on which tetanus made its appearance :

Statement Indicating the Day after Injury or Amputation on which Tetanus Appeared.

Cases.	Days after the Injury of Amputation on which Tetanus appeared.																									
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26 to 30	Above 30
367	27	8	9	9	19	30	23	37	24	27	25	20	17	12	6	7	11	5	4	4	3	1	3	3	3	7	23

In 27 cases tetanus appeared on the first day ; but 21 of these were cases of tetanus following amputation, so that in reality it only appeared in 6 cases within the first twenty-four hours after the original injury ; and it may be here stated that, with the exception of a small number of cases, tetanus in cases of amputation invariably followed within a few days after the operation. Few cases occurred on the second, third, and fourth days after injury ; but from the fifth day, when sufficient time had elapsed for inflammatory action to establish itself, the number of cases rapidly increased until the eighth, when it gradually diminished again until the fourteenth, after which period it appeared irregularly, in one instance the malady not making its appearance until seven months after the injury.

As causes of this fatal malady are cited : excessive heat, exposure to cold and damp air, draughts, neglect of thorough and early cleaning of the wound channel, pressure of missiles and bone splinters and of bandages on nerves, injuries to nerves while searching for foreign bodies, or while performing ligations and excisions.

The duration of the disease is indicated in three hundred and fifty-eight cases, of which twenty-one ended in recovery, and three hundred and thirty-seven in death, as follows :

Numerical Statement of Results of Three Hundred and Fifty-eight Cases of Tetanus, in which the Duration of the Disease was Reported.

Result.	Totals.	Days of Duration of Tetanus.																													
		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	18	19	20	21	23	24	26	27	29	33	37	39	48	49
Recoveries	21	1	1	..	..	...	...	...	...	1	1	1	...	...	2	...	1	...	...	1	3	2	1	..	...	1	1	1	1	1	1
Deaths	337	69	83	49	31	22	19	14	7	5	6	8	3	2	3	4	...	4	1	3	1	...	...	1	2	...	...	...	...	...	...
	358	70	84	49	31	22	19	14	7	6	7	9	3	2	5	4	1	4	1	4	4	2	1	1	2	1	1	1	1	1	1

In two hundred and three, or more than one-half of the cases in which this point was ascertained, the duration of the disease did not exceed three days, and of these only two recovered. In the remaining nineteen cases of recovery, the disease lasted from nine to forty-nine days, while the longest duration in the fatal cases was only twenty-seven days.

In several cases, the removal of a missile or foreign body, as pieces of bone, seems to have quieted the threatening symptoms ; in one instance they were relieved by the loosening of a bandage pressing on the brachial plexus, and in another by the removal of a neuroma. In one case an incision down to the nerve temporarily relieved the symptoms of trismus caused by the contraction of a cicatrix ; as the symptoms reappeared with increased vehemence, a portion of the nerve was dissected out, and no relief being afforded, amputation remained as the only recourse ; the patient finally recovered.

Including the case just referred to, amputation was resorted to in twenty-nine instances after incipient tetanic symptoms ; ten of the cases resulted favorably, and in several instances it is noted that the symptoms ceased after the operation.

The treatment was empirical to the last degree, and the formidable list of remedial agents employed in combating it presents a curious study of the diverse pathological and therapeutical views entertained by the medical profession on this subject.

In the cases of recovery, it is impossible to say how far any individual remedy or class of remedies was of avail : chloroform, ether, opiates, stimulants, and external irritants, embrocations, and fomentations were mainly relied on.

In some instances the symptoms disappeared so speedily and permanently as to raise the question whether the same result might not have occurred spontaneously. In the fully developed cases all remedial measures failed, and the cases ran on to a fatal termination.

Sixteen, or 3.1 per cent of the five hundred and five instances of tetanus were found among the colored troops, who furnished 2.7 per cent. of the total number of shot injuries.

GANGRENE.—In studying the records of the war, it has been found impossible to classify with accuracy the cases reported as traumatic gangrene, dry gangrene, hospital gangrene, etc., as these terms seem to have been used in many instances indiscriminately, according to the views or predilection of the surgeon ; all these cases, reported to have been observed as the results of, or following, shot injuries, will, therefore, be treated under the common head of gangrene.

The total number of cases reported as occurring during the late civil war, was 2,642. Of these 60 were observed after wounds of the head, 216 after wounds of the trunk, and 2,366 after wounds of the extremities, as follows :

Summary of Two Thousand Six Hundred and Forty-two Cases of Gangrene, Indicating the Result and Relative Frequency.

Seat of injury.	Recovery.	Fatal.	Undetermined.	Total.	Per cent. of fatality.	Per cent. of relative frequency.
Flesh wounds of head, face, and neck	5	7	....	12	58.3	60 = 2.2
Fractures and penetrating wounds of head, face, and neck	32	16	....	48	33.3	
Flesh wounds of trunk	36	32	7	75	47.0	216 = 8.2
Fractures and penetrating wounds of trunk	44	97	....	141	68.7	
Flesh wounds of the upper extremities	47	50	12	109	51.5	2,366 = 89.6
Fractures of the upper extremities	476	245	14	735	33.9	
Flesh wounds of the lower extremities	125	127	92	344	50.3	
Fractures of the lower extremities	596	568	14	1,178	48.7	
Aggregates	1,361	1,142	139	2,642	45.6	

Thus it will appear that 89.6 per cent. of all the cases of gangrene were observed in wounds of the extremities, 8.4 per cent. in wounds of the trunk, and only 2.2 per cent. in wounds of the head, face, and neck, although it has been previously shown that the proportional injuries for the three regions is 70.88 per cent. for the extremities, 18.37 per cent. for the trunk, and 10.77 per cent. for the head, face, and neck. Nearly two-thirds of all the cases of gangrene occurring in the lower extremities.

The results in 139 of the 2,642 cases of gangrene were not ascertained; 1,361 terminated in recovery, and 1,142 in death, a mortality-rate of 45.6 per cent. But in a large number of these cases death was ascribed either to the injury itself, or to other complications—traumatic hemorrhage, exhaustion, pyæmia, erysipelas, pneumonia, typhoid fever, diarrhœa, and other diseases. With the exception of the penetrating wounds of the trunk, the percentage of fatality of cases of gangrene after flesh wounds is larger than that after fractures. In wounds of the trunk alone, the mortality of the fractures and penetrations exceeds that of the flesh wounds, the former being 68.7, the latter 47.0 per cent.

Of the 2,366 instances of gangrene in the extremities, 185 were cases of gangrene following excisions, and in 46 of these cases amputation of the limb had to be resorted to. In 898 instances gangrene was noted on the face of the stump. In a few of the cases the complication was caused by strangulation of the stump by tourniquet.

But the large majority of the cases were instances of hospital gangrene, caused by the crowded condition of the hospitals and the bringing together of many cases of extensive fractures and large operation-wounds.

How far the frequency of the occurrence of gangrene was influenced by the seasons of the year cannot be ascertained from the reports; it can only be stated that the highest number of cases was observed in June, July, August, May, and December; the lowest in February and March.

Only four cases of gangrene were recorded for the first eight months of the war, in 1861, but it must be remembered that the medical and surgical reports for this period are very incomplete. In the following year, 1862, the number of cases increased to two hundred and twenty-three. A few sporadic cases occurred in the hospital at Fort Hamilton, N. Y., in the month of September, among men wounded in McClellan's peninsular campaign in June and July. Of the three cases reported at that hospital, one at least was that of a soldier who had been carried to Richmond, and had then been paroled.

It was after the great battles of South Mountain and Antietam, in September, 1862, that serious outbreaks of hospital gangrene occurred at the hospitals at Frederick, Md., and at West Philadelphia.

The next appearance of the disease, more serious in character than that observed at Frederick and West Philadelphia, was at Annapolis, Md. It appears that in January, 1863, one hundred and fifty-three patients were brought to Annapolis from Richmond. Very many of these men were wounded, and all had been closely confined in the prisons and in the prison hospitals of that city. Of these men four had hospital gangrene at the time of admission to hospital at Annapolis, and thirty-one contracted the disease within a short time. On January 29th four hundred and twenty-one additional patients were admitted from the same place and under the same circumstances; of these gangrene existed in fourteen at the time of their admission.

By February 7th the number of affected patients amounted to sixty. All cases in which the process of destruction was advancing, or in which separation and granulation had not fairly set in, were collected in special wards isolated from all other buildings, and special bedding, blankets, utensils, sponges, supplies, dressings, and instruments were provided for them. The disease from this time remained almost entirely confined to the paroled prisoners. It was evident that the origin of the disease had been due to their close confinement in the Libby prison at Richmond and the adjacent hospitals. In these places all the conditions were present for engendering the disease—close confinement in crowded, unventilated rooms, bad feeding and dressings, and foul and unsanitary surroundings.

The paroled prisoners who had been captured on the Western battle-fields referred the development of their gangrene to tedious and painful transportation from the West to Richmond. The cars were closely boxed, the food was deficient and bad, and all opportunities for cleanliness were absent. The spread of the disease at Annapolis was unmistakably by contagion.

Cases which occurred at Nashville, Tenn., where the disease appeared a month or so later, were undoubtedly of indigenous origin. Thirty-eight cases occurred in one hospital within a few days, and the results of an examination made as to its origin offer striking examples of the methods of the production of gangrene, by the use of buildings constructed in utter disregard of all sanitary laws.

In February, 1863, a few cases appeared at the Douglas Hospital, Washington, D. C., in the persons of soldiers wounded at the battle of Fredericksburg, Va. The largest number of cases of gangrene (1,611) occurred in 1864, when the terrible battles of Grant in Virginia, and of Sherman in Georgia, filled the hospitals to overflowing; but the disease seems to have lost its terrors to medical officers. The cases were promptly isolated in hospitals or wards especially assigned for the purpose, and under various forms of treatment the larger proportion of cases were brought to a successful termination. The proportion of cases of gangrene to the number of troops engaged, or to the wounded treated in hospitals during the six months of 1865, was very small; only one hundred and thirty-five being recorded upon hospital registers.

Instances of dry gangrene, the result of shot injuries, were rare; nine cases are noted; in all these cases the feet or the toes were the parts affected. Interference with the arterial circulation was the cause of the gangrene, although the manner of the interference is not clear in one or two of the cases. In five of the nine cases of dry gangrene cited amputation was performed after the appearance of the disease; four recovered. The remaining four cases, in which no operative interference was resorted to, proved fatal.

The treatment of gangrene as carried out in the military hospitals consisted in facilitating and hastening the removal of the sloughs, thoroughly cleansing and keeping in a healthy condition the open wound, limiting the extension of the ulcerative action, and the administration of tonics, stimulants, and supporting and nutritive food, with the endeavor to build up the debilitated system. Locally the gangrenous ulcers were treated by applications of fuming nitric acid to the edges of the sore, to its surface, and to the healthy integument beyond the line of diseased action; also by the use of nitrate of silver, Labarraque's solution, and stimulating poultices of yeast, cinchona, and charcoal.

In the West the use of bromine as suggested by Dr. M. Goldsmith was extensively used and with undoubted good effect. It was applied in full strength by means of little swabs, after a thorough cleansing of the wound and the removal of all gangrenous and diseased tissue; the wounds were kept carefully closed from exposure to the air, were closely watched, and upon the slightest reappearance of the disease the process was repeated.

In the use of these agents, nitric acid, bromine, iodine, acetic acid, and Labarraque's solution, now well understood to be potent germicides, we see the foreshadowing of the present antiseptic treatment of wounds.

Dr. Goldsmith claimed for bromine prophylactic virtues which seem to have been in a degree substantiated. Under the present methods of antiseptic surgery, with the advanced knowledge and practice of hygiene and sanitation, it is doubtful if hospital gangrene will ever again prove to be the scourge of armies that it has been in the past.

TRAUMATIC ERYSIPELAS.—Wherever large numbers of wounded are collected together, there is always a liability to invasions of this complicating disease.

During the late war, the instances of traumatic erysipelas were much less frequent than those of hospital gangrene. Under the head of traumatic erysipelas, as occurring in groups of shot wounds, we must consider all cases in which inflammation of the skin originating from a wound quickly extends over the surrounding parts, ending in rapid resorption, while the process is accompanied by exceedingly high fever.

The total number of cases of this affection, as recorded during the war, is 1,097, or only 0.4 per thousand of all cases of wounds. Its regional distribution is shown by the following table:

Numerical Statement of One Thousand and Ninety-seven Cases of Traumatic Erysipelas.

Seat of Injury.	Cases.	Recovery.	Fatal.	Undetermined.	Regional percentage.
Head, face, and neck	154	107	44	3	14.0
Trunk	57	23	33	1	5 2
Upper extremities	457	259	180	18	41.7
Lower extremities	429	229	193	7	39.1
Aggregates	1,097	618	450	29	

The average duration of the disease was eleven days; in 31.7 per cent. it subsided in from one to five days, in 31.7 per cent. in from six to ten days, in 19.4 per cent. in from eleven to fifteen days, and in 17.2 per cent. the duration of the disease exceeded fifteen days.

A first attack of erysipelas by no means secured a patient against a second, and, as a rule, it would seem that the later attacks were the more virulent. One patient is recorded as having had nine separate attacks, and many others more than one.

Generally the disease confines itself to the parts first infected, and thence extends in a centrifugal manner, showing that, as Socin expressed it, "the matter causing the inflammation spreads itself abroad more by the way of imbibition than in the direction of the larger venous and lymphatic vessels." However, swellings and abscesses in the axillary and inguinal regions are not infrequent. Sometimes the disease spreads itself over the neighboring parts and affects nearly the whole body. Cases are on file in which the disease made its appearance in the head, and extended down the neck and chest to the pelvis; or in which it originated in a wound of the hand and spread over the arm and trunk, and even the face; or where it first showed itself in the toes and attacked the leg, thigh, and lower part of the trunk.

Four hundred and fifty of the 1,097 cases of erysipelas proved fatal, a mortality-rate of 41.0 per cent. In sixty cases the death was ascribed to pyæmia, in eight to gangrene, in five to tetanus, in twelve to hæmorrhage, and in sixty-six to other diseases. In one hundred and sixty-eight instances only was the fatal issue directly attributed to erysipelas, making a fatality of 15.3 per cent. in the total number of cases.

Erysipelas made its appearance under apparently the most favorable hygienic conditions. It was observed, however, that the disease prevailed less extensively in tents than in hospital buildings.

Generally, the disease occurred in crowded hospitals with illy ventilated rooms, and rapidly spread from one patient to another.

Erysipelas was noted in 452 cases of amputation, and in 106 excisions; of the 452 cases of amputation, the disease occurred in 151 instances before, and in 301 after the operation; of the 106 cases of excision, the affection made its appearance in all but four cases after the operation; and here it is proper to note the liability of this operation to the complication of erysipelas.

The disease was most frequently observed in periods in which the number of wounded patients was the largest; the same may be said of the season of the year, although it was generally more prevalent in cold and damp seasons, and at times when it was necessary to keep the doors and windows of hospital buildings closed.

The wounded among the colored troops seem to have been seldom affected by this disease, as only eleven are reported as having been attacked by it; but five of the eleven cases proved fatal, four from erysipelas and one from pleuritis and erysipelas.

The treatment of this affection consisted in completely isolating the patient; in a large majority of cases the disease yielded to the topical application of tincture of iodine or solution of creasote; the internal treatment most generally employed was moderate doses of the tincture of the muriate of iron, frequently repeated, quinine, and good diet. The use of bromine in the form of vapor to the affected part, as well as the direct application of the drug, was enthusiastically advocated by Dr. Goldsmith and others.

PYÆMIA.—The total number of cases of pyæmia observed after shot wounds, in the late war, was 2,818, of which 71 recovered, and 2,747 died; a mortality-rate of 97.4 per cent. In 21 only, of the total of fatal cases, were other causes than pyæmia mentioned as having influenced the fatal issue, viz., hæmorrhage, gangrene, tetanus, erysipelas, peritonitis, and typhoid pneumonia. In all of the large remainder of fatal cases, pyæmia was the only cause of death ascribed.

Whether in cases attacked by the disease the wounds were in the head, the face, the neck, the trunk, or the extremities; whether the injuries were flesh wounds or accompanied by fracture; or whether they were treated conservatively or by operation, seemed immaterial; all were alike fatal.

Summary of Two Thousand Eight Hundred and Eighteen Cases of Pyæmia, Indicating Location of Injury and Result.

Seat of Injury.		Cases.	Recoveries.	Deaths.	Death-rate.
Head, face, and neck...		66	3	63	95.4
Chest, abdomen, and pelvis		270	8	262	97 0
Upper extremities ..	Conservation	338	8	330	97 6
	Excision	165	3	162	98.2
	Amputation .	415	9	406	97 8
Lower extremities ..	Conservation	709	24	685	96 6
	Excision	55	2	53	96.3
	Amputation .	800	14	786	98 2
Aggregates		2,818	71	2,747	97.4

Over one-half of all the cases of pyæmia were found after wounds of the lower extremities; in 86,413 injuries of this class, 1,564 or 18.1 per thousand cases of pyæmia were reported; of 87,793 injuries of the upper extremities, 918 or 10.4 per thousand; of 45,184 injuries of the trunk, 270 or 5.9 per thousand; and of 26,400 injuries of the head, face, and neck, 66 or 2.5 per thousand were followed by this complication.

In the 1,721 cases, the days of appearance of the pyæmic symptoms after the injury were noted as follows: On the

2d day in 5 cases.
3d day in 6 cases.
4th day in 13 cases.
5th day in 16 cases.
6th day in 17 cases.
7th day in 24 cases.
8th day in 29 cases.
9th day in 38 cases.
10th day in 37 cases.
11th day in 37 cases.
12th day in 50 cases.
13th day in 59 cases.
14th day in 54 cases.
15th day in 60 cases.
16th day in 76 cases.
17th day in 68 cases.
18th day in 70 cases.
19th day in 66 cases.
20th day in 65 cases.
21st day in 56 cases.
22d day in 55 cases.
23d day in 42 cases.
24th day in 40 cases.
25th day in 42 cases.
26th day in 50 cases.
27th day in 31 cases.
28th day in 36 cases.
29th day in 31 cases.
30th day in 20 cases.
31st to 35th day in 135 cases.
35th to 40th day in 89 cases.
41st to 45th day in 55 cases.
46th to 50th day in 42 cases.
51st to 100th day in 151 cases.
101st to 150th day in 30 cases.
151st to 200th day in 8 cases.
201st to 250th day in 9 cases.
251st to 300th day in 5 cases.
Above 300th day in 4 cases.

1,721 cases.

From the second day after the injury the number of cases gradually and almost regularly increased until the sixteenth day, on which the highest total, viz., 76, is recorded. From the seventeenth to the thirtieth day after the injury the number decreased; after that period the disease appeared at various intervals, in some instances as late as two hundred and three hundred days; and in one case, a case of recovery, the pyæmic infection was ascribed to a wound over four and a half years after the injury.

The duration of the pyæmia, from the day on which the first symptoms were observed to the day of death, was reported in 1,687 cases.

The deaths occurred on the

1st day in 71 cases.
2d day in 96 cases.
3d day in 172 cases.
4th day in 171 cases.
5th day in 204 cases.
6th day in 161 cases.
7th day in 148 cases.
8th day in 123 cases.
9th day in 92 cases.
10th day in 81 cases.
11th day in 64 cases.
12th day in 59 cases.
13th day in 41 cases.
14th day in 29 cases.
15th day in 34 cases.
16th day in 17 cases.
17th day in 21 cases.
18th day in 14 cases.
19th day in 12 cases.
20th day in 15 cases.
21st to 25th day in 35 cases.
26th to 30th day in 18 cases.
31st to 35th day in 12 cases.
36th to 40th day in 11 cases.
41st to 45th day in 3 cases.
46th to 50th day in 1 case.
Above 50th day in 5 cases.

About two-thirds of the cases died within the first seven days; the largest number of cases was recorded on the fifth day. In 81 only of the total number did the patients survive the twentieth day after the appearance of the disease.

Traumatic pyæmia was seldom noticed unless the bony structure was injured. Of the 165,821 wounds without lesions of bone, only 564, or 3.4 per thousand, were followed by pyæmia; while of the 79,969 shot fractures, 2,254, or 28.1 per thousand, were followed by this complication.

Very little is to be said of the treatment of pyæmia; tonics, stimulants, and a supporting diet were given, but, as has already been seen, with very little effect, as 97.4 per cent. of all the cases proved fatal. In the early stages of the disease, quinine in large doses would reduce the temperature, but the improvement seemed to be only temporary unless the treatment was continued for some time, which, unfortunately, the patients were unable to bear.

In wounds of extremities amputation has been recommended for the removal of the infection when first observed, but even this extreme remedy seemed to be of little avail. Three or four cases are reported in which limbs were removed while the patients were in a pyæmic condition, and from the successful issue of these particular cases, it may be presumed that the removal of the infectious focus had a beneficial influence.

Climatic, Hygienic, and Moral Influences, as Affecting Shot Wounds and Injuries.—Of the effects of climate on the treatment and result of wounds, but little information is to be obtained from the reports of the war; casual remarks were occasionally made by medical officers, that in certain climates and localities wounds "did well" or otherwise, but so vague a statement is of little value, as it is more than probable that insufficient consideration was given to other closely related conditions which may have exerted a stronger influence than climate.

The change of climatic conditions experienced by our troops during the operations of war, in a sudden transition from the cool and healthful regions of the North to the warm, semi-tropical, and malarial regions of the South, could not fail to make itself felt on the general economy, aside from any of the contingent exposures, hardships, or privations incident to a soldier's life.

The health, vigor, and efficiency of the troops campaigning in some parts of the South, were undoubtedly impaired by climatic causes, and it is fair to presume that under the conditions so acquired wounds and surgical diseases suffered a corresponding modification.

Putting aside the consideration of other factors, it would seem that continuous dry heat is not unfavorable to the satisfactory progress of gunshot wounds; the same may be said of the same quality of cold—both, probably, acting as tonics to the system at large. Moist climates, with continuous heat, are recognized as enervating and weakening, rendering the body less capable of resisting the onset of prevailing diseases.

It has been claimed that the moist, warm climate of parts of the southern seaboard was exceedingly favorable to the healing process of wounds. It may be that the especial qualities of sea air afforded a favorable element.

The pure, bracing air of the highlands of Virginia, Tennessee, and Georgia was unquestionably especially favorable to the recovery of the wounded. The very successful results of wounds and operations during General Sherman's campaign from Atlanta to the sea was especially marked, though it must be admitted that very important factors other than that of climate had their full influence upon the men of that command.

Sudden and extreme variations of temperature and humidity were prejudicial to the favorable course of wounds, and seemed especially to favor the spread of tetanus.

Prolonged cold and moisture were generally regarded as tending to excite surgical complications, as erysipelas and gangrene, though here the probable explanation may be that these diseases were engendered by the want of free ventilation at these times.

The subject may be briefly summed up in the statement that those conditions of climate, wherever found, which allow the fullest and freest exposure to pure, fresh air are those most favorable to the rapid and uncomplicated recovery from wounds; while such conditions as tend to prevent a free, natural interchange, or compel the exclusion of large quantities of fresh air from the wards of hospitals, and from barracks and tents, or such as favor the rapid decomposition of vegetable and animal matter, are to be considered as prejudicial and harmful to the course and treatment of wounds. The influences of hygienic condition, food, and concurrent diseases upon the results of shot injuries in time of war are similar to those observed in cases treated in time of peace in civil hospitals.

The influence of mental condition on the results of wounds is noteworthy. All reports agree that the wounded of victorious armies, cheered by the successes achieved by their own bravery and that of their comrades, did better than those of defeated armies. The most striking example of this influence of mental condition on wounds in modern times is the fearful mortality among the French, after shot wounds of all kinds, in the war of 1870–71. The excessive mortality of that campaign was, undoubtedly, largely owing to the mental depression caused by a succession of reverses rarely met with in the history of warfare.

CONSERVATION, EXCISION, AMPUTATION.—The shot wounds of the extremities numbered 174,200, or over two-thirds of the whole number of shot injuries. Of these 140,124 were treated without operative interference, 4,656 were followed by excision, and 29,420 by amputation.

To the cases of amputation should be added 305 amputations following excisions and 240 re-amputations, bringing the total number of amputations to 29,965.

Eighty-seven thousand seven hundred and twenty-three, with 80,680 recoveries, 5,608 deaths, and 1,435 unknown results (a mortality rate of 6.5 per cent.), were shot injuries of the upper extremities. Of these, 32,902 were wounds complicated by fracture, and 54,821 were flesh wounds; of the latter, 87 were followed by amputation. Of the 32,902 shot fractures of the upper extremities, 3,841, or 11.6 per cent., were followed by excision; 15,707, or 47.7 per cent., by amputation; and 13,415, or 40.7 per cent., were treated without operative interference, beyond the removal of missiles, bone splinters, or other foreign substances.

Eighty-six thousand four hundred and thirteen were shot injuries of the lower extremities; the results were not ascertained in 935 cases; 73,665 resulted in recovery, and 11,813 in death—a fatality rate of 13.8 per cent.

Fifty-nine thousand one hundred and thirty-nine were flesh wounds, of which 201 were followed by amputation.

Twenty-seven thousand two hundred and seventy-four were shot injuries involving the bones of the lower extremities; of these, 815, or three per cent., were treated by excision, 13,466, or 49.1 per cent., by amputation, and 13,053, or 47.9 per cent., without operative interference.

In the upper extremities, 11.6 per cent. of the total number of fractures were treated by excision; in the lower extremities only three per cent. There is little difference in the relative percentage of amputation in the upper and lower extremities (in the first 47.7 per cent., in the second, 49.1 per cent.); the proportion of cases of conservative treatment in the lower extremities exceeded that in the upper by 7.2 per cent., being 47.9 in the former and 40.7 per cent. in the latter. It is difficult to account for this larger percentage in the attempts at conservation in shot fractures of the lower extremities, unless it be due to the instruction given by the medical directors of the armies, that amputation in the thigh should not be performed on the battle-field, and that by the time the patient reached a general hospital the favorable time for operation had passed. It is a curious anomaly that in the upper extremity conservatism was more extensively employed in the part most distant from the trunk, while in the lower extremity the reverse was the case. Of 8,245 shot fractures of the humerus, 2,960, or 35.9 per cent., and of 5,194 shot fractures of the bones of the forearm, 2,971, or 57.2 per cent., were treated by conservative measures throughout. In the lower extremities, the percentage of cases of fracture of the femur treated conservatively exceeded that of the fractures of the leg; in the former, 3,620 out of 6,738, or 53.7 per cent., being treated without operative interference; in the latter, 4,116 out of 9,171, or 44.8 per cent.

One hundred and thirteen thousand nine hundred and forty shot flesh wounds of the extremities, including cases of injuries of arteries and nerves, in which no lesions of bone were reported, gave 4,560 fatal results, a mortality of forty per cent.; of these 54,801 of the upper extremities, with 1,640 deaths, gave a mortality-rate of 2.9 per cent.; and 59,139 of the lower extremities, with 2,920 deaths, a fatality-rate of 4.9 per cent. Of the former in 82, and of the latter in 201 cases, amputation was resorted to, generally on account of hæmorrhage, aneurism, or extended sloughing or suppuration; less frequently on account of pyæmia, gangrene, and erysipelas; and in a few instances on account of laceration of nerves.

Sixty thousand two hundred and sixty-six of the 174,206 shot wounds of the extremities were complicated by injuries of the bony structure. Forty-four thousand three hundred and seventy-five recovered, 12,861 proved fatal, and the result in 3,030 cases was not recorded, a mortality-rate of 22.4 per cent. Thirty-two thousand nine hundred and ninety-two were fractures in the upper, and 27,274 in the lower extremities.

Summary of Sixty Thousand Two Hundred and Sixty-six Shot Fractures of the Extremities, Showing Treatment and Results.

Mode of Treatment.	Cases.	Recovery.	Fatal.	Undetermined.	Percentage of fatality.	Upper Extremities.				Lower Extremities.			
						Recovery.	Fatal.	Undetermined.	Percent. of fatality.	Recovery.	Fatal.	Undetermined.	Percent. of fatality.
Conservation	26,467	20,854	4,562	1,051	17.9	11,646	1,288	480	9.9	9,208	3,274	571	26.2
Excision	4,656	3,183	1,213	260	27.5	2,714	858	239	23.8	439	355	21	41.7
Amputation	29,143	20,338	7,086	1,719	25.8	12,539	1,822	1,376	12.6	7,799	5,264	343	40.2
Aggregates	60,266	44,375	12,861	3,030	22.4	26,929	3,968	2,095	12.8	17,446	8,893	935	33.7

The greatest fatality after shot injuries of the extremities, with lesions of the bone, was observed in shot wounds of the hip-joint, where the fatality reached 84.7 per cent. Next came injuries of the knee-joint, with a mortality of 53.7 per cent.; then those of the thigh, of which 52.4 perished. Injuries of the shoulder-joint gave 34.2 per cent. mortality; of the leg, 27.0; the ankle-joint, 26.9; the arm, 20.7; the elbow, 19.4; forearm, 9.4; foot, 8.3; and finally injuries of the bony structure of the hand, 3.1 per cent. fatality. The percentage of recoveries attending attempts at conservation was quite flattering, but it must be borne in mind that the cases reported as treated conservatively were cases selected as specially adapted to this mode of treatment, and probably were the least serious.

The disposition to conservation developed itself rapidly as medical officers became familiar with serious cases of shot injuries, and it is safe to say that, in the later stages of the war, many limbs were saved which at an earlier period would have been sacrificed; especially was this the case in the upper extremities, where the preservation of the hand, or even portions of the same, was considered most important for the good of the individual.

Probably, the least satisfactory ultimate results of conservative treatment were those on the foot and ankle, which, while successful in saving life, rendered it doubtful, in the light of their ultimate condition, whether conservation was the wisest course.

Excisions.—Of 4,656 excisions, 3,841, or over four-fifths, were in the upper extremities, and 815 in the lower extremities.

The excisions at the hip-joint lead with the largest mortality, 90.9 per cent.; next, excisions at the knee-joint, with 81.4 per cent.; those of the shaft of the femur show a fatality of 69.4 per cent.; of the shoulder, 36.6 per cent.; of the ankle-joint, 29.0 per cent.; of the shaft of the humerus, 28.6 per cent.; in the tibia and fibula, 28.2 per cent.; in the bones of the foot, 19.3 per cent.; at the wrist-joint, 13.8 per cent.; forearm, 11.3 per cent.; and bones of the hand, 9.6 per cent.

With the exception of the elbow, the excisions in the joints show larger mortality-rates than those in the osseous structure above the joints; the fatality of the operations in the knee-joint exceeds that in the shaft of the femur 12.0 per cent.; in the ankle-joint the fatality is 0.8 per cent. greater than in the leg; and in the wrist-joint 2.5 per cent. greater than in the bones of the forearm. The excisions at the elbow-joint, on the contrary, show more favorable results than those of the arm, the death-rate being 5.6 per cent. less in the former than in the latter. The percentage of fatality in the entire series of excisions of the extremities is disappointing, especially when it is considered that over four-fifths of the excisions were performed in the upper extremities, where the chances for success must be considered the brightest. It disproves the opinion held by the advocates of this operation, that excision involves less loss of life than amputation. That it might be possible to obtain better results in well-appointed hospitals, constructed in accord with the sanitary knowledge of the day, is not denied; and the many excellent results now obtained in conservative surgery in civil practice, under the advantages of the present antiseptic treatment of wounds, should encourage the military surgeon to persevere in his efforts in this direction.

In brief, it may be stated that the results after excision in the long bones and in the knee- and ankle-joints were little less than disastrous, and the ultimate condition of many of these cases, although considered successful shortly after the operation, proved to be deplorable.

AMPUTATIONS.—The total number of amputations reported on the records of the war is 29,980; but the whole number of amputations performed for injuries received during the war would undoubtedly exceed that number. During the first eighteen months of the strife the reports of operations are very meagre. Of the 29,980 amputations, the results were ascertained in all but 1,719, as shown in following table:

Tabular Statement of Twenty-nine Thousand Nine Hundred and Eighty Amputations, Indicating Seat of Operations and Results.

Amputations.	Cases.				
	Total.	Recovered.	Died.	Results not ascertained.	Percentage of fatality.
Upper extremities:					
Amputations of the hand or fingers	7,902	6,541	198	1,163	2.9
Amputations of the wrist joint	68	60	7	1	10.4
Amputations in the forearm	1,761	1,505	245	11	14.0
Amputations at the elbow joint	[illegible]	[illegible]	[illegible]	1	7.6
Amputations in the upper arm	[illegible]	[illegible]	1,273	[illegible]	23.8
Amputations at the shoulder joint	866	596	245	25	29.1
Lower extremities:					
Amputations of the foot or toes	1,519	1,337	81	101	5.7
Amputations at the ankle joint	161	119	40	2	25.1
Amputations in the leg	[illegible]	[illegible]	[illegible]	168	33.2
Amputations at the knee joint	195	82	111	2	57.5
Amputations in the thigh	6,369	2,878	3,411	80	54.2
Amputations at the hip joint	66	11	55		83.3
Aggregates	29,980	20,802	7,459	1,719	26.3

As in excisions, the operations at the hip give the highest rate of mortality, 83.3 per cent.; next come amputations through the knee-joint, with 57.5 per cent.; those of the thigh, with 54.2 per cent.; of the leg, with 33.2 per cent.; of the shoulder joint, with 29.1 per cent.; of the ankle-joint, with 25.1 per cent.; of the arm, with 23.8 per cent.; of the forearm, with 14.0 per cent.; of the wrist, with 10.4 per cent.; of the elbow, with 7.6 per cent.; of the foot, with 5.7 per cent.; and of the hand, with 2.9 per cent.

It will be noticed that, with the exception of the amputations at the elbow and those at the knee-joint, the ratio of mortality in the upper extremities as well as in the lower, decreases with the increasing distance of the situation from the trunk. No sufficient reason can be assigned for the exceptionally favorable results in amputations at the elbow, while the gravity of injuries as well as of operations at the knee is well known. Comparing the mortality-rate after amputations with that of excisions in the same portion of the extremities, we find the following results:

Table Indicating Rate of Mortality after Amputations and Excisions in the Extremities.

Seat of operation.	Rates of mortality after	
	Amputation.	Excision.
Upper extremities:		
Hand and fingers	2.9	[illegible]
Wrist-joint	10.4	[illegible]
Forearm	14.0	[illegible]
Elbow	7.6	[illegible]
Arm	23.8	[illegible]
Shoulder	29.1	[illegible]
Lower extremities:		
Foot and toes	5.7	[illegible]
Ankle-joint	25.1	[illegible]
Leg	33.2	[illegible]
Knee-joint	57.5	[illegible]
Thigh	54.2	[illegible]
Hip-joint	83.3	[illegible]

With the exception of the operations in the bones of the forearm and those in the bones of the leg, the excisions are uniformly followed by larger percentages of fatality than the amputations, the excisions of the knee-joint especially showing an exceedingly large excess in the mortality-rate over the amputations at the knee. The favorable results after excisions in the bones of the forearm and leg are due to the fact that in many of these cases only portions of one or the other of the two bones comprising them were excised, thus lowering considerably the percentage of fatality of the operation. All operations performed within forty-eight hours after the injury have been considered and grouped as primary, as the commencement of inflammatory symptoms rarely falls within this period. In the amputations of the hip-joint alone, the primary period has been restricted to twenty-four hours, as it is believed that in these cases the inflammatory period is hastened by the gravity of the injury. In the second or intermediary group have been placed the cases in which the operation was performed in the interval from the third to the thirtieth day (both inclusive) after the injury; this class consists mainly of the operations performed during the inflammatory stage. The third group comprises the operations performed after the thirtieth day from the date of the injury, or at a period when the inflammation has abated or entirely subsided.

Of the 29,980 amputations the date after the injury on which operations were performed was recorded in 23,993 cases; of these the results were not ascertained in 231, leaving 23,762 cases in which the results as well as the dates of operation were recorded.

Summary of Twenty-three Thousand Seven Hundred and Sixty-two Amputations, Indicating the Period of the Operation.

Seat.	Cases.			Primary.			Intermediary.			Secondary.		
	Total.	Recoveries.	Fatal.	Recoveries.	Fatal.	Percentage of fatality.	Recoveries.	Fatal.	Percentage of fatality.	Recoveries.	Fatal.	Percentage of fatality.

Total	23,762	17,268	6,494	12,246	3,992	23.9	3,583	1,918	34.8	1,439	584	28.8
Aggregates				16,238			5,501			2,023		

Primary operations were the rule, over two-thirds of all the amputations belonging to this group. In the field, where few of the appliances of conservative surgery could be had, and where, moreover, the chances of properly applying them were uncertain; where, furthermore, transportation for considerable distance was unavoidable, amputation became necessary, when attempts at conservation might be made in a general hospital.

Primary operations give the best chance of life; those performed during the inflammatory or intermediary period are the most unfavorable in their results; the experience with intermediary operations was so discouraging, that when the time for primary operation had passed the operation was deferred, if possible, until the inflammation had subsided and the lesions had become local and analogous to chronic disease.

Of the different modes of operation, each method had its advocates; but the flap operations were more frequently used, especially in amputations near the joints. Of 11,053 cases of major amputations, in which the method is specified, 6,240 were flap and 4,813 circular operations. A multitude of varieties of the flap were recorded; instances have been cited of the use of the anterior, posterior, antero-posterior, lateral, bilateral, external, internal, oval, circular, U-shaped, rectangular, and skin or muscular flap. As far as stumps are concerned, handsome rounded ones were achieved by each method, and conical stumps were noted after the circular as well as after the flap operation.

The side upon which the operation was performed was recorded in 18,718 cases. The amputations on the left side exceeded those on the right by 3.4 per cent. Whether the seat of injury was on the right or left side seems to have had no influence upon the ratio of mortality.

The number of double operations performed on account of shot injuries was 172; of these, both upper extremities were amputated in 47, one upper and one lower in 43, and both lower in 82, as follows:

Numerical Statement of One Hundred and Seventy-two Cases of Double Amputations for Shot Injuries.

Extremity.	Total cases.	Recoveries.	Fatal.	Undetermined.	Percentage of fatality.
Both amputations in the upper extremities	47	31	16	..	34.0
One amputation in upper, one in lower extremities	43	21	21	1	50.0
Both amputations in the lower extremities	82	31	50	1	61.7
Aggregates	172	83	87	2	51.1

The mortality-rate of the cases in which both the upper members were removed is 34.0 per cent.; of those in which one of the upper and one of the lower extremities were amputated, 50.0 per cent., and of those in which the two operations were performed in the lower members, 61.7 per cent. *David L. Huntington.*

WRIST, JOINTS OF THE. The skeleton of the wrist, being a series of small bones essentially similar in character, may be considered as a whole, and we may hence conceive a superior radio-carpal or wrist-joint proper, between the bones of the forearm and the carpus, and an inferior or carpo-metacarpal joint, between the carpus and the metacarpus. Again, we may consider separately the two rows of carpal bones, and regard the somewhat irregular union between them as an intracarpal or medio-carpal joint. Finally, we may consider each bone as a separate unit and its union with each of those which it touches as so many carpal joints of a secondary degree.

Of the three transverse joints formed by the rows of carpal bones, the upper one is the only one that has any very marked mobility, the middle one has somewhat less, and the lower or carpo-metacarpal joint has the least of all. It is, indeed, instructive and logical in regarding the movements to follow the plan adopted by Meyer, and consider the lower row of bones as combined for practical purposes with the metacarpal bones with which they articulate and the upper row as an articular integer or meniscus which is the essential interposed element between the forearm and the hand. Viewing the form of the surfaces, the articulation between the meniscus and the forearm is a pommel or ellipsoidal joint. Movement is necessarily freest in the direction of the axes of the ellipsoid, but still a certain amount of rotation is possible. The surfaces involved are those of the triangular cartilage and the radius above, and the scaphoid, semilunar, and cuneiform below. The ulna does not enter into the articulation, nor does the pisiform bone. Many comparative anatomists are of the opinion that the triangular fibro-cartilage represents a carpal element which in its complete form long ago vanished from the mammalian carpus and that the pisiform bone is another vestige of the same kind. Certain facts of abnormal variation seem to support this view and to show that the pentadactylate form of the human hand is not the primitive form, firmly fixed though it now is, but that a seven-digit hand was probably the original mammalian type. Odd cases of supernumerary wrist-bones and fingers, which are occasionally seen, are, according to this view, instances of atavism.

The mid-carpal joint is of a mixed character, having, like the mid-tarsal joint of the foot, a wavy outline, the comparatively large, convex upper surfaces of the os

---

[1] Medical and Surgical History of the War of the Rebellion.

magnum and unciform bones making together a sort of ball-like head which fits into the hollow socket made by the under surface of the conjoined scaphoid, semilunar, and cuneiform bones; while a comparatively small surface of the scaphoid articulates with the trapezium and trapezoid to make a curve in the opposite direction. This assists considerably in twisting movements of the hand, such as pronation and supination, which are very necessary to that nicety in the management of tools which characterizes the hand of man. The hand of the ape is by no means so delicately adjusted in this particular.

It has been well pointed out by Professor Humphry, in his classical treatise on the "Human Skeleton," that the wrist owes the security of its position not so much to the interlocking shape of the joint surfaces, or to the strength of its ligaments, as to the strong tendons which pass over it, tend to protect it and render it at the same time flexible. A short examination of the lower end of the radius will show that its dorsal aspect is deeply grooved for the extensor tendons which pass in every direction over the back of the hand. They are bound closely down in their grooves by a strong band of fascia called the posterior annular ligament, which thus becomes, as it were, one of the most powerful protecting ligaments of the radio-carpal joint. In a similar manner the anterior surface of the wrist is hollowed out by a deep archway, the carpal canal, so called because it is spread over by strong bands of fascia which confine the flexor tendons in a sort of subway.

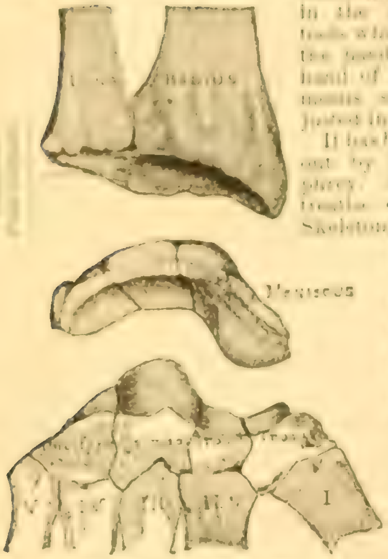

FIG. [illegible].—The Wrist-joints.

English anatomists group these bands together indiscriminately as the anterior annular ligament, but there can readily be distinguished two bands—a superficial one, to which the name of annular ligament may properly be applied, as it is a process of the deep fascia of the arm which passes over the tendon of the palmaris longus and the ulnar vessels and nerve, being continuous with the posterior annular ligament at either side; the second is more independent, partaking more of the nature of a ligament, and therefore properly designated as the ligamentum carpi volare proprium. It is a strong, firm band, attached on either side to the carpal eminences—that is to say, the pisiform and unciform bones on the inner side and the tubercle of the scaphoid and the ridge of the trapezium on the outer side. It passes under the tendon of the palmaris longus and the ulnar vessels and nerve. Beneath it pass the great flexor tendons and the median nerve, confined by several strong sheaths which blend with each other and send fascial processes to the ligament above and the attachments of the carpal bones below. It is to this arrangement, combined with protection, that we owe the surprising flexibility which characterizes the wrist, a flexibility which permits the extraordinary twists so famous in the pitching of a ball, the handling of a tennis racket, and the parrying of the thrust of a foil.

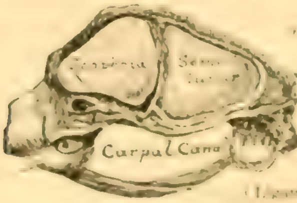

FIG. [illegible].—The Carpal Canal.

Viewing the wrist-joint with reference to its synovial cavities, we find that the radio-carpal joint has its own cavity, the mid-carpal and carpo-metacarpal having a common cavity, there being excluded two bones, the pisiform and the metacarpal bone of the thumb, each of which has its own special articulation—the first with the cuneiform, the second with the trapezium.

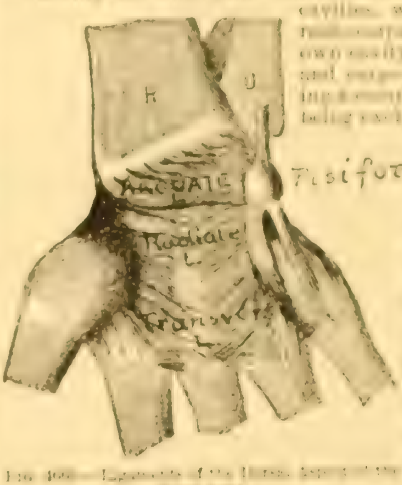

FIG. [illegible].—Ligaments of the Hand. Aspect of the Wrist-joint.

The intrinsic ligaments of the carpus are of two classes: one being external strengthening bands, the others internal, interosseous, serving as these interties to keep the whole system firm. On the palmar surface a somewhat irregular mass of fibres stretching from the bones of the forearm to the metacarpal bones, has received the name of the ligamentum carpi volare profundum.

Separate portions of this have received different names. Thus the arcuate ligament is that portion which passes downward and inward from the radius to the cuneiform bone; the straight ligament (ligamentum carpi rectum) is a rounded fasciculus that passes from the styloid process of the ulna to the semilunar and cuneiform bones, and the funiculus ligamentosus a similar one extending from the same to the cuneiform and pisiform bones. Bands from the pisiform bone to the unciform and to the fifth metacarpal (lig. piso-hamatum, lig. piso-metacarpeum) are considered as extensions of the insertion of the flexor carpi ulnaris. A series of short bands connecting the os magnum with the contiguous bones is known as the radiate ligament. Finally the most distal band, connecting the bases of the metacarpal bones, is known as the deep transverse ligament. All these divisions seem hardly necessary.

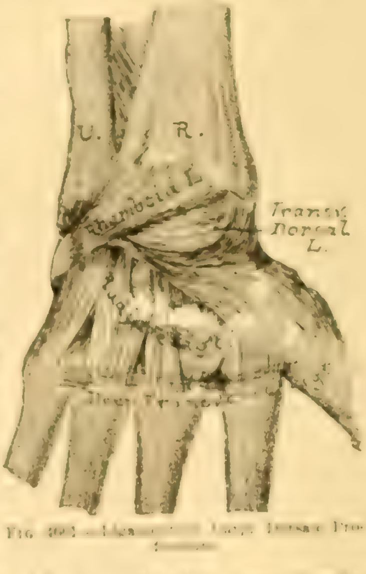

FIG. [illegible].—Ligamentum Carpi Dorsale Profundum.

The investment on the dorsal surface is not usually so complete. The strengthening bands are mainly two—the rhomboid ligament, passing downward and inward from the lower end of the radius to the cuneiform and unciform bones, and the transverse dorsal ligament, extending from the scaphoid outward to the same. There is also a dorsal radiate ligament diverging from the os magnum.

The only other joint requiring especial mention is that of the metacarpal bone of the thumb with the trapezium. This is an excellent example of the joint by reciprocal reception, sometimes termed the saddle-joint. Its motions are freest in two directions, which correspond to the motions of adduction and abduction on the one hand, and of the various adjustments of opposition on the other. *Frank Baker.*

XANTHOMA. Xanthoma, or xanthelasma, as it is sometimes called, is one of the benign new-formations of the skin. It has at different times received the names *fibroma lipomatodes*, *vitiligoidea*, and *molluscum cholestérique*. Rayer, of Paris, first described the affection, with the title *Plaques jaunâtres des paupières*. The new-growth is one of connective tissue, and while it has a decided predilection for the upper eyelids, the yellow, or buff-colored nodules of which the patch is composed may form upon various other portions of the body. I have seen it affecting several other regions, and Bulkley, Hardaway, Robinson, Barlow, Hyde, and others have recently reported cases in which the disease appeared upon the extremities and trunk. It often occurs about the elbows and knees, but rarely unless the eyelids are at the same time affected.

Varieties.—There are two forms in which the disease occurs, *xanthoma planum*, and *xanthoma tuberosum*.

The plane variety consists of plates or patches of yellowish or chamois-skin-like tissue situated in the corium, and projecting but slightly if at all above the skin level. The patches are, for the most part, small, smooth, and soft, with well-defined borders, and are usually elongated or oval. The color may vary from a creamy-white to a bronze, or an orange-yellow, and upon the eyelids the patches may have an arched configuration. In the beginning the lesion has only the size of a pin's head, but this is added to gradually, until after several years of slow growth one or more good-sized patches are formed. These are mostly found upon the upper lid, more seldom upon the lower, and at times in the skin surrounding the eye. Sometimes patches are found upon the body when none exist or have existed upon the lids. Dr. Robinson showed such a case several years ago at the New York Dermatological Society, and Hyde had an illustration of a case in which the knees and elbows were alone affected, in the *Journal of Cutaneous and Genito-Urinary Diseases* of 1887.

Xanthoma tuberosum differs from the preceding variety in that it occurs as papules, or tubercles, varying from the size of a pin's head to that of a bean, isolated or aggregated into plaques. The lesions are more elevated, more firm to the touch, and more likely to occur on other parts than upon the eyelids. Both forms may, however, coexist, and patches of the plane xanthoma may show tuberous elevations.

Xanthoma Multiplex.—In this rare form the lesions are scattered over the body, invading the face, flexures of joints, soles, palms, possibly the genital organs, and also mucous membranes, as the tongue (see article Tongue, Diseases of the). It has in one instance been known to rapidly spread over the whole body.

Symptoms are almost wholly wanting. In the usual course of the disease yellowish macules are first noticed upon the upper lid, near the external or internal canthus, and spreading occurs without subjective manifestations. In the tubercular form there may be some pain, and this has been especially noted when the palms and soles were involved. In xanthoma multiplex there is often much itching of the skin, even in the absence of jaundice.

Etiology.—Xanthoma is more frequent in women than in men. It is not usually met with before middle life, though occasional cases in quite young subjects have been recorded.

Nothing definite has been discovered in regard to the true cause of the condition. Heredity has been shown, by Church and others, to play a part in certain forms of the disease. Many cases are associated with jaundice and disorders of the liver, and while some observers have considered the jaundice to be a secondary condition due to the xanthomatous disease of the liver or bile-ducts, others have regarded it as causative. In thirty cases collected by Hebra and Kaposi, icterus was present in fifteen. Murchison and others have believed the circulation of bile-pigment in the blood to be an etiological factor. I have seen xanthoma in diabetic subjects, and it is said to be quite frequent in this disease. Hutchinson has shown its pathological relation with icterus and arthritis.

In 1883 Balzer described microbes found in the granular matter of the excised tumors, but so far as I am aware, they have never been proven to bear a causative relation to the affection. Balzer was led to seek a parasitic origin for the disease from the analogy which exists between it and tuberculosis, lepra, etc.

Jaundice in many cases first shows itself long after the xanthoma lesions, and in many cases is wholly absent, as are also all signs of liver derangement.

Pathology.—Though all observers are not in strict accord, it is now generally agreed that xanthoma consists of a connective-tissue new-growth. Robinson states that connective tissue forms the basis of the tumor, in which fatty degeneration readily occurs. Some observers have found the changes in the skin identical with those found in the early stages of atheroma. Pye Smith says "young leucocytes never form true tissue elements, molecular fatty degeneration rapidly overtaking them, and leading to their ultimate disappearance in a detritus of oil-drops, calcareous masses, and cholesterine crystals." Instead of following this course, which he designates the inflammatory type of the disease, the new cells may grow to a considerable size, and form fusiform and stellate corpuscles of connective tissue. Fatty degeneration may occur in this form as well, but is here a much slower process.

Diagnosis.—The only disease at all likely to be mistaken for xanthoma is that known as milium. The distinction is not difficult, though the situation of the lesion and the gross appearances when milium papules are aggregated may be quite similar in the two diseases. Pressing out the contents of the milium papules shows at once the nature of the affection.

Prognosis.—Some cases spontaneously recover, but this is as rare as it is a fortunate occurrence, and one not likely to be looked for. Degeneration into malignant growth has never been observed. Most cases last many years or during one's whole life, unless actively treated.

Treatment.—Excision, carefully done to avoid ectropion, when the eyelids are affected, offers the best means of removing the growth. This operation is often resorted to for cosmetic effect. The dermal curette has been advocated by some.

Co-existing disorders, such as disease of the liver, diabetes, etc., should be discovered and treated.

I have seen one case, in a woman with diabetes, where the xanthoma diminished as the diabetes improved. The use of phosphorus followed by turpentine has, according to Besnier, produced rapid disappearance of the tubercles.

XERODERMA PIGMENTOSUM. The name "xeroderma" is one of those formerly given to the milder form of ichthyosis, but of late years it has been used in connection with the qualification "pigmentosum," to designate a peculiar and rare affection first described by Hebra and Kaposi, of Vienna, and recently thoroughly investigated by R. W. Taylor, of New York.

The affection is characterized by the appearance of minute telangiectases, pigmentations, and atrophic changes, all of which bear the most intimate pathological relations. Superadded to these polymorphous lesions there are others in the shape of new growths, which are at first of a benign nature and may thus remain, or may degenerate into malignant growths.

The disease in most cases begins in infancy, though some two or three doubtful cases are said to have begun in early adult life.

The invasion of the disease is very constant, beginning about the face or under the eyes as a well-marked, smooth, superficial erythema, which is often regarded as the result of sunburn. The patient's health remains good while the erythematous patches extend, coalesce, and gradually creep over the face and neck, usually stopping at about the third rib by an abrupt margin. This condition of the face, neck, and trunk is of variable duration—from one to several months—during which the erythema may become less red. As this preliminary hyperæmia disappears, pigmented and red spots, or telangiectases, make their appearance, scattered irregularly over the affected regions, becoming fully developed over the face and neck in about six months. In Taylor's opinion, the pigmented spots follow and result from the telangiectatic lesions, though J. C. White and Duhring deny this relationship.

The course of the disease, though varying from time to time, tends to pass from bad to worse, until, as the child grows older, the disfigurement becomes very marked. The maximum of pigmentation is reached in early childhood. After the fifteenth or sixteenth year the pigmented lesions rarely appear in such profusion as in the early years.

These two orders of lesions—the telangiectases and the pigmentations—are peculiar to the early stages of the disease. Later—beginning, however, in some cases as early as the end of the first year after the appearance of the morbid lesions, atrophy begins to show itself, sometimes slight, at other times extensive and deep. Upon the face this form of atrophy reduces the skin to the thinness of parchment, and destroys nearly all of the follicles, producing at times great disfigurement. It may occur elsewhere, especially, as upon the knuckles, at points subject to tension.

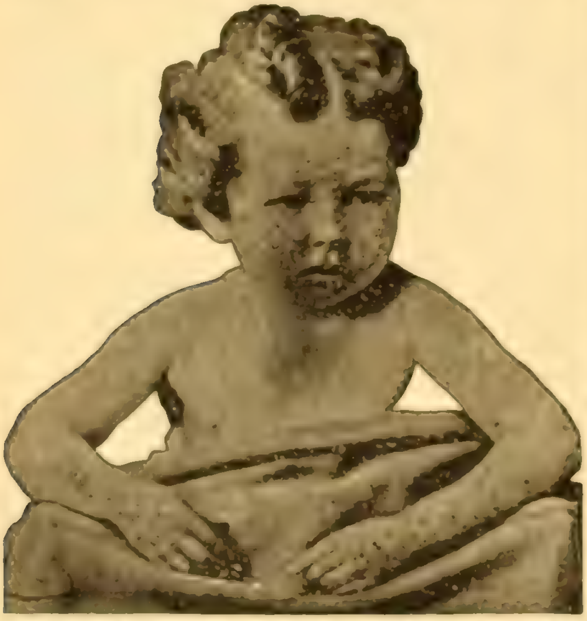

FIG. 4992.—Xeroderma Pigmentosum in a Child Three Years of Age. (Taylor.)

In almost all cases, particularly in those in which the pigmentations are deep and extensive, hypertrophic changes take place, very often coincidently with the atrophic processes, forming epithelial new growths. These may at first resemble keratosis senilis, but in some cases, especially about the muco-cutaneous junctures of the head, sessile or pedunculated, more or less elevated tumors form, with a tendency to increase in size and take on a fungating form. At first these tumors are of a deep-red or purple-blue color, soft, and compressible. They frequently become pale, less vascular, and so brittle and friable that they fall off, leaving sometimes a surface which heals spontaneously, or an ulcer which may be very intractable, extending in depth and breadth, and becoming frequently surrounded by thickened and everted edges, which may become the seat of malignant degeneration. The latter is, in some cases, epithelioma, in others melanotic sarcoma, sarcocarcinoma, or cancer.

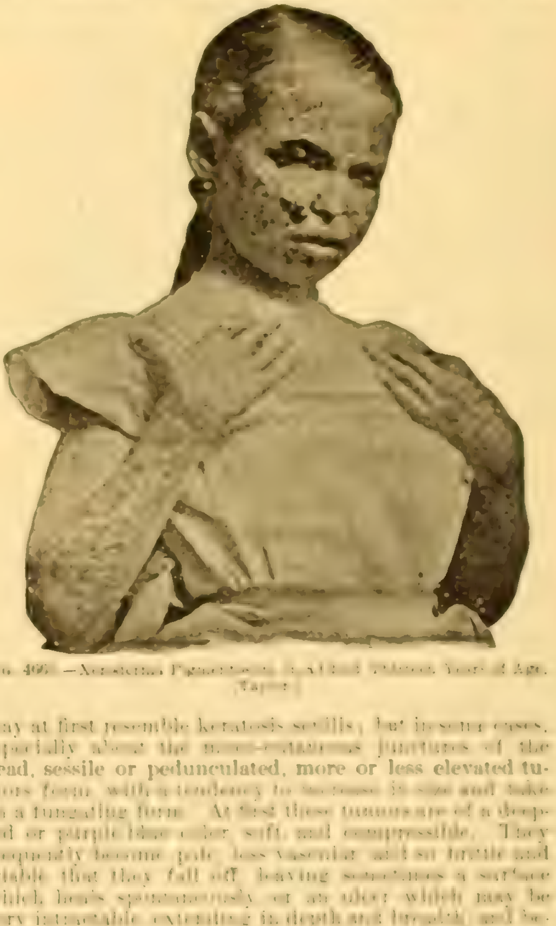

FIG. 4993.—Xeroderma Pigmentosum in a Girl Fifteen Years of Age. (Taylor.)

The treatment of xeroderma is exceedingly unsatisfactory. No case has ever been cured. The skin should be placed at rest, and all external sources of irritation should be avoided. All tumors, small and large, should be removed as soon as they make their appearance; and this is particularly necessary around the eyes, nose, mouth, etc., where malignant degeneration may be expected.

Arthur Van Harlingen.

XYLOL. A hydrocarbon, or mixture of isomeric hydrocarbons of the composition $C_6H_4(CH_3)_2$, occurs as a constituent of coal tar, and is known as *xylol* or *xylene*. This substance is principally *metaxylene* (*metadimethylbenzene*), with a certain proportion of *paraxylene* (*paradimethylbenzene*), and possibly some other hydrocarbons. Pure metaxylene can be obtained by special processes. Xylol is a thin, colorless fluid of a faint odor, reminding somewhat of that of benzene, and of a burning taste. It is insoluble in water, but soluble in alcohol. Medicinally, xylol has been used in the treatment of small-pox, and had at one time an ephemeral, but undeserved, reputation as a remedy for the disease. It was administered internally in doses of from ten to fifteen drops, in emulsion, and was also applied locally to the throat. It is now practically obsolete as a medicine.

Edward Curtis.

YARROW (*Millfoil; Millefeuille*, Codex Med.), *Achillea millefolium*; Order *Compositæ*. This is a very familiar plant, both in Europe and America. Its half-domesticated way of growing in old pastures, waysides, and gardens in this country makes it seem like an introduced herb. It has a perennial root, from which arise one or more, often several or many, upright simple stems a foot or eighteen inches high, leaves narrow, twice pinnately parted, with linear divisions also cleft or gashed inflorescence, a flat-topped compound corymb, of many small heads of white flowers. Heads radiate, small, with many tubular and four or five ray flowers. A pink variety is not rare, and occasionally cultivated.

Yarrow has a bitterish, fragrant odor and a very bitter taste. The former is due to an *essential oil* of composite character, and of different physical properties, according as it is distilled from the flowers, herb, or root. The ordinary oil (from both flowers and leaves) is of a dull, greenish-blue color, pungent aromatic odor, and burning camphoraceous taste. The yield is very small. Its bitterness is due to a dark-red uncrystallizable substance called *achillein*, also present in other species of *achilleæ*. It is a doubtful alkaloid, and may also be decomposed into glucose and *achilletin* by the usual treatment with acid.

Yarrow, like thoroughwort, is an aromatic bitter tonic, with far more emphasis upon the bitter than aromatic properties. It has been given, like most of its class, in intermittent fever, with reputed benefit, and it still is given for amenorrhœa, etc., occasionally as a popular remedy. It has no special value in any of the above directions.

Dose rather indefinite, best given in infusion.

Allied Plants, etc.—Thoroughwort, Chamomile, etc. *Santolina chamæcyparissus*, by some botanists included in the same genus with yarrow, is the *santoline* or *aurone femelle* of the Codex.

W. P. Bolles.

YAWNING. Synonyms: Gaping, Oscitation; Germ., Gähnen; Fr., Bâillement.

Definition.—Yawning is a physiological modification of respiration by which the act is intensified. It consists in an involuntary, forcible, and profound inspiration, followed by a pause and a prolonged expiration. When fully developed, it is accompanied by a wide opening of the mouth, an elevation of the velum palati, and depression of the larynx, a roaring sound, and usually a click in each ear, a flow of saliva, and a suffusion of the eyes with tears, and a more or less imperative impulse to extend the limbs, especially the arms (pandiculation), to bow and twist the trunk, and to throw back the head. The inspiratory act is frequently audible, and the expiration usually acquires a distinct blowing sound. The elevation of the palate closes the posterior nares and causes the air to be admitted wholly through the mouth. In the same way the Eustachian tubes are closed, causing momentary obtunding of hearing. The contraction of the palatal muscles often precedes the opening of the mouth, and tends to persist for a moment after its closure. The commencement of their contraction is not infrequently accompanied by a rapid succession of three or four short, broken inspiratory efforts.

Physiology.—Yawning is a physiological expression of fatigue and a disposition to sleep. It may, however, arise from a retardation of the respiration, or from any influence which will impair the oxygenation of the blood. It is frequently, therefore, a product of melancholy, languor, ennui, torpor, or debility, or of the malaise which precedes the onset of disease. It is liable to follow prolonged abstraction of mind or concentration of thought. It is sometimes the result of feeble or laborious digestion, of gastralgia, or of other disorder of the digestive organs; or it may occur in response to a demand for increased activity of circulation. It may be sympathetic. To some individuals it is habitual, occurring without fatigue, and being but the outgrowth of the lassitude or indolence of their natures. It may sometimes be attributed to the possession of an inferior degree of intelligence, a slothful, inactive, effeminate, timid, or lustful disposition, incapable alike of vigorous mental exertion or of prolonged physical activity.

That yawning may be the response to a demand for increased activity of oxygenation in the lungs, is demonstrated by placing an animal in an irrespirable atmosphere. Repeated yawning occurs shortly before the animal succumbs to asphyxia. The phenomenon is therefore usually explained on the supposition that it is due to a stimulus transmitted from the central nervous system in response to a peripheral impression, in most cases arising, in part at least, from the respiratory apparatus. Longet has attributed it to the accumulation of too great a quantity of venous blood in the right side of the heart, whence the peripheral impression is supposed to proceed. From whatever source we derive the peripheral impression, however, the act is generally admitted to be reflex in character. Of the reflex nature of the stimulus which produces the muscle-contractions in the extremities, there can be no doubt; for it is a matter of repeated observation that the hand which, owing to paralysis, has been for years beyond control of the will, and has become firmly contracted by post-paralytic rigidity of its flexor muscles, will often become distended during yawning. It is evident here that the stimulus can emanate only from the spinal centres.

The mechanism of yawning is the same as that of normal respiration; the same muscles are called into action, but their movements are more extended. (See Respiration, Vol. VI., p. 205.) The diaphragm, the scaleni, the sterno-cleido-mastoids, the clavicular portions of the trapesii, the lesser pectorals, the subclaviculars, the external intercostals, the serrati magni, the rhomboids—in fact, all the muscles which normally act as direct or as auxiliary forces in the full expansion of the chest, take part in the inspiratory movement. And all the muscles of forced expiration are called into action in the expiratory stage. In the fully developed yawn there is the action also of the muscles of the face, the depressors of the lower jaw, the dilators of the nostrils and upper lip, the orbiculares palpebrarum, the zygomatics, and of the depressors of the hyoid bone and larynx, and finally of the muscles of the back in the bowing of the trunk, and of the extensors of the extremities when stretching occurs.

Yawning is involuntary. It begins without the sanction of the will, and, once begun, it cannot be arrested. In this it resembles sighing, sneezing, hiccough, and other modifications of respiration, without, however, possessing their full spasmodic quality. Yet the will is not entirely deprived of influence over it; for a yawn may be often in a measure concealed by a forcible effort at closure of the jaws, and the mouth may be closed before the yawn has subsided. It may be imitated, but no amount of effort will induce it unless a sufficient cause for it exist. As Carpenter says, "this act may be performed by the will, though not completely; and is one that is particularly excited by an involuntary tendency to imitation, as everyone must have experienced who has ever been in company with a set of yawners."

After yawning there is usually a momentary pause in the respiratory movements, followed by normal, tranquil breathing. The forced respiration has not only supplied the blood with its needed oxygen, but, aided by the muscular contractions, has removed venous engorgement and accelerated the systemic circulation. At the same time, a moment's relaxation has been given to the fatigued body, and a sense of relief is usually afforded.

Symptomatology.—The value of yawning as a symptom has been at different times very differently estimated. Hippocrates recognized it as a precursor of a fever, particularly of intermittent fever. From its frequency and intensity, he prognosticated the severity and duration of the disease. Yawning, with suffusion of the eyes and [illegible], was actually found present [illegible] known in the diagnosis of the [illegible] type. Occurring during menstruation, it was as well known. [illegible] in 1756, believed that he had observed a death from it. The yawning of the animal was also a cause for [illegible].

It is now comparatively seldom, however, that we think of yawning as being an indication of [illegible], [illegible] a diseased state of the system. But this is not denied, a diseased state of the system, it is a well-recognized fact. As indicative of fatigue it may be a symptom of profound mental or physical exhaustion. It may, in fact, if it is persistent, constitute a morbid condition of spasmodic nature and of grave import. It is not infrequently indicative of a deficient oxygenation of the blood, especially when it is associated with the dyspnœa which results from the lung accumulations in cases of pneumonia, the lung complications of hydrothorax or pneumothorax, or after profuse and exhausting hemorrhages. In the latter connection, it is at times a valuable factor in the diagnosis of concealed hemorrhage.

Modern experience has but confirmed the observations of the ancients with regard to the occurrence of yawning in the prodromal stage of fevers, particularly of the intermittents. In these, as also in such morbid affections as epilepsy, hysteria, catalepsy, and [illegible], frequent yawning often signifies the immediate supervention of a seizure. When it occurs during the course of a disease it not seldom indicates the approach of resolution or of a crisis. It is so frequently observed during parturition, however, as a consequence merely of fatigue, that no great significance is now attached to it.

As a symptom of hysteria in suppressed menstruation in young girls it is probably in most instances a manifestation of hysteria, or at least a complication of this disorder. It is probable also that many of the reported cases of spasmodic yawning have been of hysterical origin. Nevertheless, cases have been reported in which yawning of a spasmodic character developed without hysteria, and [illegible] spasmodic [illegible], crying, sneezing, etc. Of a more [illegible], the affection may be indicative of various disorders of the central nervous system, particularly of cerebral anæmia, of circulatory disturbances in the medulla oblongata, or it may occur in the wake of cerebral hæmorrhage. It also shows a predilection for individuals who, from necessity, are confined in small, closely crowded work rooms, and for convalescents from paralytic affections, especially paralysis and [illegible].

In the surgical yawning is of interest chiefly on account of its occasionally producing luxation of the lower jaw. The mechanism of this accident is considered under Dislocations, Vol. II., p. 486. *James M. French.*

YEAST (*Cerevisiæ Fermentum*, Br. Ph.; also Leaven, Yeast cake or powder, and the now almost universally used term, "Compressed," or German Yeast).

The well-known alcohol ferment. It consists essentially of living minute Saccharomyces (Torula) Cerevisiæ Meyen, Order, Saccharomycetes, mixed or diluted, according to circumstances, with starch, sugar, malt, meal, or even other farinaceous or saccharine substances, and sometimes with hops.

This little plant consists in its usual form of single ovoid cells, containing turbid protoplasm and vacuoles (see Fig. 4881), about the $\frac{1}{3000}$ of an inch in length. These cells, in active state, increase in numbers to an almost limitless extent by budding (Fig. 4881, ii, iii, iv), usually separating sooner or later as the new cells attain any considerable size, but also often, especially upon the surface or where the fermentation is closed, cohering into a chain or colonies. In, under rare circumstances, certain cells are [illegible] formed in which two or several cells are [illegible], and finally liberated by the disappearance of the original cell wall. These then grow and bud in the usual way as the parent. During the growth and multiplication of these little cells sugar and the albuminous matters are [illegible] decomposed into alcohol and carbon dioxide (see FERMENTATION, Vol. III.).

The early history of yeast is lost in antiquity. It is frequently mentioned in the Bible as leaven, and in some shape or another has been and is used by nearly all races of mankind. Its production in the great beer and spirit breweries of Europe and America amounts to thousands of tons, and it is consumed and often made in nearly every family of Christendom.

As a commercial product, yeast exists in three principal forms: 1. Brewer's Yeast (official in England), the sediment of the fermenting beer-vats, containing the plant in a state of high activity, of which the following is the official description: "Viscid, semi-fluid, frothy, exhibiting, under the microscope, numerous isolated, rounded or oval cells, or short-branched filaments composed of united cells; odor peculiar; taste bitter." 2. Cake yeast (dry), consisting of the above mixed with starch, flour, or, in this country, Indian meal, rolled and cut into little blocks and dried; and finally, 3, superseding both the above forms for domestic use in cities and towns, the German or Compressed Yeast in little moist cakes enclosed in tinfoil, which consists of an almost solid mass of yeast cells with a minimum of starch or sugar. This is made by taking the beer skimmings and repeatedly washing and straining them, and allowing the cells to settle, and finally pressing nearly dry between cloths; or by propagating them in a [illegible] mixture of barley-malt, rye-flour, and barley, and collecting, washing, and pressing in the same way. "Compressed" Yeast is a very concentrated and active form of Yeast. In its moist state, however, it does not keep very well, and should be obtained fresh every day or two, and laid in the coolest place until wanted.

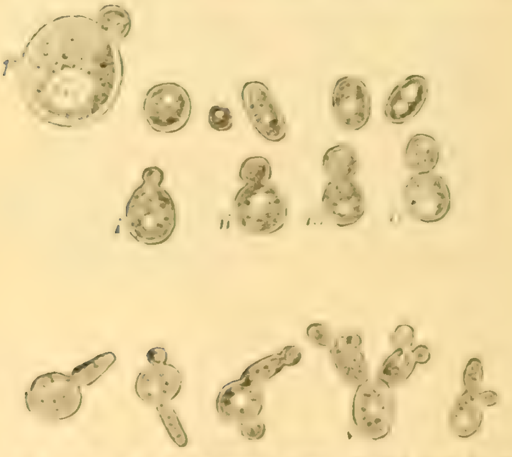

FIG. 4881.—Cells of Ordinary Brewers' Yeast. (Copied from [illegible]) [illegible]

Into the general uses of yeast it is not the design of this article to enter. It is concerned in the production of all beers, wines, and liquors, and of the common "raised" breads and cakes. As a [illegible] of food in these latter, it has considerable hygienic importance, which, mixed with a moderately thick dough, the development of carbonic acid taking place throughout fills it with innumerable minute vesicular bubbles, or makes it "spongy," as the housewives say, or "light." If baked in this condition these bubbles expand with the heat, making the bread still "lighter," or more porous, and in a condition for more ready disintegration in the stomach and intestine than breads made without yeast, and depending upon the evaporation of water only for their lightness. The alcohol is mostly dissipated in the baking and cooling of the bread; the cooked yeast itself is probably of no special dietetic consequence.

In medicine Yeast is now scarcely used. It has been given in indigestion, dyspepsia, etc., but is of little consequence (there are yeast-cells in or upon our food almost always). Dose of liquid yeast, fifteen or twenty grams (℥ ss.). It still survives to a moderate extent as a poultice (*Cataplasma Fermenti*, Br. Ph.), which is simply a thin raised dough.

"Take of

Beer yeast...........................	6 fluid ounces.
Wheaten flour......................	14 ounces.
Water heated to 100 F. (37.8 C.)....	6 fluid ounces.

Mix the yeast with the water and stir in the flour. Place the mass near the fire till it rises" (Br. Ph.).

Yeast poultice is a light, agreeable application, and is thought to overcome the odor and reduce the decomposition of sloughing sores. It is seldom used in this country.

ALLIED PLANTS.—The species of *Saccharomyces* and related ferment-forms are as great a puzzle to botanists as their actions are to chemists, but so much is certain that there are several distinct forms, each of which is capable of producing a specific change in a number of substances; their forms are not always easily distinguishable. The lactic, butyric, and acetic acid fermentations, and others, have each been shown to have peculiar cell-growths accompanying them which can be propagated and isolated like Yeast, for the purpose of producing them. See FERMENTATION. *W. P. Bolles.*

YELLOW FEVER. *Definition.*—A specific infectious disease, contracted by exposure in infected localities; characterized by a single febrile paroxysm of short duration (two to five days , by the presence of albumen in the urine, an icteric color of the skin, and a tendency to passive hæmorrhages from mucous surfaces—especially from the stomach—producing "black vomit."

History and Geographical Distribution.—The geographical range of yellow fever is more restricted than that of any other acute infectious disease, and within the area of its prevalence it is essentially a disease of the littoral, and especially of seaport cities. While occasional epidemics have occurred upon the southwest coast of the Iberian peninsula, the disease, as an epidemic, is unknown elsewhere in Europe, and there is no evidence that it has ever invaded the great and populous continent of Asia. In Africa it is limited to the west coast. In North America, although it has occasionally prevailed as an epidemic in every one of our seaport cities as far north as Boston, and in the Mississippi Valley as far north as St. Louis, it has never established itself as an endemic disease within the limits of the United States. Vera Cruz, and probably other points on the Gulf coast of Mexico, are however at the present time, endemic foci of the disease. In South America it has prevailed as an epidemic at all of the sea-ports on the Gulf and Atlantic coasts, as far south as Montevideo and Buenos Ayres, and on the Pacific along the coast of Peru.

The region in which the disease has had the greatest and most frequent prevalence is bounded by the shores of the Gulf of Mexico, and includes the West India islands. Within the past few years yellow fever has been carried to the west coast of North America, and has prevailed as an epidemic as far north as the Mexican port of Guaymas, on the Gulf of California.

The idea that yellow fever may originate *de novo*, within the area of its occasional prevalence, was entertained by many medical authors during the first half of the present century, and is still held by a few. Thus Cornillac (1886) says: "In the zone which is habitual to it, yellow fever may develop at a given moment without apparent cause. It is born spontaneously at a point of this zone, or at several at a time, and neither the temperature, moisture, barometric pressure, electricity, or finally effluvia given off from the soil, can explain this sudden invasion." It is true that, in localities where the disease is endemic, cases occur which are not directly traceable to importation, but it is also true that in the principal endemic foci of the disease, such as Vera Cruz, Havana, and Rio Janeiro, yellow fever was at one time unknown, and we have reliable historical data fixing the date of its importation. In short, a careful consideration of the historical evidence relating to the disease gives no support to the idea of independent local origin, any more than in the case of small-pox, cholera, or other specific infectious diseases.

But the early history of the disease is involved in obscurity, and we are at present unable to determine whether, as maintained by some, it was endemic at certain points on the shores of the Gulf of Mexico at the time of the discovery of the "new world," or whether it was imported to the West Indies from the African coast, as maintained by others. The early historians, Herréra, Oviédo, Rochefort, and others, make reference to epidemics among the natives which occurred prior to the discovery of the Antilles, and to fatal pestilential diseases among the first settlers of these islands; but their accounts are not sufficiently exact to enable us to affirm that the disease referred to by them was yellow fever. The west coast of Africa was discovered and colonized to some extent before the discovery of America, but the first authentic accounts of the prevalence of yellow fever on this coast date back only to the year 1778, over two centuries after the first settlements had been established. On the other hand, this very epidemic of 1778 at St. Louis (Senegal), was traced to importation from Sierra Leone, a portion of the African coast which, according to Hirsch, "appears to be the head-quarters of the disease, and the starting-point of its epidemic inroad into the territories lying to the north and south, as well as into the West African islands."

Rochefort, whose "Histoire naturelle et morale des isles Antilles de l'Amérique" was published in Holland in 1558, says of the West Indies: "The air of all those islands is very temperate, and healthy when one is accustomed to it. The *peste* was formerly unknown there as well as in China and other places in the Orient; but some years since the islands were afflicted with malignant fevers, which the physicians considered contagious. The bad air was brought there by some ships which came from the coast of Africa, but at present we hear nothing more of these maladies."

It seems very probable that a pestilential malady which prevailed for a time in these usually healthy islands and then disappeared, was in fact yellow fever, and that it was introduced by ships from the west coast of Africa is not at all incredible. Indeed, it almost seems necessary to look for an original endemic focus of the disease outside of the West Indies, for the reason that, in the comparatively few places where it is now endemic, there is historical evidence to show that there was a first importation and a previous period of exemption; while, on the other hand, the conditions upon which endemicity at the present day seems mainly to depend, were formerly unknown—conditions arising from the aggregation of population at seaport cities, as at Havana, Vera Cruz, and Rio Janeiro.

Some authors have attempted to identify the epidemic disease mentioned by Humboldt—called by the natives "Matlazahuatl"—which prevailed in Mexico in 1545, 1576, 1736–37, and 1761–62, with yellow fever; but, as pointed out by Hirsch, this disease prevailed almost exclusively among the natives of the interior and of the table-land of Mexico, while yellow fever is essentially a disease of the littoral.

Cornillac, a recent French author who has made a careful study of the sanitary history of the West Indies, as contained in the works of Oviédo, Herréra, Gomara, and other Spanish authors of the sixteenth century, arrives at the conclusion that the pestilential disease from which the settlers in the first Spanish colony at Nueva Isabella, and at Santo Domingo (1494–1514), are said to have suffered, and which was characterized by a "saffron-yellow" color of the skin, was in truth yellow fever. While it appears quite probable that this was so, we cannot accept it as demonstrated, as the first authentic accounts of yellow fever in the West Indies date from about the middle of the following century.

In 1635 a French colony was established upon the island of Guadeloupe, and shortly after their arrival a pestilential disease appeared among the colonists which, from the account given by Dutertre, a Catholic priest who resided in the island five years (1640–47), is accepted by Hirsch and by Cornilliac as having been yellow fever. From Dutertre's account, however, as quoted by Cornilliac, it would appear that yellow fever was first imported into the island of Guadeloupe in the year 1648, and that the great mortality previously reported was due to other causes. Dutertre says: "During this same year 1648 the [illegible] which was unknown in these islands since they were inhabited by the French, was brought there by a ship. It commenced at Saint Christophe, and during the eighteen months that it lasted carried away nearly one-third of the inhabitants. The epidemic [illegible] in those who were attacked a violent pain in the head, great [illegible] in all the members, and continual vomiting, so that in three days it put a man in his tomb. This [illegible] certainly was brought to Guadeloupe by a ship from La Rochelle, called Le Bœuf."

At Barbadoes the disease may have prevailed for some years prior to its introduction to Guadeloupe, but the first authentic account relates to the year 1647. Richard Ligon, who arrived at the island in the month of September of that year, says that the city of Barbadoes was at that time suffering from a scourge which caused great ravages, so that the living scarcely sufficed to bury the dead. According to this author, the cause of this epidemic was unknown; it was uncertain whether it had been imported, or whether it originated from bad food, the use of impure water, and the intemperance of the colonists. Ligon inclines to attribute it largely to the latter cause, and remarks that not more than one [illegible]. We may safely assume, from the subsequent history of the island of Barbadoes, that the malignant plague referred to by Ligon was not of local origin, but with a rapidly increasing population this island has enjoyed considerable periods of immunity from yellow fever, and when epidemics have occurred they have, as a rule, been clearly traced to importation. From this time—1647–48—the history of yellow fever in the West Indies is a history of epidemic outbreaks at varying intervals, at the principal seaport towns, traced sometimes to importation, but more commonly assumed to be of local origin. It was epidemic in Jamaica in 1655, and again in 1671; at Santo Domingo in 1656; at Martinique in 1686 and 1690. In 1699 it prevailed widely as an epidemic in the West Indies, and, according to Hinemann, made its first appearance at Vera Cruz, the principal seaport on the Gulf coast of Mexico.

Cuba.—I cannot attempt to follow here the history of yellow fever in the West Indies generally, but shall give an account of its prevalence in Havana, as this is now the endemic focus of the disease and the point which is the most dangerous to the United States, on account of its proximity and the constant commercial intercourse between this city and our own seaports.

The historian Pezuela records the prevalence of a malignant pestilential disease in Havana in 1648, a year in which, as we have seen, yellow fever was epidemic in the islands of Guadeloupe and of Barbadoes. He says: "In this year there occurred in Havana a great and [illegible] pestilential fever which prevailed in the port almost all the summer. A large part of the garrison and a larger part of the crew and passengers in the vessels died." The epidemic continued the following year, and in 1653–54, according to the author above quoted, "the epidemic was renewed with equal fury," and in 1655 "in the capital continued to carry away its victims without regard to condition and position." According to Dr. S. E. Chaillé, President of the Havana Yellow Fever Commission (1879), from whose report we have quoted the above extracts from Pezuela, there is no historical evidence of the prevalence of yellow fever in Havana for more than a hundred years after the date mentioned. On the contrary, there are repeated records of the great salubrity of the climate and the absence of epidemic disease.

It was not until the year 1761 that yellow fever established itself in the previously healthy city. Pezuela gives the following account of its introduction: "Although Havana is situated on the northern boundary of the torrid zone, it was very justly considered one of the most healthy localities on the island before its invasion, in a permanent manner, by the vomito negro, imported from Vera Cruz in the summer of 1761. . . . . In May there came from Vera Cruz, with materials and some prisoners destined for the works on the exterior fortifications of Havana, the men-of-war Reina and América, which communicated to the neighborhood the epidemic known by the name of 'vomito negro.' At the end of the following June there were stationed in this port nine men-of-war, despatched from Cadiz, and sent to the chief of the squadron, Don Gutierre de Hevia; they brought a reinforcement of 2,000 men. More than 3,000 persons succumbed to the epidemic on this *the first appearance* of the vomito."

From this time to the present day the new levies of troops sent from Spain to Cuba have continued to suffer enormous losses from the endemic pestilence. In 1779 there arrived from Spain, then at war with Great Britain, "an army of 8,000 men, which was immediately decimated by the vomito." In 1780 during the month of August, an army of 8,000 men was landed in Havana, which during the two following months suffered a loss of about 2,000 men with the vomito. Pezuela records the fact that in 1794, in the garrison and squadron, there were more than 1,600 victims to the disease.

The endemicity of yellow fever in Havana was fully established by the researches of the commission sent to that city in 1879, by the National Board of Health. Dr. Chaillé, president of this commission, says in his preliminary report, published in 1881: "Since 1761 yellow fever has prevailed certainly in Havana, and probably in other places in Cuba, every year, and the dates of prevalence recorded in our text-books indicate no more than the years of greatest prevalence. The disease prevails in Havana, and in some other places in Cuba, not only every year, but also every month in the year; records in 1857 indicate that at that date the monthly prevalence had become habitual in Havana; the statistics, solely of the military and civil hospitals, prove that during the 108 months, 1870–79, there was only one single month free from an officially recorded case of yellow fever."

The following tables are from the "Preliminary Report of the Havana Yellow Fever Commission:"

Monthly Maximum and Minimum Deaths by Yellow Fever in Havana during the Ten Years 1870–79.

Month.	Minimum.	Maximum.	Month.	Minimum.	Maximum.
January	[illegible]	[illegible]	July	68	[illegible]
February	4	29	August	7	[illegible]
March	[illegible]	[illegible]	September	46	[illegible]
April	4	[illegible]	October	27	[illegible]
May	11	[illegible]	November	[illegible]	[illegible]
June	66	[illegible]	December	[illegible]	[illegible]

In no one of the ten years 1870–79 has there ever been fewer deaths than in the first, nor more than in the second column, and the total deaths by yellow fever for each year were as follows:

Total Deaths by Yellow Fever in Havana.

In 1870	[illegible]	In 1875	[illegible]
In 1871	991	In 1876	[illegible]
In 1872	[illegible]	In 1877	[illegible]
In 1873	1,244	In 1878	1,559
In 1874	[illegible]	In 1879 (to December 1)	[illegible]

Matanzas has the reputation of having long suffered seriously with yellow fever; the earliest positive date secured by me was reported by Dr. Gutierrez, a member of the Commission, a native of Matanzas, who was assured by one of the oldest physicians that the city suffered with the disease in 1828, when he came to Matanzas, and had prevailed every year since." (Chaillé, op. cit.)

Cienfuegos.—"Yellow fever every year since 1850, except in 1862 and 1874."

Santiago de Cuba.—"Yellow fever prevailed every year, and nearly every month, from 1850 to the present time."

Manzanillo.—"Yellow fever every year since 1866."

Vera Cruz, the principal seaport on the Gulf coast of Mexico, is also the principal endemic focus of yellow fever upon this coast. According to Hinemann, the first epidemic occurred in 1699, a year in which yellow fever was widely prevalent in the West Indies, and in which it prevailed for the first time as an epidemic in the city of Philadelphia.

The following table, which I copy from a paper by Dr. Zacarias R. Molina, a medical officer of the Mexican Army who has for a number of years been on duty in the Military Hospital at Vera Cruz, shows the continued prevalence of the disease in that city during a period of nearly fifteen years:

Mortality from Yellow Fever in the City of Vera Cruz from July, 1867, to December, 1881.

Months.	1867.	1868.	1869.	1870.	1871.	1872.	1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.

There is no evidence of continued prevalence at other towns upon the Mexican coast, but epidemics, which have usually been traced to importation from Vera Cruz, have occurred at *Matamoras* (1858, 1863, 1867); at *Tampico* (1821, 1836, 1845, 1847, 1853, 1864); at *Tuxpan* (1863, 1875, 1877); at *Campeché* (1865, 1877), and at *Manzanillo* (1868).

The Gulf coast of South America, and especially the English and French settlements in Guiana, have been frequently visited by epidemics of yellow fever, and it is probable that the disease is endemic at one or more points upon this coast. Its epidemic prevalence is recorded for the following years at *Demerara:* 1793–96, 1800, 1803, 1818, 1819, 1820, 1821, 1825, 1827, 1828, 1831, 1837–39, 1841–45, 1851–53, 1861–66 (Hirsch).

In Venezuela the disease has prevailed at the capital, *Caracas*, and the neighboring seaport, *La Guayra*, in the years 1693, 1696, 1793, 1797, 1802, and 1869.

In Central America epidemics have occurred at all of the principal seaports: *Panama*, 1740, 1858, 1859, 1867. *Portobello*, 1726, 1729, 1740, 1793, 1860, 1866, 1867; *Belize*, 1860; *Nicaragua*, 1868.

Brazil.—The Portuguese author El hastião da Rocha Pitti has given an account, in his "History of Portuguese America," published in Lisbon in the year 1730, of an epidemic malady which prevailed in Pernambuco in the year 1686, which very probably was yellow fever. This author says (Book VII., p. 427 et seq.): "In the year 1686, commenced in Pernambuco that terrible plague (contagious disease, *Bicha*) which must be attributed to the sins of the population of these provinces, corrupted by the vices into which they were enticed by the wealth and freedom of Brazil. Many causes are alleged, the most worthy of attention being the arrival of some barrels of meat which returned from the island of São Thomé (St. Thomas). These were opened by a cooper, who shortly afterward fell dead. Soon after several persons of his family, to whom he had communicated the disease, also died. The epidemic spread to such an extent among the inhabitants of Recipe (Pernambuco) that the mortality exceeded 2,000, which was very large in proportion to the population. Thence the disease extended to Olinda and its vicinity, and very few were the persons who escaped it, such were its virulence and intensity."

The account given by the historian of the clinical features of this pestilential disease is, of course, very imperfect, but it seems to justify the belief that the disease was really yellow fever.

The highest medical authorities in Brazil agree that yellow fever was not endemic in the principal seaports of the empire prior to the year 1849, when it was introduced to the city of Bahia by the North American brig Brazil, which sailed from New Orleans, where yellow fever was prevailing, and touched at Havana. Two of the crew of this brig died of yellow fever during her voyage from the latter port to Bahia. Soon after her arrival the disease made its appearance among those who had communicated with the ship, and later, on other vessels in the harbor. The first case occurred a few days after the arrival of this brig (November 3d). A part of her cargo is said to have consisted of little barrels of beef which had become putrid. From Bahia the disease was carried to Rio Janeiro, where during the epidemic season of 1850 it caused a mortality of 4,160.

According to Professor Barata, of the Faculty of Medicine of Rio Janeiro, yellow fever continued to prevail in Brazil until the year 1861, when it disappeared for eight years, to reappear in 1869–70, as the result of a fresh importation. The Italian ship Creolla del Plata, which had touched at St. Iago, where yellow fever was prevailing, is named as the vessel which introduced the disease on this occasion.

The mortality from the disease under consideration in the city of Rio, from the time of its introduction in 1850 to a recent date, is shown by the following table:

	Mortality.		Mortality.
1850	4,160	1869	274
1851	475	1870	1.117
1852	1,943	1871	8
1853	853	1872	102
1854	21	1873	3 659
1855	0	1874	829
1856	0	1875	1.292
1857	1,425	1876	3,317
1858	800	1877	282
1859	500	1878	1.174
1860	1,249	1879	974
1861	247	1880	1 433
1862	12	1881	219
1863	0	1882	95
1864	0	1883	1.336
1865	0	1884	618
1866	0	1885	278
1867	0	1886	1 397
1868	0		

In 1855 yellow fever is said, by Hirsch, to have prevailed extensively in Brazil, although this was not an epidemic year in Rio Janeiro. The following year it extended along the Amazon far into the interior of the country. The years of greatest epidemic prevalence since that date have been 1859–60, 1862, 1869–70, 1872–73, 1875–77 (Hirsch).

From Brazilian ports the disease has occasionally been introduced to the cities at the mouth of the Rio de la Plata, and has there caused great loss of life. The first epidemic at *Montevideo* was in 1857, and it was again introduced into this city, from Pernambuco, in 1872. It prevailed in the city of *Buenos Ayres* in 1858 and in 1870.

Yellow fever is said to have been conveyed to the Pacific coast of South America by a party of German emigrants, who landed at Callao, *Peru*, in 1854. The disease spread from this port to the capital, and in the course of the next two or three years to the principal towns upon the Peruvian coast, where it continued to prevail up to the year 1869.

Chili, up to the present time, has remained exempt from the disease (Hirsch).

Upon the *West Coast of Africa* the head-quarters of yellow fever is that portion of the coast which belongs to the province of *Sierra Leone*, and epidemics at other points upon the African coast have frequently been traced to this locality. It seems very doubtful, however, whether, as some authors suppose, this is really the original source of the disease. The French authors Bérenger Feraud and Bourru both call attention to the fact that we have no account of the disease prior to the year 1775, although the African coast was discovered and colonized long before the discovery of the West Indies, and that, on the other hand, the early settlers in these islands suffered from a pestilential malady which very probably was yellow fever.

At St. Louis (Senegal) an epidemic occurred in 1778, and this is the first outbreak of the disease of which we have any reliable information in this portion of the world. The disease in this instance is said by Schotte to have been imported from Sierra Leone, where epidemics are recorded to have occurred during the present century in 1823, 1829, 1837, 1838–39, 1847–59, 1845–47, 1859, 1862, 1864, 1865–66, 1866, 1878 (Hirsch). Frequent epidemics have also occurred at Senegambia, and the disease has prevailed upon the Gold Coast (1852, 1857, 1862), the Loango Coast (1816, 1861, 1862, 1865), at the Cape Verd Islands (1845, 1862, 1868), and the Canary Islands (1701, 1771, 1810, 1846, 1862).

In Europe the ravages of yellow fever have been restricted mainly to the Iberian peninsula. This is due, no doubt, to the frequent intercourse between Spain and Portugal and the West Indian ports, in which the disease is most prevalent, and to the fact that the summer temperature of these countries is favorable for the epidemic extension of the disease; whereas the more northern portions of Europe are practically outside of the yellow-fever zone.

The first epidemic in Spain occurred in the year 1700, at Cadiz. This city also suffered in 1730–31, 1733–34, 1764, 1780, 1800, 1804, 1810, 1819–21. The epidemics of 1800, 1810, and 1819 were not limited to the city of Cadiz, but the disease extended to the interior and caused a considerable loss of life in the provinces of Granada and Andalusia, and also in some of the towns of Murcia and Catalonia—especially in Barcelona, from which city the disease was conveyed to the island of Majorca during the last epidemic. No subsequent epidemic has occurred in Spain since 1821, but local outbreaks, as a result of importations from the West Indies, have occurred in Gibraltar (1828), Barcelona (1870), and Madrid (1878).

The first epidemic at Lisbon was in 1723; a second was inaugurated in 1856, and during the following year developed into a devastating scourge which extended to the towns of Belem, Olivaes, and Almada.

In *Italy* yellow fever has only once effected a temporary lodgment—at Leghorn, in 1804, where it was imported from Spain.

Ships with yellow fever on board have occasionally arrived at English and French ports, but local conditions have apparently not been favorable to an extension of the disease, except to a limited extent at Brest in 1856, at St. Nazaire in 1861, and at Swansea (Wales) in 1864.

Bahama Islands.—Yellow fever prevailed as an epidemic at Nassau in 1861, 1862, 1864, and in 1869.

According to Hirsch, yellow fever prevailed to a limited extent at Halifax (latitude 44° 20') in 1861, and at Quebec (latitude 46° 50'), in 1805.

PREVALENCE OF YELLOW FEVER IN THE UNITED STATES. *New Hampshire.*—Portsmouth is the most northern point in the United States which has suffered an epidemic of yellow fever. In 1798 and again in 1802, during which year the disease was epidemic in New York and in Philadelphia, it was also epidemic in this city.

Massachusetts.—In 1693 an English expedition sailed from Boston for the purpose of taking from the French the island of Martinique. The expedition failed in its object and returned to Boston on June 11th, with yellow fever on board the vessels of the fleet. Hutchinson, in his "History of Massachusetts Bay," says the mortality among the sailors had been 1,300, out of a total strength of 2,100, and that out of the same number of soldiers the loss was 1,800. He states that the disease spread from the fleet to the town, and that many families left town and resided in the country until the infection had ceased. This is the first authentic account of the occurrence of yellow fever within the present limits of the United States. In 1796 the disease prevailed to a limited extent in Boston and in Newburyport. In 1798 it prevailed as an epidemic in Boston, where the mortality was 200, and in 1802 66 fatal cases occurred in the same city. Some cases also occurred in the years 1800, 1819, and 1858.

Rhode Island.—The city of Providence was several times visited by yellow fever during the latter part of the eighteenth and the beginning of the present century—1794, 1796 (mortality 45), 1797 (mortality 45), 1800, 1805. The disease prevailed at Newport in 1798, and at Bristol in 1797.

Connecticut.—The disease prevailed at New London in 1795, and again in 1798, when the mortality was 81. Hirsch records the occurrence of the disease at New Haven in 1743, 1794, and 1805; at Middletown in 1820; at Chatham in 1796, and at Hartford in 1799.

New York.—Epidemics of greater or less extent have occurred in New York City and its immediate vicinity in 1668, 1702, 1743 (mortality 217), 1745, 1762, 1791, 1794, 1795 (mortality 730), 1798 (mortality 2,086), 1799 (mortality 76), 1800, 1801, 1803 (mortality 700), 1805 (mortality 400), 1809, 1819, 1822 (mortality 230), 1848, 1853, 1854, 1856, 1870 (mortality 49).

New Jersey.—Hirsch records the following local epidemics: Bridgetown, 1798; Chews, 1798; Woodbury, 1798; Perth Amboy, 1811.

Pennsylvania.—According to La Roche, "the earliest onset of the disease occurred in 1699, when Philadelphia, then but seventeen years of age, was little more in point of extent than an ordinary country town." There are no medical accounts of this epidemic, but there is no doubt as to the nature of the disease, which caused a mortality of 220 in the new city, estimated to have contained less than four thousand inhabitants. The next epidemic in Philadelphia occurred in 1741, when the mortality was 250. Subsequent epidemics occurred in 1747, 1762, 1793 (mortality 4,041), 1794, 1797 (mortality 1,300), 1798 (mortality 3,500), 1799 (mortality 1,000), 1802 (mortality 307), 1803 (mortality 195), 1805 (mortality 400), 1819, 1820 (mortality 83), 1853 (mortality 128), 1870 (mortality 18).

Delaware.—In the epidemic of 1798 the city of Wilmington suffered a loss of 250.

Maryland.—Epidemics, for the most part of limited extent, have occurred in Baltimore in the years 1783, 1794, 1797, 1798, 1799, 1800, 1802, 1819, 1820, 1821, 1822, 1868, 1876.

Virginia.—At Norfolk epidemics are recorded as follows: 1737, 1741, 1794, 1795, 1797, 1799, 1800 (mortality 250), 1801, 1821, 1826, 1855 (mortality 1,807). An epidemic occurred at Petersburg in 1798, and at Alexandria in 1803. At Portsmouth the disease prevailed in 1852, 1854, and 1855 (mortality 1,000).

North Carolina.—Wilmington, 1796, 1800, 1821, 1862 (mortality 446); Newbern, 1799, 1864 (mortality 700); Beaufort, 1854, 1864 (mortality 68), 1871; Washington, 1800; Smithville, 1862.

South Carolina.—The first epidemic of which we have any account, at Charleston, occurred in 1693; from this time epidemics have been numerous, and during the first half of the present century the physicians of Charleston generally considered the disease endemic in that city. That it was not seems to be demonstrated by the immunity enjoyed since 1871, an immunity which is probably due to the diminished commerce with infected ports in the West Indies, and to a more efficient quarantine service, since the fact has been recognized that the disease is not endemic.

The prevalence of yellow fever in Charleston during the present century is shown in the following table; recorded epidemics, prior to the year 1800, are as follows: 1693, 1699, 1700, 1703, 1728, 1732, 1734, 1739, 1745, 1748, 1753, 1755, 1761, 1762, 1768, 1770, 1792, 1794, 1795, 1796, 1797, 1798, 1799 (mortality 239). An epidemic occurred among the troops stationed at Hilton Head in 1862; Port Royal, 1877 (mortality 35).

Georgia.—At Savannah epidemics are recorded in the years 1800, 1807, 1808, 1817, 1819, 1820, 1827, 1852, 1853, 1854 (mortality 580), 1858, 1876; at St. Mary's in 1808 (mortality 84), and in 1876; at Augusta in 1839 and 1854; at Bainbridge in 1877; Brunswick, 1876.

Mortality from Yellow Fever in Charleston, S. C., Pensacola, Fla., Mobile, Ala., New Orleans, La., and Galveston, Tex., during the Present Century.

* Number of deaths not stated.

Florida.—The principal sea-port, Pensacola, has suffered frequent epidemics of yellow fever. Those occurring during the present century are included in the table given above. Two epidemics are recorded as occurring prior to the year 1800—1764 and 1765. At St. Augustine epidemics occurred in 1807, 1821, 1838, 1839, and 1841; at Key West in 1823, 1829, 1841, 1862, 1867, 1875, 1878, 1887; at Jacksonville in 1857, 1877, and 1888; at Fernandina in 1877 (mortality 498); at Tampa in 1839, 1853, 1871, 1887.

Alabama.—The recorded epidemics in Mobile, prior to the year 1800, were in 1705, 1765, and 1766; subsequent epidemics are included in the table. Montgomery, 1853 (mortality 35), 1854 (mortality 45), 1855 (mortality 30), 1873 (mortality 102); Selma, 1853 (mortality 32); Florence, 1878.

Mississippi.—The town of Biloxi, on the Gulf, has suffered from epidemics as follows: 1702, 1839, 1847, 1853, 1858, 1878, 1884; Pascagoula, 1847, 1853, 1875, 1878; Port Gibson, 1878; Shieldsborough, 1820, 1829, 1839; Port Adams, 1839, 1853; Grand Gulf, 1853; Natchez, on the Mississippi River, 1817, 1819 (mortality 180), 1823 (mortality 312), 1825 (mortality 150), 1827, 1829 (mortality 90), 1837 (mortality 280), 1839 (mortality 235), 1848, 1853, 1855, 1858; Vicksburg, 1839, 1841, 1847, 1853, 1855, 1858, 1871, 1873, 1878 (mortality 872); Jackson, 1853, 1854, 1878 (mortality 86); Holly Springs, 1878 (mortality 309); Greenville, 1878 (mortality 301); Grenada, 1878 (mortality 326); Canton, 1878 (mortality 180). Our record does not include numerous smaller places which suffered during the epidemic of 1878.

Louisiana.—The first recorded epidemic in New Orleans was in the year 1769; other outbreaks prior to the present century were in 1791, 1793, 1794, 1795, 1796, 1797, 1799. The prevalence of the disease in this city subsequent to the year 1800 is given in the table. Baton Rouge, 1817, 1819, 1822, 1827, 1829, 1837, 1843, 1847, 1853, 1858, 1878 (mortality 193); Opelousas, 1837, 1839 1842, 1853; St. Francisville, 1811, 1817, 1819, 1823, 1827, 1829, 1839, 1843, 1846, 1848, 1853; Shreveport, 1853, 1873 (mortality 759); Port Hudson, 1839, 1841, 1843, 1853, 1878; Thibodeaux, 1846, 1853, 1854, 1878; Washington, 1837, 1839, 1852, 1853, 1854, 1867; Morgan City, 1878 (mortality 109). Numerous smaller places during the epidemics of 1873 and of 1878.

Texas.—The epidemics at Galveston are included in our table. Houston, 1839, 1844, 1847, 1848, 1853, 1854, 1858, 1859, 1864, 1867, 1870; Huntsville, 1867 (mortality 130); Hempstead, 1867 (mortality 151); Indianola, 1852, 1853, 1858, 1859, 1862, 1867 (mortality 80); La Grange, 1867 (mortality 200); Matagorda, 1862 (mortality 120); Navazota, 1867 (mortality 154); Rio Grande City, 1867 (mortality 150); Victoria, 1867 (mortality 200); Brenham, 1867 (mortality 120); Calvert, 1867 (mortality 250); Chapel Hill, 1867 (mortality 123); Columbia, 1867 (mortality 132); Brownsville, 1853, 1858, 1862, 1882.

Tennessee.—Memphis, 1828, 1853, 1855, 1867, 1873 (mortality 1,244), 1878 (mortality 5,000), 1879 (mortality 485); Chattanooga, 1878 (mortality 135); Brownsville, 1878 (mortality 212); numerous smaller towns in 1878.

Arkansas.—Columbia, 1853; Fort Smith, 1823; Little Rock, 1873; Napoleon, 1853.

Kentucky.—Bowling Green, 1878; Hickman, 1878 (mortality 153); Louisville, 1878 (mortality 64).

Ohio.—Cincinnati, 1871, 1873, 1878 (mortality 17); Gallipolis, 1796, 1878 (mortality 18).

Illinois.—Cairo, 1873 (mortality 17), 1878 (mortality 51).

Missouri.—St. Louis, 1854, 1855, 1878 (mortality 16); New Design, 1797 (mortality 57).

Great Epidemics in the United States. 1793.—The city of Philadelphia, after enjoying an immunity from yellow fever for thirty-one years, suffered in 1793 a devastating epidemic. This epidemic, no doubt, resulted from importation, although a clear history of its introduction was not made out at the time, and the leading physicians of the city were inclined to attribute it to local origin, as a result of unsanitary conditions in connection with an unusually high temperature. La Roche says: "Dr. Rush and others laid great stress on a quantity of damaged coffee which was exposed, during the latter part of July, in a place (on a wharf and in the adjoining dock) and under circumstances which favored decomposition. Its smell was highly putrid and offensive, insomuch that the inhabitants of the houses in Water and Front Streets, who were near to it, were obliged in the hottest weather to exclude it by shutting the doors and windows. Even persons who only walked along those streets complained of intolerable fetor, which, upon inquiry, was constantly traced to the putrid coffee."

It appears probable that this "putrid coffee" was indeed the nidus in which the deadly exotic germ first developed which gave rise to this fatal epidemic. Whether the coffee was infected at the port of shipment, or whether it was transported in an infected vessel, we cannot now determine; but that the outbreak of yellow fever in Philadelphia was due to the fact that the coffee was imported from a region where yellow fever was prevailing, or in an infected ship, rather than to the fact that it was putrid, cannot be doubted, in view of the subsequent history of yellow-fever epidemics in the United States.

As usual, the early cases were not recognized as yellow fever. Dr. Rush says: "The report of a malignant and fatal fever being in town spread in every direction, but it did not gain universal credit. Some of those physicians who had not seen patients in it denied that any such fever existed, and asserted (though its mortality was not denied) that it was nothing but the common annual remittent of the city. Many of the citizens joined the physicians in endeavoring to discredit the account I had given of this fever, and, for a while, it was treated with ridicule or contempt. Indignation in some instances was exerted against me." History has repeated itself, in this particular, many times in subsequent epidemics. The early cases, even in cities like New Orleans, where the physicians are well acquainted with the disease are frequently called by some other name—"bilious fever," "putrid fever," "remittent fever," etc.—and the physician who first ventures to name the prevailing disease "yellow fever" is treated with ridicule or with indignation.

It was not until the middle of August that a rapid succession of fatal cases convinced the physicians of the city that the dread West India pestilence was again present in Philadelphia.

The presence of the disease was officially recognized on the 22d of August, when the Mayor of the city gave orders for the cleansing of streets and general purification of the city. The disease continued to extend until early in October, when it reached its height. It did not cease entirely until about the 8th of November. During this short season of prevalence it caused an enormous mortality, distributed as follows: "August, 325; September, 1,442; October, 1,975; November, 118" (La Roche).

The population of the city at this time is estimated to have been a little more than 40,000, which gives a mortality of ten per cent. of the total population (total mortality 4,040). As more than 12,000 of the inhabitants fled from the city, the proportion of those who were attacked is very great. La Roche estimates the total number of cases at 11,000.

1797.—The epidemic of this year in the city of Philadelphia was less extended and less fatal. The whole number of deaths is estimated to have been about 1,300. The disease, as usual, commenced in the vicinity of the wharves about the end of July. Unsanitary conditions, described by physicians who were witnesses of the epidemic, furnished the favorable local conditions for the extension of the germ, which, according to a report of the College of Physicians of Philadelphia made in response to a request from the Governor, was imported by two vessels, one from Havana and the other from Port au Prince. In this report the College of Physicians, contrary to the prevailing popular opinion, and that of many prominent physicians, took the ground that the insanitary local conditions were simply secondary or accessory causes, and recommended "a more stringent system of quarantine regulations, as the most effectual means of preventing the recurrence of the disease" (La Roche).

1798.—The epidemic of 1797 was followed the next year by a still greater one, which was not confined to the city of Philadelphia alone. The disease prevailed also in Boston (mortality 200), in Portsmouth, N. H. (mortality 100), in Newport, R. I. (mortality 21), in New London, Conn. (mortality 81), in New York (mortality 2,080), in Wilmington, Del. (mortality 250), and in Charleston, S. C. The mortality in Philadelphia was 3,645, distributed as follows: August, 626; September, 2,004; October, 956; November (from the 1st to the 5th), 59. The mortality, in proportion to the number of cases, in the city of Philadelphia was excessive, being, according to La Roche, about as 1 to 1.27 of those attacked, or nearly eighty per cent. This is accounted for partly by the fact that the better classes of the community left the city as soon as possible after the outbreak of the disease, and the cases which occurred were consequently among the poorer classes who inhabited the worst portions of the city. The prevailing ideas as to the treatment of fevers by depleting measures were doubtless responsible in some degree for the excessive mortality. "The College of Physicians, faithful to the theory so long entertained by it in relation to the origin of the disease, assigned to the epidemic this year, as it had done to those of preceding seasons, a foreign origin" (La Roche).

1802.—An epidemic of smaller proportions prevailed in the year 1802, causing a mortality in Boston of 60, in Philadelphia of 307, in Wilmington of 86, in Charleston of 96. The disease also prevailed extensively in Baltimore, but no record of mortality is given. The prevalence of the disease at the seaports mentioned, especially before the days of railroad communication, is not to be ascribed to an extension from one to the others, or to "an epidemic constitution of the atmosphere," but is doubtless accounted for, for the most part, as a result of independent importation from the usual source of the disease—the West Indies. Thus we find that in 1802, while Boston and Philadelphia suffered epidemics, New York, lying between the two infected points, was free from the disease (two cases only are reported).

1853.—Passing over the minor epidemics, for the most part limited to a single city, or by coincidence [illegible] to two or more distant seaports, we come to the epidemic of 1853, which extended through portions of the States of Florida, Alabama, Louisiana, Mississippi, Arkansas, and Texas. The towns which suffered in *Florida* were Pensacola, Milton, and Tampa. In *Alabama* Mobile (mortality 1,191), Cahawba, Citronelle, Demopolis, Fulton, Hollywood, Montgomery (mortality 55), Selma (mortality 32), were the principal towns visited by the scourge. In *Louisiana* the disease prevailed at New Orleans, with a mortality of 7,970, at Alexandria, Algiers, Bay St. Louis, Baton Rouge, Centreville, Clinton, Donaldsonville, Franklin, Opelousas, Pattersonville, Plaquemine, Shreveport, Thibodeaux, Trenton, Washington, and various smaller places. In *Mississippi*, Biloxi, Brandon, Clinton, Grand Gulf, Greenwood, Jackson, Natchez, Pascagoula, Pass Christian, Port Gibson, Washington, Woodville, Yazoo. In *Arkansas* Columbia, Grand Lake, Napoleon. In *Texas* Brownsville, Cypress City, Galveston, Hockley, Houston, Indianola, Liverpool, Richmond, Sabine.

1867.—The epidemic of this year was widely extended in the State of Texas. The first recognized case in New Orleans occurred on the 10th of June. The total mortality in this city was 3,093. Other towns visited in Louisiana were New Iberia and Opelousas. In *Texas* the first cases occurred at Galveston on the 25th of June, and the total mortality in this city was 1,150. Other places visited by the epidemic were Alleyton, Anderson, Austin, Bastrop, Brenham, Calvert (mortality 250), Chapel Hill (mortality 128), Corpus Christi, Danville, Goliad, Hempstead (mortality 151), Huntsville (mortality 150), Independence, Indianola (mortality 80), La Grange (mortality 200), Liberty, Millican, Navasota (mortality 154), Oldtown, Port Lavaca, Rio Grande City (mortality 150), Victoria (mortality 200).

1873.—Florida, Alabama, Mississippi, Louisiana, and Texas again suffered from an epidemic of yellow fever in the year 1873. At Pensacola, Fla., the first recorded case occurred August 6th, and the total mortality was 61. In *Alabama* the disease appeared at Mobile on the 21st of August, and the total mortality was but 27. Montgomery suffered a loss of 102. In *Louisiana* the mortality in the city of New Orleans was only 225, although the epidemic had its origin in this city. It was imported by the Spanish bark Valparaiso, which sailed from Havana, June 15th, in ballast, arrived at the New Orleans quarantine station June 24th, was detained two days, and came to the city June 26th. The first case was the mate of this vessel, who was taken sick on board July 4th, while she was lying at the wharf. But for the sickness and death of the mate of the Valparaiso, the origin of this epidemic would have remained obscure, and the believers in the local origin of the disease would have had a strong case, for no other cases of the disease occurred on the Valparaiso. This is explained by the fact that the crew consisted of acclimated Spaniards, and the mate seems to have been the only susceptible person on board who could serve as a test of the infection of the vessel at her port of departure. From New Orleans the disease was carried to Memphis by the river steamer Bee. It caused a mortality in this city of 2,000. River steamers from New Orleans also carried the disease to Shreveport, La., where the mortality was 759. From Shreveport a refugee fled to the town of Calvert, Tex., where he was taken sick and died; an epidemic followed with a total mortality of 125. The disease was also introduced by refugees to the town of Marshall, Tex., where 36 deaths occurred. The epidemic of this year at Pensacola, Fla., was due to an independent importation by the ship Golden Dream, and Montgomery, Ala., became infected through refugees from Pensacola.

1878. The last and most extended epidemic of yellow fever in the United States is that of 1878, which invaded

132 towns, and caused a mortality of 15,934, out of a total number of cases exceeding 74,000.

The origin of this epidemic was traced by the president of the Louisiana State Board of Health (Chopin) to the steamer Emily B. Souder, which arrived from Havana May 23d, and was moored at the foot of Calliope Street, New Orleans. Dr. Chopin says: "The first cases of yellow fever in New Orleans in 1878 were, undoubtedly, two of the officers of the above steamship, namely, Clarke, the purser, and Elliott, one of the engineers. Infected centres were developed in the vicinity of the houses in which these men were sick, but not until after an interval of several weeks, during which, probably owing to unfavorable conditions as to temperature, the 'germs' remained dormant, or at least multiplied so slowly as not to cause an outbreak of the disease."

Fortunately, this great epidemic has been carefully studied by a "Board of Experts, authorized by Congress," and we have a very complete history of its geographical extension, and of the deadly results which marked its course. The following data are from the report of this "Board of Experts."

Louisiana.—New Orleans mortality, 4,600; Allemands Station, 17; Baton Rouge, 193; Bayou Cypre, 7; Berwick City, 7; Buras Settlement, 3; Clinton, 15; Delhi, 34; Delta, 47; Donaldsonville, 71; Gretna, 53; Hammond, 5; Henderson, 18; Houma, 6; Jesuits Bend, 2; Labadieville, 24; La Fourche, 26; Lagonda and other plantations, 42; Morgan City, 100; Napoleonville, 8; Paincourtville, 15; Pattersonville, 47; Pilot Town, 17; Plaquemine, 125; Ponchatoula, 3; Port Eads, 13; Port Hudson, 11; St. Bernard Parish, 7; Tangipahoa, 50; Thibodeaux, 65; Teche Country plantations, 81.

Tennessee.—Bartlett, 9; Brownsville, 212; Chattanooga, 135; Colliersville, 56; Germantown, 35; Grand Junction, 74; La Grange, 37; Martin, 40; Mason, 24; Memphis, 5,000; Milan, 12; Moscow, 35; Nashville, 6 (all imported cases); Paris and suburbs, 23; Somerville, 57; White Station, 50; Williston, 11.

Alabama.—Decatur, 44; Florence, 50; Huntsville, 12; Leighton, 1; Mobile, 90; Stevenson, 6; Town Creek, 4; Tuscaloosa, 2; Tuscumbia, 31.

Mississippi.—Bay St. Louis, 82; Benton, 1; Biloxi, 45; Bolton, 34; Bovina, 7; Brown's plantations, 4; Canton, 180; Vicinity of Canton, 47; Dry Grove, 41; Friar's Point, 7; Gainsville, 2; Goodrich Landing, 12; Greenville, 301; Grenada and vicinity, 343; Horn Lake, 2; Handsboro, 16; Hernando, 80; Holly Springs, 309; Iuka, 3; Jackson, 86; Lake, 86; Lebanon, 10; Livingston, 10; McComb City, 21; Meridian, 91; Mississippi City, 15; Ocean Springs, 30; Osyka, 45; Pass Christian, 23; Pearlington, 24; Port Gibson, 115; Country about Port Gibson, 150; Refuge Landing, 11; Rocky Springs, 38; Scranton, 20; Stoneville, 15; Spring Hill, 6; Sulphur Springs, 5; Senatobia, 7; Terrene, 4; Vicksburg, 872; Vicinity of Vicksburg, 300; Water Valley, 64; Winona, 3; Winterville and vicinity, 26; Yazoo City, 9.

Kentucky.—Bowling Green, 19; Hickman, 153; Louisville, 64 (mostly refugees).

Ohio.—Cincinnati, 17 (refugees); Gallipolis, 18.

Illinois.—Cairo, 51.

Missouri.—St. Louis, 16; Quarantine (near St. Louis), 42.

ETIOLOGY.—The preceding historical record shows that in the United States, as elsewhere, yellow fever has prevailed more frequently in seaports than in inland towns, and that, when epidemics prevail in the interior, their origin can commonly be traced to the nearest seaport, or to intermediate towns in communication with it. Towns upon or near the coast which have no commerce are no more subject to invasion by yellow fever than are interior towns, unless it be by reason of their proximity to a seaport. Moreover, the frequency of epidemics in our southern seaports, before the era of efficient quarantine administration, bears a direct ratio to their commercial importance, and especially to their commercial intercourse with Havana or other endemic foci of the disease. Thus New Orleans suffered epidemics of greater or less magnitude in 48 out of the first 60 years of the present century. During the same period (1800–1860) Charleston suffered 28 epidemics; Mobile, 22; Pensacola, 17; Savannah, 9; Galveston, 7. That local conditions are favorable for the development of an epidemic at many of our interior towns, especially those located on great rivers, near the sea-level, in the Southern States, is amply proved by the epidemic of 1878. That yellow fever does not occur at these towns, except as a result of the introduction of infected persons or articles, is beyond question. So, too, in sea-port cities there is no reason for believing that any radical change has occurred in local conditions during the past twenty-eight years; yet during this time New Orleans has only suffered 6 epidemics, while during a corresponding period (twenty-eight years) prior to 1860 there were twenty-two years of epidemic prevalence of the disease. A similar comparison for Charleston shows fourteen years of epidemic prevalence prior to 1860, and only one since.

Up to the year 1860 there were many advocates of the *local origin* of the disease in these seaports, and the disease was considered endemic by many physicians, both in Charleston and in New Orleans. But to-day scarcely anyone questions the fact that the disease, notwithstanding its frequent prevalence, was due to importation, and that it is nowhere endemic within the boundaries of the United States. It is not improbable, however, that in certain instances the "germs" of the disease have survived the winter season, and that "sporadic cases" and epidemics have occurred as a result of importation, dating back one or more years. It is claimed that the epidemic of 1879, in the city of Memphis, was not due to a new importation, but resulted from the hibernation of germs in houses infected in 1878. Dr. Thornton, President of the Memphis Board of Health during these epidemics, says: "The disease appeared in houses in the suburbs, which were infected last year;" and states further that the first case reported to the health office occurred on the 8th of July, at which date the disease was not prevailing in any part of the United States. In New Orleans, in epidemic years, cases have sometimes continued to occur during the greater part of the month of December, and in Tampa and Plant City, Florida, where yellow fever was epidemic in the summer of 1887, cases are said to have occurred at intervals throughout the winter. Admitting, then, the probability that the recurrence of the disease in our southern seaports has sometimes been due to the preservation of infectious material in an active state throughout the winter, we must insist, nevertheless, that there is no satisfactory evidence of the *de novo* origin of the disease from local causes, either in our own country or elsewhere; and that, wherever its original habitat may have been, the prevalence of the disease within the period to which our authentic historical records relate has been due to the importation of cases, or of infected material, from a previously infected place. In other words, the disease is due to a specific infectious agent.

As to the nature of the *specific cause* of the disease there can scarcely be two opinions. The present state of science justifies the belief that it is a living micro-organism; and facts relating to the origin and extension of epidemics show that, as in cholera and in typhoid fever, this micro-organism is capable of development outside of the human body under favorable conditions, which will be discussed hereafter. Unfortunately, the present state of science does not enable us to give an account of the exact nature of the deadly *microbe* which we assume to be the cause of the disease under consideration. We know to-day the morphological and physiological characters and the habitat within the body of an infected individual of the specific cause of cholera, of typhoid fever, and of relapsing fever, but the researches made up to the present time have failed to demonstrate the "germ" of yellow fever.

In 1879 the writer went to Havana, as a member of a commission appointed by the National Board of Health, for the investigation of questions relating to the etiology of yellow fever. One of the main objects in view in the appointment of this commission was the discovery, if possible, of the specific cause of the disease.

The commission was fully equipped with the best microscopical apparatus and with whatever else seemed necessary to promote the accomplishment of the object in view.

Examination of the Blood for Micro-organisms.—The prevailing opinion with reference to the pathology of yellow fever, and the fact that in anthrax and in relapsing fever the specific micro-organism is found in the blood, led to the assumption that the same might be true in yellow fever. Accordingly, the writer devoted himself especially to the examination of this fluid. The result was entirely negative, and is stated as follows in the Preliminary Report of the Commission:

"The patients from whom specimens of blood were obtained were mostly soldiers in the military hospital of San Ambrosio. Ninety-eight specimens, from forty-one unselected cases of yellow fever, were carefully studied, and one hundred and two photographic negatives were made which show satisfactorily everything demonstrable by the microscope. These photographs were mostly made with a magnifying power of 1,450 diameters, obtained by the use of Zeiss' 1/18 homogeneous oil-immersion objective and Tolles' amplifier. Probably no better lens than the Zeiss' homogeneous oil-immersion could have been obtained for this work, and it is doubtful whether any objective has ever been made capable of showing more than is revealed by this magnificent lens. With the power used, organisms much smaller than those described as existing in the blood of anthrax or of relapsing fever would be clearly defined.

"If there is any micro-organism in the blood of yellow fever, demonstrable by the highest powers of the microscope as at present perfected, the photo-micrographs taken in Havana should show it. *No such organism is shown in any preparation photographed immediately after collection.* But in certain specimens kept under observation in culture-cells, bacilli (?) fungi and spherical bacteria made their appearance after an interval of one to seven days. The appearance of these organisms was, however, exceptional, and in several specimens taken from the same individual at the same time it occurred that in one or two a certain fungus made its appearance and in others it did not. This fact shows that the method employed cannot be depended upon for the exclusion of atmospheric germs, but does not affect the value of the result in the considerable number of instances in which no development of organisms occurred in culture-cells in which blood, in a moist state, was kept under daily observation for a week or more."

The method employed seemed the only one practicable for obtaining blood from a large number of individuals without inflicting unwarrantable pain and disturbance upon the sick. It was as follows: "One of the patient's fingers was carefully washed with a wet towel (wet sometimes with alcohol and at others with water), and a puncture was made just back of the nail with a small triangular pointed lancet. As quickly as possible a number of thin glass covers were applied to the drop of blood which flowed, and these were then inverted over shallow cells in clean glass slips, being attached usually by a circle of white zinc cement."

The method as above detailed was imperfect, on account of the fact that the finger from which blood was obtained was not properly sterilized; and if positive results had been reported the criticism would have made it unsafe to draw the conclusion that micro-organisms developed in these culture-cells had their origin from others of the same sort present in the blood of the individual. Subsequent researches have demonstrated the fact that, even when the finger is carefully washed with a 1 to 1,000 solution of mercuric chloride, sterilization of the surface is not always secured. Thus during the past year, in Rio Janeiro and in Vera Cruz, I have repeated my culture experiments with blood drawn from the fingers of patients in various stages of the disease. But in these more recent experiments I have carefully washed the finger, first with soap and water, then with a 1 to 1,000 solution of mercuric chloride, and finally with alcohol to remove the bichloride of mercury. The blood in these experiments was introduced with proper precautions into various culture-media in test-tubes—nutrient flesh-peptone gelatin, solidified blood-serum, peptonized bouillon. Out of a total of thirty-four test-tubes inoculated in this way with blood from five typical cases of the disease, twenty-eight remained sterile, while various organisms appeared in six.

If the same micro-organism had presented itself in the six exceptional tubes, one might suppose that it came from the blood of the patients, and that failure to develop in the others was due to the fact that it was not constantly present in the circulating fluid, as is the case in typhoid fever, for example, in which disease the bacilli are found in the spleen, the lymphatic glands, the liver, and the kidney, but are only exceptionally present in the blood of the general circulation. But in this series the six exceptional tubes contained different micro-organisms, and the inference is that they were present as a result of accidental contamination of the blood drawn, either by micro-organisms on the surface of the finger not destroyed by the disinfecting agents, or by floating atmospheric organisms attached, perhaps, to epithelial cells or to minute particles of dust, etc., which are extremely abundant in the atmosphere of hospital wards.

It would not be safe, from these experiments with blood drawn from the finger alone, to infer that there is not present in the blood or tissues a specific micro-organism in this disease. Evidently, the solution of this question requires a careful study of stained sections of the various organs, and especially of those which show the most constant pathological changes—liver and kidney.

Examination of the Tissues for Micro-organisms.—In the infectious diseases which have been proved to be due to the presence of a parasitic micro-organism in the blood, this organism may be demonstrated in properly stained thin sections of the tissues. In such sections we frequently obtain cross-sections of small blood-vessels in which the blood corpuscles are *in situ*, and in which a stained micro-organism, if present, would be very apparent. We also have a very satisfactory view of the contents of the capillary vessels of the various organs, as well as of their cellular histological elements. Pathologists therefore look upon a careful research by the methods which have been perfected with this object in view, as of prime importance in any attempt to prove whether a given infectious disease depends upon the presence in the blood of a specific micro-organism. The Havana Commission adopted this method, and numerous sections were made by Dr. Guiteras, a member of the Commission. A careful study of these gave an entirely negative result so far as the presence of micro-organisms is concerned. But inasmuch as new and valuable methods of staining have been devised since the date of the research referred to, the writer has considered it important that further investigations in this direction should be made, and during the past three years he has made a very large number of preparations, chiefly from the liver, the kidney, the stomach, and the intestine. These have been stained in various ways and have been carefully studied. The material employed in this research has been obtained from Havana, and the autopsies there were all made within a short time after death—one to three hours. The sections were stained by various methods, but chiefly with Löffler's alkaline solution of methylene blue, by Gram's method, and by the method of Weigert.

The result of this research has been negative so far as the general presence of any particular micro-organism is concerned. But in one case I found in the kidney a minute bacillus which apparently invaded by preference the glomeruli. It was not found in the capillaries generally, but a certain number of foci were seen in the sections, as shown in Fig. 5067. These involved a portion of a glomerulus as seen in the figure, or in certain instances a whole glomerulus and the tissues immediately surrounding it. The appearance was such as one would expect to see in a case in which solitary bacilli, carried in the first place by the blood-current, had ef fected a lodgement and established a centre of infection in tissues already, perhaps, necrotic. The exceptional appearance of this bacillus (in a single case) justifies the opinion that it is some common saprophyte which had effected a lodgement in the kidney, probably during the last hours of life, when the vital resistance of the tissues was slight; or when, possibly as a result of blood stasis in the organ, local necrosis had already occurred at certain points before death. It is quite probable that during the last hours of life, in this and in other diseases, a certain number of micro-organisms from the intestine succeed in passing through the enfeebled tissues to the interior of the capillaries, and are thus distributed throughout the body, ready to produce those putrefactive changes which occur so promptly in hot climates. This view is supported by the results of my recent culture experiments with material obtained from the interior of the liver and kidney as soon as possible after death, which will be given hereafter. I have, in one instance, encountered a group of slender bacilli in the liver, and, in the course of my extended observations, seen two or three groups of micrococci, or what appeared to be micrococci; but I attach no importance to these observations. Evidently, any organism concerned in the etiology of an infectious disease should be found, not occasionally and in certain cases only, but if seen at all by the staining methods adopted, it should be found distributed through the organs involved in sufficient numbers to leave no doubt as to its presence, not as an accident, but as a general and constant thing in all cases of the disease under investigation.

Extracts from an unpublished report to the President of the United States, submitted June 22, 1888:

"Having heretofore failed to find any specific micro-organism in the blood and tissues of yellow fever cases by the methods detailed in my previous report, I desired to test the reliability of this negative result by inoculating various culture-media with material obtained from the interior of the organs which show the principal pathological changes in this disease—liver and kidney—and with blood drawn from the cavities of the heart, and urine obtained through the walls of the bladder, at the earliest possible moment after death. . . .

"In four cases, at the time of making the autopsy, I have taken pieces of liver and kidney of considerable size, and have enveloped them in many folds of muslin, or of tissue paper, saturated with a one per cent. solution of mercuric chloride. These pieces were kept in the laboratory for forty-eight hours, and at the end of this time the antiseptic wrapping was removed and material obtained from the interior, by making an incision with a sterilized knife. In every case I obtained positive results from my cultures made from this material, although the same liver and kidney had given me negative results in cultures made immediately after death. These pieces of liver and kidney were perfectly antiseptic so far as the exterior was concerned, but the effect of the bichloride solution was quite superficial, as could be seen by the whitish color of that portion of the tissue which had been acted upon, and in which, no doubt, the albuminous material had served to neutralize the mercuric solution, and to prevent its further penetration. The interior of the pieces, on the other hand, preserved its fresh appearance, and on staining a little of this fresh-looking material it was found to contain numerous and various micro-organisms."

This must be taken as evidence that, notwithstanding the negative results of my cultures from the same material made immediately after death, micro-organisms were present in the tissues, but in such limited numbers that, until time was given for their multiplication, they were not likely to be discovered either by the microscopical examination of stained sections, or by the method of cultivation.

Results of Culture Experiments.—The general results of my culture experiments are as follows:

"*Blood.*—In eight of the ten cases, my cultures from blood drawn from the heart have remained sterile. This result fully confirms the conclusion heretofore reached by the method of direct examination and cultivation of blood drawn from the finger of patients during life. In the two exceptional cases a few colonies appeared, in one my bacillus *a*, to be described hereafter; in the other bacillus *a* and another bacillus resembling it in its morphology, but shown to be different by the appearance of its colonies in gelatine."

"*Urine.*—In seven cases my cultures from urine drawn through the walls of the bladder have remained sterile; in three cases micro-organisms were present." . . .

"*Kidney.*—In six of the ten cases I have obtained micro-organisms from the kidney, and in four cases my cultures remained sterile." . . .

"*Liver.*—In seven cases my cultures from the liver have remained sterile, and in three they have given me colonies."

I may say here, that in those cases in which my cultures, in Esmarch tubes, from the blood, urine, kidney, and liver, gave a positive result, several different micro-organisms were encountered, the most common form being the bacillus which I have designated with the letter *a*, and which appears to be identical with the bacillus found by Emmerich in cholera cadavers, at Naples, in 1884. I have not yet determined definitely the question of identity, however, and must reserve my opinion until I have an opportunity of making a careful comparison of the micro-organisms from the two sources. If my bacillus *a* is indeed identical with the bacillus of Emmerich, it must be excluded as a specific etiological agent in yellow fever. Considering, however, the close resemblance of the spirillum of Asiatic cholera with the spirillum of Finkler and Prior, and that of Deneke (cheese spirillum), it is evident that this question cannot be settled upon morphological grounds alone. Its occasional presence in the tissues cannot alone be accorded any great weight, but considered in connection with the fact that, in my cultures from the contents of the stomach and intestine, I found it to be the most abundant organism, and present in all of the cases, it becomes a matter of great interest to know whether it is identical with any known micro-organism found in the same situation in health or in other diseases. I am called upon to write this paper before this question is definitely settled, but I may say now that I strongly suspect that my bacillus *a* is identical with the bacillus of Emmerich, which for a time he supposed to be the specific cause of cholera. I may remark here, that in my cultures from the contents of the stomach and intestine of ten cases of yellow fever, I have not encountered any micro-organism resembling the cholera spirillum of Koch.

In none of my cultures from the blood and tissues have I encountered a micro-organism corresponding with the *cryptococcus xanthogenicus* of Dr. Domingos Freire, of Brazil. The conclusions reached as a result of the investigations recently made in Havana, are formulated in my report as follows:

"The specific cause of yellow fever has not yet been demonstrated.

"It is demonstrated that micro-organisms capable of development in the culture-media usually employed by bacteriologists, are only found in the blood and tissues of yellow fever cadavers in exceptional cases, when cultures are made very soon after death."

Can we accept the evidence presented as conclusive as to the absence of any specific micro-organism in the blood and tissues? It may be supposed that the "germ" we are in search of is ultra-microscopic, or that it will not grow in the culture-media which have been employed. I would reply to the first hypothesis, that an ultra-microscopic bacterium capable of growth in our culture-media would form colonies visible to the naked eye, and that in all the experience of bacteriologists no such ultra-microscopic micro-organism has been encountered. As to the hypothesis that a germ is present which will not grow in our culture-media, this is opposed by the fact that no micro-organism has been demonstrated to be constantly present, by the extended researches made by myself and others, in which thin sections of the various organs have been examined, after having been stained by those methods which are the most successful in such researches. Moreover, all of the evidence relating to the epidemic extension of yellow fever points to a micro-organism capable of rapid development in filth-laden outside of the human body, as is the case with the spirillum of cholera, and the bacillus of typhoid fever; and such a micro-organism ought not to be difficult to cultivate in artificial media. Unless, indeed, it should prove to be an anaërobic organism, in which case special methods of cultivation, not yet employed in these researches, would be required.

Finally, there is experimental evidence of another kind to show that the specific infectious agent in yellow fever is not present in the blood. The direct experiment has been made of injecting blood drawn from the median vein of a yellow fever patient into an unacclimated individual. This experiment was made, at my request, in Vera Cruz, by Dr. Daniel Ruiz, director of the civil hospital in that city, in September, 1887. The entire contents of a hypodermatic syringe, just filled from the median vein of a patient in the eighth day of the disease, was injected subcutaneously in the deltoid region of an adult negro recently from the interior. In this case the criticism may be made that the febrile stage had passed, and I was extremely anxious to see the experiment repeated with blood from an earlier period. No opportunity, however, offered itself. But Dr. Ruiz states that he had previously (1885) made the experiment in two cases, with an entirely negative result.

The failure thus far to find a specific micro-organism in the blood leads to the supposition that it may be in the alimentary canal, and that, as in cholera, the phenomena of the disease are due to the absorption of a toxic substance formed in the intestine during the active growth of the yellow-fever microbe. In cholera the clinical features of the disease naturally called attention to the alimentary canal as the habitat of the pathogenic micro-organism; and Dr. Koch, having perfected his plate method for the isolation of such organisms, experienced no difficulty in establishing the fact that his "comma bacillus" is uniformly present, and often "almost in a pure culture," in the contents of the intestine of those recently dead from cholera.

In yellow fever, on the other hand, prevailing opinions as to the nature of the disease, and the absence of clinical or pathological features pointing especially to the alimentary canal, have possibly led investigators to neglect this in their bacteriological investigations. In my recent researches in Havana I have, however, given special attention to the micro-organisms found in the stomach and intestine.

As was to have been expected, I have encountered a variety of micro-organisms in my cultures from material obtained post mortem from the alimentary canal. Some of these are common forms which can be obtained by the same method from the stomach and intestine of persons in health, or by those dying from other diseases. The organism which has particularly attracted my attention is my bacillus x, referred to above as occasionally found in my cultures from the liver and kidney.

This bacillus was present in the cultures from material obtained from the intestine in every case (ten), and it was shown to be the micro-organism most abundantly present in the very numerous colonies, compared with all other bacteria present, which developed in Esmarch tubes inoculated with such material. I cannot attempt at present to give a complete account of the various micro-organisms which I have encountered in my cultures. More time will be required to determine their characters with precision.

Bacillus x is from one and a half to four times as long as it is broad, and has a diameter of about one-half of a micromillimetre; the dimensions vary considerably, however, in different cultures, and even in the same culture. Under certain circumstances the ends of the rods are seen to be more deeply stained than the central portion. This appearance is not, however, constant, and seems to depend upon the age of the culture, and upon the time during which it is subjected to the action of the staining reagent. The ends of the rods are more or less rounded, and they are often associated in pairs.

Young colonies in gelatine (Esmarch tubes) have a pale straw-color, which afterward becomes pale brown; they are spherical and homogeneous in interior. Colonies which have come to the surface often present the appearance of a rosette, or of a flower with its petals expanded, as in the daisy. From cultures in which lobate colonies and rosettes were the prevailing form, I have obtained, in a second series of Esmarch tubes made from a single rosette, colonies which were not lobate, and which did not form rosettes (spherical, straw-colored, homogeneous colonies); and in these cultures superficial colonies have the appearance of a fragment of broken glass; later they present an irregular margin, and a more or less wrinkled appearance of the interior. Later these colonies have an irregular, vitreous-looking margin, and the interior has a brown color, more or less intense. These are the characters given by Flügge of gelatine colonies of the bacillus of Emmerich, discovered in cholera cadavers at Naples in 1884; and the morphology of this bacillus, as given by Flügge, resembles that of the bacillus which I have found as the prevalent form present in the intestine of yellow-fever cadavers in Havana. Weisser, who has made an extended study of the bacillus of Emmerich, finds that it is present in certain cases in the fæces of healthy individuals, and in the intestinal contents of those dying from other diseases than cholera, and that, therefore, the claim of Emmerich that it is the specific microbe of cholera was unfounded. He also showed that a micro-organism very similar to it, and which can only be differentiated by the appearance of its colonies in certain culture-media, is found quite constantly in the large intestine of healthy persons. The history of the spirillum of Asiatic cholera—"comma bacillus" of Koch—and of other spirilla which closely resemble it—Finkler-Prior spirillum, Deneke's cheese spirillum—shows that it is not safe to assume identity upon morphological grounds, and that even in their colonies in gelatine and in their mode of development, micro-organisms which are specifically different may resemble each other very closely. Since the above was written I have made an extended series of experiments with reference to this bacillus x, and believe it to be identical with the Naples bacillus of Emmerich, and with the *Bacterium coli commune* of Escherich.

The material which has served for my cultures from the intestine has usually been obtained from the ileum, where the characteristic black matter is the most abundant—sometimes as a fluid filling the lumen of the intestine, but more frequently as a viscid material, from admixture with mucus which adheres to its walls.

I have also made numerous cultures from vomited material obtained at the bedside of patients—both black vomit, "coffee-ground vomit," and the colorless fluid ejected in many cases during the first days of the attack. These cultures have given very various results. My bacillus x has been present in some cases; in certain cases a torula has been the most abundant organism present. In one case I obtained a short bacillus in chains resembling that of Babes. In one case, in which the vomited matter was alkaline, the cultures contained a great variety of bacilli and micrococci. On the other hand, cultures from several specimens of highly acid black vomit remained sterile.

The microscopical examination of stained specimens of the material from the intestine, and particularly from the stomach, shows the presence of a variety of micro-organisms, some of which did not appear in my cultures. Thus the various micro-organisms of the mouth, the entrance of which may be recognized by the fact that they are attached to the epithelial cells from the buccal mucous membrane, do not as a rule develop in our culture-media under ordinary conditions.

If by exclusion we should finally ascertain that there is no specific micro-organism in the body of the victims of yellow fever, we have left the supposition, already entertained by some authors, that the attack is due to the toxic action of a volatile chemical poison produced in infected localities external to the human body. In this case we might suppose that a specific micro-organism, capable of developing in a suitable nidus, under certain conditions as to temperature, etc., produces a volatile ptomaine which, being respired by a susceptible individual, gives rise to the morbid phenomena which characterize the disease. Certain facts favor this view, but others seem to make it untenable. On the one hand, it is well known that the incubation period is often very brief, and that the attack may occur within twenty-four hours after exposure in an infected locality. We have also ample evidence that the disease may be contracted by respiring an infected atmosphere. Indeed, I know of no satisfactory evidence that it is ever contracted in any other way, *i.e.*, by the use of infected water or food. Moreover, it has frequently been observed that persons sleeping near the ground are more subject to attack than those occupying apartments elevated some distance above the ground. During the epidemic prevalence of the disease, it has several times been noted that persons living within an enclosure surrounded by a high wall, as prisoners in jail, escape attack, although their food and water is from the same source as that used by individuals outside of the enclosure. In infected cities, like Havana, which have a common water-supply, there is no evidence that susceptible strangers contract the disease by drinking this water, or through contaminated articles of food. But in such cities there are localities which are the favorite resort of the disease during its epidemic prevalence, and in which it remains, to give evidence of its endemic presence throughout the winter months. It is by visiting these infected localities that strangers, as a rule, contract yellow fever in Havana, Rio Janeiro, and other seaports in which it prevails annually. In this respect yellow fever seems to differ essentially from cholera and typhoid fever, which are propagated largely through the use of contaminated drinking-water. This seems to be opposed to the view that, as in the diseases mentioned, yellow fever is due to a micro-organism which multiplies in the intestine, for in this case we should expect to encounter local outbreaks directly traceable to the contamination of a common water-supply. That this never occurs we cannot assert, but, as stated, I know of no evidence in support of the view that the disease may be transmitted in this way. There are numerous instances, however, of attacks occurring after a brief visit to an infected locality, and presumably as a result of breathing an infected atmosphere. These facts give some support to the view that the attack is a direct result of intoxication by a volatile chemical poison, as maintained by Corré and others. But, on the other hand, the period of incubation is often prolonged to three or four days after removal from the infected locality, and, it is difficult to account for this delay in the development of the morbid phenomena upon the theory under consideration. Then, too, there is ample evidence to show that yellow-fever patients establish new centres of infection when the external local conditions are favorable, and that the bedding used by them, even after a long interval, contains the infectious agent—as proved by the fact that susceptible persons who handle it may contract the disease directly from such infected bedding, or that it may serve for the development of new foci of infection in distant localities to which it has been transported. This fact again brings yellow fever into line with cholera, and gives support to the hypothesis that the specific infectious agent is present in or about the body of the sick.

The supposition that it multiplies upon the surface of the body and produces a poisonous ptomaïne, which is absorbed through the skin, would account for the infection of the bedding; but there is nothing to support this supposition in our knowledge of other infectious diseases, and it seems to be untenable in view of the fact that the disease is not transmitted by personal contact. There is abundant evidence in support of this statement, which will be referred to hereafter.

The explanation that the bedding is infected by the alvine discharges of the sick does not appear as satisfactory as it is in cholera and typhoid fever, which diseases are characterized by frequent liquid discharges from the bowels. But in fatal cases of yellow fever a dark-colored fluid, similar to the "black vomit," is frequently discharged from the bowels, and the bedding is liable to be soiled with it as well as with the contents of the stomach, which in the later stages of the disease are often ejected with great force at a time when the patient is lethargic or quite unconscious.

MICRO-ORGANISMS which have been described as the specific cause of yellow fever:

Cryptococcus xanthogenicus of Dr. Domingos Freire, of Brazil. In his principal work, published in 1885, Dr. Freire gives the following account of his cryptococcus: "When we follow with care and attention the march of the development which characterizes the germs which produce yellow fever, we acquire a certainty that, commencing to present themselves under the form of little points almost imperceptible, they afterward gradually increase in diameter until they attain considerable dimensions; so that the little beings, which at the outset had the appearance of little grains of sand, not measuring more than 0.001 millimetre to 0.002 millimetre in diameter, arrive little by little to such a development that they reach the dimensions of 0.005, 0.007, 0.008 millimetre, and sometimes even more in certain conditions. When they have attained the adult age, these cells are broken at divers points, and discharge their contents, composed of spores already formed, mixed with a viscous substance of a yellow color, composed of a pigment and protoplasmic substance, and of the liquids elaborated by the cells."

In an address delivered in Paris in 1887, Dr. Freire repeats this account of the mode of development of his cryptococcus; he says: "Each adult cell is ruptured at one or several points, and allows to escape its contents, composed of germs which are to perpetuate the species, and two pigments—one yellow, destined to infiltrate the tissues, and to produce the icteric color which has given name to the malady; the other black, insoluble, and destined to be carried along the circulatory current, producing either capillary obstructions or blood stasis in the parenchyma of the organs."

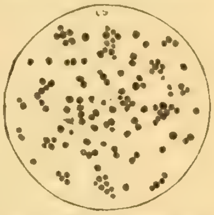

FIG. 4665.—Micrococcus of Freire. Culture brought from Paris in 1887, and presented to the writer as the microbe of yellow fever. Drawn from a preparation made in Dr. Freire's laboratory. × 1,000.

This account is entirely fanciful, and is evidently based upon erroneous observation and misinterpretation of what has been seen under the microscope, and to imperfect methods of research. No such micro-organism as Dr. Freire has described is known to bacteriologists, and certainly nothing of the kind is to be found in the blood and tissues of yellow-fever cases, as Dr. Freire asserts.

At the time of my visit to Brazil (1887), Dr. Freire, who had just returned from France, presented to me, as his yellow-fever germ, a liquefying staphylococcus. This had been isolated from his impure cultures in bouillon by a French bacteriologist, Dr. Paul Gibier. Like other micro-organisms of the same class, it multiplies only by binary division, and having cultivated it in various media, I can say with confidence it does not form a black or a yellow pigment, and consequently does not correspond with the *cryptococcus xanthogenicus* as previously described by Dr. Freire. Nor is it found in the blood and tissues of yellow-fever patients.

Peronospora lutea of Dr. Carmona y Valle. In Dr. Carmona's work, published in 1885, the following account is given of his yellow-fever microbe:

"Admitting but two phases in the development of the fungus which produces yellow fever, I shall recapitulate the succession of the phenomena which occur in order to fix them well in your memory.

"Let us take as point of departure the urine eliminated by yellow-fever patients. It contains, as you know, a great number of zoospores, or very small granulations endowed with proper movements, and which only measure a thousandth of a millimetre in diameter. These granulations unite in pairs, and (that is, later) they unite into a single one which grows gradually. This element appears and assumes a glistening yellow color by reflected light, and greenish and as glassy by refraction. Some of these appear, the dimensions of which are more considerable, attain sometimes 1/5 of a millimetre in diameter. They [illegible] in many cases, being [illegible] to dissolve tissue and in other compensatory processes to produce the cases under which we have observed. The spores of this organism penetrating into the animal economy, give birth in a proportion to the cryptococcus elements which appear a great number of [illegible] filled with cryptococci. When the [illegible] are examined the cryptococci are distributed throughout the structure."

At the time of my visit to Rio de Janeiro (1887) Dr. Carmona had modified his views as to the morphology of the yellow fever parasite. He had given up the spores and the (mycelial or filamentous) forms of the "cryptococcus" found in the urine, but believed that these conidiæ developed into rods—bacilli—and that these again produced the cryptococcus. He was kind enough to show me a stained preparation of the cryptococcus and of the bacilli, and to give me cultures of the same. The so-called cryptococcus were in fact micrococci, which do not differ in their morphology from those constantly found in urine which has undergone alkaline fermentation. Evidently Dr. Carmona's inference, that the micrococcus and the bacillus which developed in his cultures from the same source represent different phases in the development of the same micro-organism, is a mistake.

My recent researches in Havana show that, as a rule, culture-media inoculated with urine drawn through the walls of the bladder, immediately after death, remain sterile. In seven cases out of ten this was the result, while in three cases micro-organisms developed. In one my bacillus x associated with at least two other bacilli; in one a liquefying bacillus which forms a green pigment; in one a common putrefactive bacillus.

The Bacillus of Lacerda and Babes.—In 1883 Dr. Lacerda, of Rio Janeiro, having discovered what he believed to be micro-organisms in the liver and kidney of yellow-fever cases, sent some of the material to Paris, to Dr. Babes. This bacteriologist distinguished the presence of a micrococcus (in the material), and described it as follows:

"The filaments appear solid and homogeneous with a magnification of 600 diameters, but with a high power (1/18 hom. im. or No. 12 of Vérick, which corresponds with the 1/12 of Zeiss) one can assure himself that these filaments are composed of elliptical grains, almost cylindrical, arranged in pairs, forming little groups in which they are united by an intermediary pale substance. The filaments are thus composed of diplococci or, if one wishes, of very short rods with rounded angles."

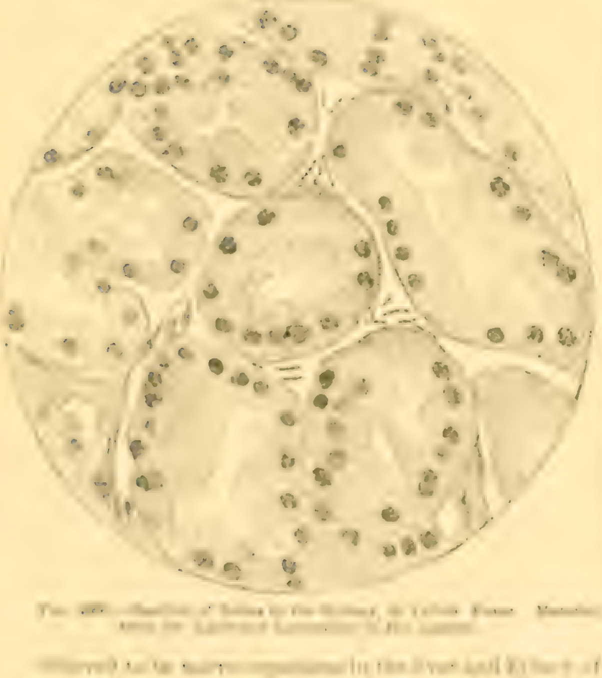

FIG. 4866.—Bacillus of Babes in the Kidney, in Yellow Fever. Magnified [illegible] Lacerda's Laboratory in Rio Janeiro.

Dr. Lacerda has described the organism referred to as in filaments which branch dichotomously, and believes this branching to be a constant and distinctive characteristic of the parasite which he accepts as the veritable yellow fever microbe. He is without doubt mistaken. The apparent branching of the filaments which he has described and drawn, and which he showed me in some of his preparations at the time of my visit to Rio, is due simply to the accidental juxtaposition of the bacilli-like chains. He is also mistaken in supposing that this organism is only to be satisfactorily demonstrated by Gram's method of staining. My friend Dr. Goes shared this belief at the time of my visit to Rio, but I demonstrated to him the facility with which the organism may be stained with a solution of methyline blue, upon sections which he made for me from material in Dr. Lacerda's laboratory. Since my return to Baltimore, I have made numerous sections from the same material, and find no difficulty in staining the organism present in the tissues with methyline blue or with fuchsin.

This bacillus, which is easily demonstrated, I have not been able to find in the tissues of six undoubted cases of yellow fever sent to me from Havana, and which I have carefully studied during the past year.

Babes himself has renounced the idea that this micro-organism bears an etiological relation to the disease under consideration. In the second edition of "Les Bactéries" he says:

"Since these researches we have had the opportunity to examine several series of sections from yellow fever. First, the liver and kidney of two individuals dead from this malady, collected by Dr. Alvarez, were examined in the Laboratory of Pathological Anatomy of the Faculty of Paris, without any bacteria having been found; second, material from three cases of yellow fever which Koch was kind enough to confide to one of us. In these last three cases, notwithstanding the most scrupulous research, and notwithstanding the advice of Koch, it was impossible to find the bacilli chains in the brain, the kidneys, the liver, and the spleen. We must suppose, then, that in yellow fever, as in other infectious maladies, microbes are only found in the parenchymatous organs in certain cases, and not in all. The question whether these micro-organisms really constitute the cause of the malady, or simply a complication, is consequently not resolved."

In my cultures from ten yellow fever cadavers in Havana (1888), I have not encountered this short bacillus in culture, except perhaps in a single instance. In my first case I obtained several different micro-organisms from the urine drawn through the walls of the bladder. One of these is a short bacillus with stained ends, which resembles that of Babes (my bacillus [illegible]). It is very aerobic, grows slowly, does not liquefy gelatine, and upon the surface of gelatine or agar forms a rose-pink mass. The colonies in gelatine are spherical and homogeneous.

As the bacillus of Babes was only seen in sections made from alcoholic preparations, it is impossible to establish identity.

In a single case, I have found in sections of the kidney a straight bacillus, which is shown in Fig. 4867. The material was from Havana, and was put into strong alcohol within three hours after the death of the patient. These bacilli were for the most part in the glomeruli; sometimes they were collected in small foci, as seen in the drawing, and at other times the whole glomerulus and the tissues about it were invaded. The presence of this bacillus is quite exceptional, and I attach no importance to the observation, except as showing that invasion of the tissues by a non-specific micro-organism sometimes occurs in this disease during the last hours of life.

Tetragenus febris flavæ of Dr. Carlos Finlay, of Havana. In a paper published in Havana in 1887, entitled *Etiologia y Profilaxis de la Fiebre Amarilla*, Dr. Finlay arrives at the following conclusions:

"In the studies which we have made up to the present time we believe that we have demonstrated:

"1. That the micrococcus tetragenus febris flavæ is the characteristic form of the microbe of yellow fever.

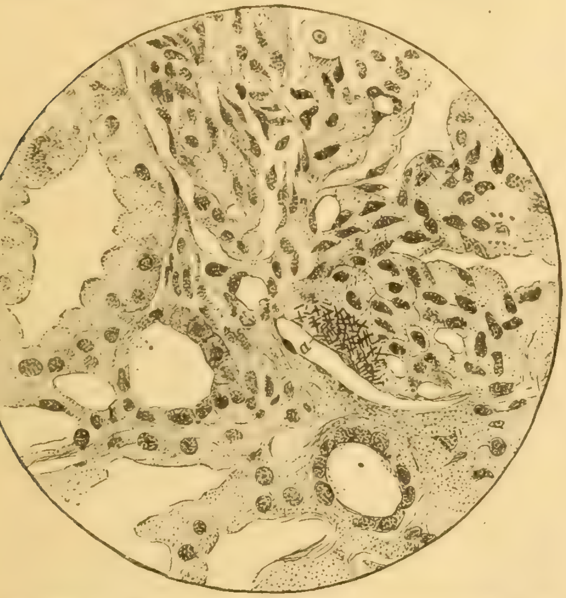

FIG. 4667.—Collection of Straight Bacilli in a Glomerulus of the Kidney in Yellow Fever. Material from Havana.

"2. That the culex mosquito is the known natural agent which transmits this disease.

"3. That, according to the results of our experiments up to the present time, it is possible to protect non-acclimated individuals from contracting *grave* yellow fever by inoculations with the mosquito."

Dr. Finlay kindly sent me some of his cultures from yellow fever blood, and from mosquitoes, in November last (1887), and I spent some time in making a bacteriological analysis of the same. The culture from blood was found to contain the following micro-organisms:

a. Pale-yellow spherical colonies; a large coccus in tetrads and irregular groups.

b. Cream-white colonies, spherical or lobate; a large coccus in tetrads; varies very much in its dimensions and mode of grouping.

c. Pale-white colonies; a small micrococcus in tetrads.

d. Pale-yellow spherical colonies; a short oval bacillus (very common in Havana and elsewhere).

e. A large liquefying bacillus in pairs and chains.

My researches at Vera Cruz and in Havana have shown me that the most common micro-organisms upon the surface of the body of yellow fever patients, and of healthy individuals as well, are micrococci of various species, and that among these the large coccus in tetrads (*a*) which forms yellow colonies, is one of the most common. I therefore infer that the micro-organisms found by Dr. Finlay in his cultures from blood drawn from the finger, and from the mosquitoes which had filled themselves from yellow fever patients, are from the surface and not from the circulating fluid, which has been repeatedly proved by my culture experiments to be free from such micro-organisms. At the time of my visit to Havana (1888), Dr. Finlay, in view of the facts above stated and others, read a paper before the Academy of Sciences in which he substantially withdrew his claim to have discovered the specific cause of yellow fever. He informs me that his *tetragenus febris flavæ* is the micro-organism described above (*b*), which forms cream-white colonies. In my cultures from the blood and tissues of yellow fever cases, I have encountered this in a single instance. It was associated with a liquefying staphylococcus in a piece of kidney which I had kept in the laboratory for forty-eight hours, enveloped in an antiseptic wrapping which insured the exclusion of germs from without.

The Bacillus of Dr. Paul Gibier.—I quote as follows from my report submitted to the President of the United States immediately after my return from Havana (June, 1888):

"In three cases I have obtained from the stomach or intestine a liquefying bacillus (*g*), which appears to be identical with that isolated from material from the same source by Dr. Paul Gibier, who, under instructions from the French government, has been pursuing similar researches during the past six months, in the city of Havana.

"This bacillus, which in the list of micro-organisms that I have encountered, I have designated with the letter *g*, is a long-oval bacillus with rounded or pointed extremities. Like many of the micro-organisms of the same class, it presents under certain circumstances the appearance of end-staining. I see no reason for considering this micro-organism a spirillum, as Dr. Gibier is disposed to do.

"In my cultures it has not presented the character to which he attaches special importance in selecting it as the probable cause of the disease under investigation. Dr. Gibier states that, under certain conditions, this bacillus forms a black pigment which he supposes to be identical with that found in the stomach and intestine of yellow fever patients. As I have no doubt that the pigment in black vomit comes from the blood which has escaped into the stomach by passive hæmorrhage—having repeatedly verified by microscopic examination the abundant presence of the red blood-corpuscles—I do not attach any value to the idea that this pigment is the product of a micro-organism, as has been asserted by Freire, Carmona, and Gibier. Nor have I seen any black pigment in the numerous cultures which I have made of this liquefying bacillus, some of which were made directly from an agar-agar tube which Dr. Gibier kindly presented to me as a pure culture of the micro-organism which he had isolated from the intestinal contents of yellow fever cadavers. It is quite possible that I would have encountered this liquefying bacillus more frequently, if I had used gelatine in all cases as my culture-medium. But in my last case, in which the autopsy was practised within two hours after death, and which was in every way a typical case, I did not encounter this bacillus, notwithstanding the fact that the characteristic black matter from the small intestine (ileum) was put up in a series of gelatine Esmarch tubes.

"Dr. Gibier has reported successful results in inoculation experiments in guinea-pigs, in which he used the black material from the intestine, and in which he assumes that the black matter was the toxic agent—produced by his bacillus—which killed the animals. As the material injected contained a variety of micro-organisms mixed with intestinal mucus, together with the black pigment, and probably more than one toxic ptomaine, it is evident that these experiments cannot be accorded any great scientific value."

This bacillus of Gibier, having been found in the intestine of yellow fever patients in a certain number of cases, stands beside other micro-organisms from the same source as a possible yellow fever germ.

The evidence heretofore recorded has led me, in my last report to the President of the United States, to formulate the following conclusions:

"*The specific cause of yellow fever has not yet been demonstrated.*

"*It is demonstrated that micro-organisms, capable of development in the culture-media usually employed by bacteriologists, are only found in the blood and tissues of yellow fever cadavers in exceptional cases, when cultures are made very soon after death.*"

SUSCEPTIBILITY.—Individuals of every race and of all ages, who are exposed to the yellow fever poison, for the first time. Among the [illegible] of the disease, are sure to be attacked. But there is a wide difference in the degree of this susceptibility among them, some having [illegible] of the same race.

Race.—It has been asserted that the negro race has a complete immunity from yellow fever, but this is a mistake. The susceptibility of the negro is, however, much less than that of the white race, and among those attacked the mortality, as a rule, is small. This is shown by the statistics recorded by [illegible] troops in the British service at West India stations. "While in Jamaica the yearly loss among the troops was [illegible] per 1,000 of the mean strength, the deaths among the blacks did not exceed [illegible] per 1,000. In the Bahamas the proportion of the whites was [illegible] to 1,000, that of the blacks [illegible] to 1,000" (La Roche).

In the report of the Board of Experts appointed by Congress to investigate the epidemic of 1878, we find the following remarks: "[illegible] City: 40 cases among colored, no deaths." "Morgan City, 11 deaths among colored persons." "Brownsville, Tenn.: of 160 colored cases, 15 died." "Chattanooga: of 600 cases, 350 whites, 250 colored; of 134 deaths, 118 whites, 16 colored." "Decatur, Ala.: of 66 white cases, 30 died; of 108 colored, 21 died."

The indigenous races of the West Indies and of the continents of North and South America have no immunity, except such as is acquired by residence in an endemic focus of the disease, and the same is true of the Mongolian race; but like the negro, they have, although to a less degree, less susceptibility than the white race, and the mortality among those attacked is not so great.

In general, it may be stated that the natives of northern latitudes are more susceptible than those born in tropical or subtropical climates. Barr, who had an extended experience in Havana, says: "The lower the winter temperature in the native country of those attacked, the more severe was their sickness; so that, while the mortality among West Indians amounted to only 6.9 per cent. of the sick, it rose to 18.4 among the Italians and French, 23.2 among the English, 28.2 among the Germans and Dutch, and 31.7 among Scandinavians and Russians."

Barton gives the following figures, showing the mortality per thousand among different races, and those of the same race from different latitudes, in the city of New Orleans in the great epidemic of 1853:

		Per thousand.
Born in Orleans		[illegible]
Emigrants from	West Indies, Mexico, and South America	[illegible]
	Southern States of the Union	[illegible]
	Spain and Italy	[illegible]
	Middle States of the Union	[illegible]
	New York and New England States	[illegible]
	Western States of the Union	[illegible]
	France	[illegible]
	British America	[illegible]
	Great Britain	[illegible]
	Germany	[illegible]
	[illegible]	[illegible]
	Austria and Switzerland	[illegible]
	Scandinavia	[illegible]

Sex.—There is probably no difference in the susceptibility of the sexes, but males are attacked in greater proportion than females, because they more frequently and more constantly visit infected localities. The mortality is, as a rule, considerably greater among males. Lopez, in giving an account of the pestilence at Barbadoes in [illegible], of which he was an eye-witness, says: "The cause was unknown; one could not say if the ships of commerce had imported the contagion, or if it came from bad food, [illegible] water, the intemperance of the colonists, and above all, the great quantity of [illegible] which they drank. . . . It was the most debauched who perished first, and not one woman died for ten men." No doubt Lopez was right in ascribing the difference in the mortality of the sexes largely to the difference in their habits with reference to the use of alcoholics. Those who habitually use spirituous liquors are less likely to recover from an attack than the temperate, and a recent debauch is a recognized predisposing cause. Sailors who go on shore at an infected port for "a little spree," very commonly have to go to the hospital, or are taken sick after their return on board ship, and serve as the starting point of an epidemic among their comrades, and subsequently, perhaps, at the port of destination of the vessel. The greater prevalence and severity of the disease, in epidemics, among males has been noticed by numerous authors, and has been verified in the writer's personal experience.

Age.—Infants and old persons enjoy a comparative immunity, due in part, no doubt, to the fact that they are less exposed than active individuals in middle life. Dr. Rush records the fact that he has "met with a violent case of the disease in a child of four months, and a moderate case in a child of only ten weeks" (La Roche). Very young infants, however, commonly escape, or suffer so mild an attack that the nature of the disease is not recognized. In cities like New Orleans, which have suffered repeated epidemics, the proportion of children attacked is often exceptionally large, because they constitute a large share of the unacclimated population, having been born since the last epidemic. Dr. Bemiss has given the following table, showing the number attacked and the comparative mortality for different ages, in the great epidemic of 1878.

The results of private practice in New Orleans are exhibited in the following statistics. Four of the principal practitioners in the city treated, in private practice, 975 patients—909 white and 66 colored. Of the former, 92, or 10.11 per cent., died; of the colored only 2 died. The cases and deaths among the whites, classified by age, are as follows:

Age.	Cases.	Deaths.	Per cent.
Under 1 year of age	[illegible]	[illegible]	[illegible]
From 1 to 5 years of age	[illegible]	[illegible]	[illegible]
From [illegible]	[illegible]	[illegible]	[illegible]
From [illegible]	[illegible]	[illegible]	[illegible]
From [illegible]	[illegible]	[illegible]	[illegible]
Over [illegible]	[illegible]	[illegible]	[illegible]

This table does not support the statement that adults are more likely to be attacked than children, but it must be remembered that it relates to cases occurring in private practice, in a community in which the adults were largely protected by previous attacks, or by passing through repeated epidemics.

In a review of the mortality in the same epidemic, with reference to age, Dr. C. B. White arrives at the following conclusions:

"First. That the mortality of boys at four years is not because a very much larger number of boys were taken sick, but that there is an actual greater mortality.

"Second. It is seen that, though the deaths decline with great rapidity—being at four years, 344; at five years, 169; at six years, 65; the cases do not decrease in the same ratio, but decline as follows: Cases at four years, 822; cases at five years, 740; cases at six years, 624; the recoveries being proportionally much larger.

"Third. From seven to eleven years of age the death-rate remains nearly uniform, the disease being comparatively much less fatal. According to Dowler, the mortality among children in the epidemic of 1841, in New Orleans, was very small. On the other hand, in the epidemic of [illegible], in the same city, it was considerable."

Dr. Charles Delery has given the following table, compiled from the official reports in the office of the Board of Health, showing the mortality during the epidemic of 1867, among children born in the city of New Orleans:

Age.	Males.	Females.	Total.
Under one year	[illegible]	[illegible]	[illegible]
1 to 2 years	[illegible]	[illegible]	[illegible]
2 to 3 years	[illegible]	[illegible]	[illegible]
3 to 4 years	[illegible]	[illegible]	[illegible]
4 to 5 years	[illegible]	[illegible]	[illegible]
5 to 6 years	[illegible]	[illegible]	[illegible]
6 to 7 years	[illegible]	[illegible]	[illegible]
7 to 8 years	[illegible]	[illegible]	[illegible]
8 to 9 years	[illegible]	[illegible]	[illegible]
9 to 10 years	[illegible]	[illegible]	[illegible]
Total	[illegible]	[illegible]	[illegible]

Total deaths from July 29, to November 7, 1867: Males, 167; females, 133 (of these 5 colored, 2 males and 3 females).

Dr. Henry Smith reports that in the epidemic at Shreveport, La., in 1873, out of a total of 584 deaths in which the age was ascertained,

"100 died under 10 years of age.
93 died between 10 and 20 years of age.
156 " " 20 " 30 " " "
134 " " 30 " 40 " " "
59 " " 40 " 50 " " "
29 " " 50 " 60 " " "
13 " above 60 years of age."

IMMUNITY is acquired by suffering an attack of the disease, or by long residence in localities where it is endemic or prevails frequently as an epidemic; this acquired immunity is not, however, absolute.

Second attacks no doubt occasionally occur, although this has been denied by some authors. Blair, whose experience was very great, says that he does not believe there is an instance of a second attack after a month's perfect restoration to health. Other authors are equally positive in their statements. On the other hand, we have numerous authentic accounts of second attacks. Thus "Dr. Jackson states that in Spain, during the epidemic of 1820, twenty well-authenticated instances came within his knowledge, of persons being attacked who had the disease before." Dr. Wragg, speaking of the epidemic in Charleston in 1854, reports the occurrence of second attacks in a number of instances, and says: "Six of these were so well proved as to admit of no doubt on the subject. Some of the patients were identified as having gone through the fever in this (the Roper) hospital in 1852, throwing up black vomit on both occasions" (La Roche). Dr. Rush has given evidence of the same kind, and says that a second attack was more common when the first had been comparatively mild.

Dr. Deléry, in his account of the epidemic of 1867, in the city of New Orleans, gives three cases of second attacks—one fatal, in which the first attack occurred in a previous epidemic in the same city, and was vouched for by experienced physicians known to him. While, then, it cannot be denied that second attacks occasionally occur, the evidence of experienced observers in all parts of the yellow-fever zone is opposed to the view that this is a common occurrence. Those who have considered yellow fever nothing more than a grave form of malarial fever—an idea which was entertained by numerous physicians in this country and in the West Indies in the early part of the present century, very naturally failed to differentiate the disease from the endemic malarial fevers which they encountered, and believed that it might recur an indefinite number of times.

Acclimatization.—It is a remarkable fact that the population of a large city like Havana, or Rio Janeiro, in which yellow fever has been endemic for a series of years, enjoys such a degree of immunity from the effects of the deadly poison that there is no interruption of business or pleasure at a time when strangers in the city are falling sick on every side. The development of an *epidemic* in these cities depends upon the presence of susceptible strangers in sufficient number to furnish a series of cases considered large enough to justify the use of the word. The presence of but few strangers during the epidemic season leads to the announcement that the disease is not epidemic, but that sporadic cases occur from time to time. Under exceptional circumstances, however, epidemics are developed in these endemic foci of the disease, in which those who, by birth or long residence, were supposed to be acclimatized, furnish a certain quota to the general mortality. This has frequently occurred, for example, in the city of New Orleans, where yellow fever formerly prevailed almost annually, and where the *creole* population was supposed to enjoy an hereditary immunity. Dowler, who has made a special study of the question, says of the creole population of New Orleans:

"A few physicians and others, mostly advocates of the contagiousness of yellow fever, maintain that all the creoles of New Orleans, not less than strangers, have this disease once during life, for the most part during childhood, and that it proves fatal to many of them. . . . This sweeping statement, however, is with few exceptions erroneous, as may be proved by authentic documents concerning all of the epidemics witnessed by the writer for seventeen years, not excepting the extraordinary one of 1853 itself.

"It will have been remarked by careful observers that many families have been settled in New Orleans for half a lifetime without ever having had yellow fever. Indeed, it has been thought by many physicians, previous to 1853, that at least one-third of all strangers settling permanently in New Orleans escaped yellow fever altogether. . . .

"The exemption of the creolized of the city is a fact which every epidemic has confirmed; for example, take that of 1841, in which 1,800 died; five of whom only were natives of the city; one aged three weeks; three, two years. In 1843, among 692 deaths from yellow fever, but two are certified as having been born in New Orleans."

The writer quoted believes, with many other physicians residing in endemic foci of the disease, that immunity is, "to a great degree, hereditary, or transmissible from parents to children." This is generally accepted among the physicians and the native population of the city of Havana, but there is reason to believe that it is a mistake, and that the creole child owes his immunity not to his parents, but to individual acclimatization, and not infrequently, to say the least, to a mild, unrecognized attack of yellow fever. Dr. Dowler says "that many creole children had, during the epidemic of 1853, a fever—a slight fever—yellow fever if you please—known as such rather by the co-existence of the epidemic than from any severe symptoms among these children—a slight fever never yet described, having generally but one paroxysm, lasting from six hours to one, two, or three days, scarcely ever requiring medication. That a few of these cases acquired an alarming violence, and even proved fatal, is most true—most deplorable."

Hinemann writes with reference to Vera Cruz: "Until lately the physicians and people of Vera Cruz supported with fanaticism the dogma that natives were absolutely exempt from yellow fever. But the fearful epidemics of recent years (1875, 1877, 1878) have worked a change; for so many native children and adults suffered, that the truth could no longer be denied that these do not enjoy an absolute immunity."

In Cuba, the dogma that creoles are exempt from yellow fever, did not withstand the searching investigation made by the Havana Yellow Fever Commission of 1879. We quote some of the evidence collected and reported by Dr. Chaillé, President of this Commission. "Dr. Navea, of San José de las Lajas, an inland town some twenty miles southeast of Havana, presented the following interesting report after it had received the full approval of Drs. Cabrera and Bofil, his colleagues at San José: 'We have here annually, in the practice of the three physicians, from 20 to 30 Cuban children, and from 30 to 40 Cuban adults, attacked with bilious remittent fever which is popularly designated typhus. There is nothing whatever to constitute a differential diagnosis between this fever of the natives and the yellow fever of strangers. It is characterized by its hæmorrhagic tendency, albuminuria, black vomit, and all the symptoms of yellow fever. It is so well marked that, even when seen by the uneducated they exclaim "Vomito." The treatment for the one is best for the other. We have never seen a second attack of this bilious remittent fever, nor one who had recovered from it attacked with yellow fever. If anyone of us three physicians here sees this fever attack a native Cuban, we say, "bilious remittent fever," and if it attacks a person not a native of Cuba we say "yellow fever;" but at bottom it is the same disease; and we agree to call it bilious remittent fever in Cubans, solely because these believe themselves exempt from yellow fever, and are so prejudiced that they would be [illegible] (I assumed these [illegible] [illegible] [illegible] yellow fever.

"Dr. Mackintosh, of [illegible], reported as follows: 'During [illegible] 18[illegible], the sanitary condition [illegible] good, but a remittent fever has prevailed among children, which, however, had a typhoid, although it resembles in severity the fevers to which Europeans give this name, and which no other infective cause. By the [illegible] I have had one patient which must [illegible] any [illegible] in the town. It presented all the symptoms of yellow fever, for, on the second day, this patient had the characteristic vomit and [illegible], and died on the third day. In a consultation with three other physicians, they agreed with me in my diagnosis, with this difference, that they said that these same symptoms, which constituted yellow fever in strangers, constituted in natives typhoid. I have never had the right to see children born [illegible] of this disease.'

"Dr. [illegible], a graduate of Paris, who has had [illegible] some experience in [illegible], writes as follows: 'In my own practice I have seen cases of yellow fever in children from one to five years of age, and [illegible] but very few of age, by whom it has been [illegible], and I am well convinced that children born in [illegible] are exempt in the same conditions [illegible] first years of their lives as are other new-comers, and [illegible] liable to be attacked. Nevertheless, I consider that children are generally less prone to suffer severely.' [illegible] Worthy practitioners of this locality give the name of typhus fever to these cases, and [illegible] they admit that no difference whatever exists between the symptoms, course, and duration of this [illegible] with yellow fever, still they think the former a [illegible] fever, and [illegible] more amenable to [illegible]."

Blair, who has written a classical account of the epidemic of 1837–41 in British Guiana, says that "infancy was one of the most [illegible] causes of the action of the yellow fever poison. The constitution of the new born or young white creole was highly susceptible. [illegible] to the category of new-comers."

Recent experience at Key West (epidemic of 1887) shows that the children of [illegible] Cubans, born since the arrival of their parents at Key West, have the same susceptibility to the disease as other [illegible] born of unacclimated parents. We cannot, therefore, admit that inherited immunity has been established.

On the other hand, we are not prepared to assert that there is no immunity independent of an attack of the disease. Unrecognized mild attacks in adults, and especially in the young and among newly-born children, are no doubt of frequent occurrence. But it cannot be claimed that, independently of any febrile manifestation, individuals of all ages, who have resided in an infected locality for some time, acquire a comparative immunity, which increases with length of residence and degree of exposure to the action of the specific cause of the disease.

It is generally conceded that this acclimatization is lost, or at least, reduced to a considerable extent, by residence for some years in a latitude outside of the "yellow fever zone." And some authors maintain that the immunity due to an attack of the disease is in like manner lost, or is [illegible] by [illegible] absence from its accustomed haunts. The writer's observations are opposed to the latter statement. In the epidemic at Fort Barrancas, Fla., in 1875, in which nearly every unprotected person who remained in the infected area suffered an attack, three officers, who had previously had yellow fever, remained in perfect health, although they had all resided for several years in a northern locality since the date of their attack—one for more than twenty years.

[illegible], who has had an extended experience at Vera Cruz, says that "even foreigners may remain immune to the disease for a considerable number of years, provided they do not leave the focus of the disease during that period. An absence of a few months only is sufficient to take away this immunity."

That foreigners may remain for years in Havana, in Rio Janeiro, or other endemic foci of the disease without suffering an attack is undeniable. I found this especially to be the case in Rio, where there is a large foreign population. It is true that some who have escaped for a series of years often fall sick at last in a season of unusual epidemic prevalence, but comparative immunity is shown by the fact that, as among the creole population, the disease is not so fatal with them as among newly arrived strangers. The effects of acclimatization in large cities like Rio Janeiro and Havana are illustrated by the fact that in these cities yellow fever is, for the native population, a disease of minor importance. This is shown by the following tables.

In Rio, a city having a population of 400,000, the mortality from some of the principal causes of death is given in the official report of the Superior Board of Health as follows for the year 1886, which was considered an epidemic year so far as yellow fever is concerned:

		Deaths.
1.	Tuberculosis	[illegible]
2.	Diseases of the respiratory organs	[illegible]
3.	Diseases of [illegible]	[illegible]
4.	Diseases of the digestive system	[illegible]
5.	Infectious diseases	[illegible]
6.	Yellow fever	[illegible]

In Havana, the principal causes of death among the civil population, in the year 1886 are given officially as follows:

		Whites.	Colored.
1.	Phthisis pulmonalis	[illegible]	[illegible]
2.	Enteritis [illegible]	[illegible]	[illegible]
3.	Yellow fever	[illegible]	[illegible]

That acclimatization is not due to the influence of climate, but is an acquired tolerance to the action of the yellow fever poison, is shown by the history of this disease in Rio Janeiro. At the time of its introduction, in 1849, it found an unprotected population, and for a series of years prevailed as an epidemic among this population, causing a mortality quite comparable to that in similarly situated cities in other parts of the world when first invaded by the scourge. At present the native population furnishes but a comparatively small proportion of the total number of deaths by this disease.

PREDISPOSING CAUSES.—*Plethora* is considered by some physicians, in the regions where yellow fever prevails, to be a predisposing cause, and to account for the greater susceptibility of strangers from northern latitudes. *Constipation* is generally regarded as an unfavorable condition. Other predisposing causes are, *fatigue* from excessive exertion, *debility* resulting from a recent debauch, or from any other cause, *exposure* to the direct rays of the sun, violent mental emotions, such as *grief* or *fear*; and, in general, any influence capable of depressing the vital powers, or any disturbance of the normal functional activities of the body.

MODE OF INFECTION.—Yellow fever is contracted by exposure in infected localities, and not directly by contact with the sick. This is established by a mass of evidence which is recorded in the literature of the subject, but is still denied by some physicians, who regard it as a contagious disease in the same sense that small-pox and measles are contagious. In this respect it is like cholera and typhoid fever. There is something given off from the body of the sick by which, when external conditions are favorable, new centres of infection are established; and it seems probable that, as in the diseases mentioned, this germinal principle of the disease is contained in the alvine discharges of the sick. That it is not given off from the general surface of the body is an inference which we base upon the established fact that the disease is not transmitted directly from individual to individual. It is true that the contagionists bring forward a mass of facts which, regarded alone, seem to give some support to their views, but we believe these facts to be explicable in accordance with the statement above made. Persons who successively fall sick in the same house, or on board ship, are not infected one from another, but contract the disease from a common source, the infected premises, or ship. Indirectly, of course, they contract the disease through the agency of the individual or families through whom the house or ship first became infected.

Formerly the battle between the contagionists and the non-contagionists was one involving the question of local origin on one side, together with a strenuous denial of the transmissibility of the disease and the value of quarantine restrictions. The contagionists, on the other hand, insisted upon the exotic origin of the disease and its transmissibility by ships and persons. And to this extent they were right. There can be no doubt that the prevalence of the disease in the United States depends upon the introduction of an exotic germ; but it also depends upon local conditions which favor the development of this germ. The yellow fever patient, however many germs he may carry in his intestine or elsewhere, does not directly endanger those who come near him, any more than a gelatine culture of the spirillum of Asiatic cholera or of the anthrax bacillus places in danger the student of bacteriology who is engaged in studying it.

It is well known to the people of the City of Mexico that a visit to the sea-coast city of Vera Cruz during the epidemic season is likely to result in an attack of yellow fever. It is also well established that those who fall sick with the disease after their return to the City of Mexico never communicate it to others who are closely associated with them as attendants, etc. The same is true at the health-resort Petropolis, located in the mountains within a few hours' ride of the city of Rio Janeiro. Frequently individuals fall sick in Petropolis who have visited the infected city of Rio. Never do they communicate the disease to others. This is also the experience of the physicians in charge of hospitals—*e.g.*, the Charity Hospital of New Orleans; so long as the hospital and its vicinity remain uninfected cases do not originate in the hospital, although yellow fever patients may be admitted to the wards with unacclimatized persons suffering with other diseases, and be cared for by susceptible attendants.

In his report upon the camps established near Memphis in the epidemics of 1878 and 1879, Colonel Cameron makes the following statement: "It was found necessary that the officer in authority should set an example of constant indifference to attack in order to appease, as far as possible, the constant anxiety of the population under his charge. Especially was this true in 1878, as depopulation went on slowly that year, and infected people poured daily into the camps from the more pestilential portions of the city. Very many reached camp with the fever on them, so that as many as seventeen persons fell victims in one night, not a few in their tents. *In no instance, however, did they communicate the disease to their families or bed-fellows*, as far as could be traced."

In the same epidemic (1878) Dr. Minor reports that over thirty cases were discovered among refugees in Cincinnati, O., and says: "No physician or nurse contracted the disease, and in no instance did it exhibit any tendency to spread." The same was true in Nashville, the same year; twenty imported cases occurred in different parts of the city without any local cases resulting from them (Report of Nashville Board of Health). Evidence of this kind could be extended to fill a volume, but sufficient has been presented to establish the statement made, and the reader may be referred to the "Proofs of Non-contagion" in the second volume of the classical work of La Roche (pages 236–566).

We have already, in discussing the nature of the specific cause of the disease, referred to the fact that there is no satisfactory evidence that the disease is contracted by the use of contaminated water, as is the case in cholera and typhoid fever. We quote the following conclusions of the Board of Experts appointed to investigate the epidemic of 1878:

(6) "Yellow fever is a disease of singular local attachments. It often becomes epidemic in one section of a city, and sometimes a very small section of it, while it fails to present itself at all in other sections of the same city, and in these localizations it exhibits a remarkable indifference to topographical and social surroundings."

(7) "In the dissemination of yellow fever, atmospheric air is the usual medium through which the infection is received into the human system."

ETIOLOGY OF EPIDEMICS.—The development of an epidemic of yellow fever, in places removed from the endemic foci of the disease, depends upon: (*a*) the introduction of the specific cause by yellow fever patients, or through infected articles—fomites; (*b*) local conditions which favor the multiplication of the specific germ external to the body; (*c*) favorable meteorological conditions; (*d*) the presence of susceptible individuals in the infected locality.

We quite agree with the Board of Experts above quoted in the following conclusion also: (31) "The most frequent agency in the dissemination of yellow fever from place to place is found in yellow fever patients; and more epidemics of yellow fever have resulted from the introduction into previously exempt places of persons sick of the disease, or falling sick after arrival, than from all other causes. To what extent the body of the sick person is responsible for this result, and to what extent his clothing and baggage is responsible for it, is not known."

The last clause in the above-quoted conclusion shows that the Board of Experts admitted the possibility that the yellow fever patient acts simply as a carrier of the infectious agent, about his person or in his baggage. The fact that he has yellow fever is evidence that he comes from an infected locality, and he may be instrumental in establishing a new centre of infection for this reason, rather than because he is himself a victim to the disease. This is a possibility which should not be lost sight of; but, reasoning from analogy and from known facts, it seems extremely probable—indeed we may almost say certain—that the sick establish new centres of infection because the infectious agent is reproduced in their bodies and is contained in their excreta.

That infected centres may be established independently of the arrival of sick persons is, however, beyond question. A striking instance of this is afforded by an outbreak which occurred in Madrid in 1878. A circumscribed epidemic was developed in this city about the first of September, which resulted in a mortality of thirty-five out of fifty cases taken sick. This outbreak was traced to importation, although all of the cases occurred among the permanent residents of the infected area. Associated with the young people who first fell sick, crowded in the same rooms with them to the number of ten or fifteen in a room, were a number of soldiers recently returned from Cuba, *with their baggage*. These men had themselves suffered from yellow fever in Cuba, or were acclimatized by long residence there.

We have on record instances which appear to be authentic, of the development of an epidemic as a result of the opening of a trunk containing *infected clothing*, sent from a locality where the disease was prevailing to one previously healthy. Epidemics have also been traced to the unloading of earth *ballast* from the shores of an infected port upon the wharves of a healthy place in the yellow fever zone.

The first cases of local origin in an epidemic do not, as a rule, occur until some time has elapsed after the arrival of the infected ship, or fomites, or sick person responsible for the introduction of the "germ." This interval may vary from a few days to several weeks, according as local conditions are favorable or otherwise for the development of the infectious agent.

In the great epidemic of 1878, which was traced by Dr. Choppin, President of the Louisiana State Board of Health, to importation by the steamship Emily B. Souder, which arrived from Havana on the 23d of May, the first cases of local origin did not occur until after an interval of five or six weeks. But these first cases occurred, according to Dr. Choppin, in the immediate vicinity of the houses in which two of the officers of the Souder (Clarke, the purser, and Elliott, one of the engineers) died soon after the arrival of that vessel.

The *local conditions* which favor the development of the exotic germ are various: (a) *Latitude*. Our account of the geographical limits of the prevalence of the disease suffices to show the influence of latitude, which appears to be simply a question of temperature. (b) *Alti-*

ease. The facts do not justify the conclusion that the limitation as to altitude depend solely upon the lower temperature of elevated regions. As pointed out by Hirsch, "the disease occurs about as rarely points in the West Indies where the climate is still in the highest degree tropical. On the other hand, there have been epidemics in cool weather or from considerable altitudes, as, for example, at Newcastle in Jamaica," (elevation about 4,000 feet). In the Antilles the disease has rarely appeared at a height of more than 700 feet. In Mexico it has prevailed at Cordova (2,800 feet), but is unknown in the cities of Orizaba, Jalapa, and Puebla, which have an elevation of more than 4,000 feet. In Spain a single limited outbreak has occurred at Madrid, which is about 2,000 feet above the sea-level; but with this exception the altitudinal range has rarely exceeded 1,000 feet. In the United States the most elevated locality in which the disease has prevailed as an epidemic is Chattanooga, Tenn., which is 745 feet above the sea-level. (c) Yellow fever is essentially a disease of the seacoast, and while in great epidemics it may become widely diffused in the interior it follows for the most part the routes of commercial travel. (d) It is a disease of towns and towns of considerable size, and rarely extends to small country villages or among the scattered rural population. (e) In seaport towns it frequently makes its first appearance in the vicinity of the wharves, or in localities frequented by sailors. (f) Above all, it is a disease which is influenced by local sanitary conditions. In those places where it is endemic it haunts the low-lying and filthy portions of the towns, and in epidemics it exhibits a marked preference for towns which are in an unsanitary condition. It frequently happens that when a town is invaded the disease is limited, for a considerable time at least, to the filthy portions of the place, in which the degraded victims of poverty and vice congregate in ill-ventilated apartments surrounded by the filth which accumulates in such localities when not kept under a rigid sanitary supervision. (g) Decomposing organic matter of animal origin seems to furnish an especially favorable nidus for the germ. This is shown by its favorite haunts, and by the fact that in marshy places, in the vicinity of rivers, where malaria prevails and where vegetable decomposition is active, it does not effect a lodgment. On the other hand, the influence of putrefying organic matter of animal origin in the production of epidemics has several times been made apparent. Dr. Parkes the famous English hygienist maintained the fæcal origin of the disease, and there seems to be good reason for the belief that the accumulation of this kind of filth in exposed situations is favorable to the development of an epidemic. Conditions relating to soil and geological formation have not been shown to influence in an essential manner the development or diffusion of the disease. On the other hand, the numerous epidemics which have occurred on shipboard show that the disease is quite independent of such conditions, and at the same time disprove the theory, so vigorously maintained by numerous authors during the first half of the present century, that the disease is due to emanations of the same nature as those which produce the so-called "malarial fevers." Meteorological conditions exercise a most decided influence upon the prevalence of the disease in localities where it is endemic, and its epidemic extension when new infected centres are established among a susceptible population. The influence of temperature is shown by the fact that it is a disease of the tropics and of hot seasons; that it prevails throughout the year in the cities of Rio Janeiro, Havana, and Vera Cruz, although to a much less extent during the cool season; while in more temperate regions its prevalence is limited to the summer season. It does not prevail as an endemic disease in places which have a mean winter temperature much below 68°, and as a rule epidemics are not developed at a lower temperature than 72° to 75° Fahr. The approach of cool weather checks the progress of an epidemic, and it terminates completely when the temperature falls to the freezing point. There are, however, numerous facts which indicate that the infectious agent is not destroyed by a freezing temperature, although rendered inactive. Epidemics which have been checked by frost have been revived by the recurrence of warm weather, and in certain instances in temperate regions the germ has survived the winter, and a second epidemic has occurred without a new importation (Memphis, 1878-9; Cadiz, 1800-1; Malaga, 1803-4). Epidemics which originate early in the season often terminate before there is frost, simply because the susceptible material is exhausted; but when strangers venture within the infected area they furnish evidence of the continued activity of the infectious agent, by falling victims to the disease. The influence of season is shown by the following tables:

Mortality from Yellow Fever in Rio Janeiro during the Year 1886.

Month.	Total deaths.	Mean temp.	Rain-fall.
January	143	77.6	7.40
February	298	79.0	10.64
March	503	77.8	9.08
April	344	75.90	8.81
May	17	69.9	3.06
June	58	67.90	1.08
July	9	66.97	1.55
August	2	67.86	5.27
September	1	68.81	4.39
October	1	69.62	1.97
November	1	73.57	1.17
December	1	74.95	5.42
Total	1,449		[illegible]

Mortality from Yellow Fever in Rio Janeiro from January, 1851, to July, 1870 (Hirsch).

Warmer season.		Cooler season.	
January	1,118	July	212
February	1,766	August	164
March	1,722	September	148
April	1,384	October	173
May	596	November	146
June	501	December	122
Total	7,087 = 88 per cent.	Total	965 = 12 per cent.

Mortality from Yellow Fever in the City of Havana for ten years—1870 to 1879, inclusive.—(Chaillé: Report to National Board of Health).

Month.	1870	1871	1872	1873	1874	1875	1876	1877	1878	1879	Average for ten years.
January	6	58	20	42	7	16	24	8	26	11	17
February	1	22	11	26	3	9	23	7	19	13	13
March	1	72	4	27	18	12	29	11	4	4	18
April	6	54	3	67	22	31	32	8	26	11	26
May	14	91	11	237	95	42	108	16	36	40	69
June	46	287	66	376	175	184	296	110	151	211	190
July	112	289	68	416	301	187	622	440	448	477	336
August	207	158	70	317	319	141	536	426	352	315	282
September	51	75	50	145	180	146	275	264	175	148	150
October	17	44	28	55	91	109	42	150	86	11	63
November	6	11	12	9	32	132	27	28	26	11	29
December	10	11	70	9	21	58	39	73	12	9	30
Total	666	991	415	1,586	1,426	1,012	1,619	1,374	1,559	1,445	

These above tables show us that temperature is only one of several factors which control the prevalence of the disease, for with a tolerably uniform temperature during a series of years at Vera Cruz for example, we have some years marked by a very considerable mortality—e.g., 1875, 1881—and others in which but few cases occur, even during the hottest part of the season—e.g., 1869, 1870, 1879. Again it happens that after a summer of almost complete exemption an epidemic is developed in the autumn which runs through the entire winter (1880-81; see p. 41). An important factor, which does not usually appear in statistical tables, relates to the number of susceptible individuals present at different times. The arrival, for example, of contingents or of bodies of unacclimated troops at Havana or Vera Cruz would almost inevitably be followed by a marked increase in the mortality from yellow fever

Although the development of an epidemic seems to require a comparatively high temperature (75° to 80°), experience shows that it may continue in full force at a much lower temperature (60° to 70°), when local conditions are favorable and a susceptible population is exposed in the infected area. A good example of this is given by the epidemic at Chattanooga, Tenn., which city was invaded for the first time in 1878. We obtain our data from a paper by Dr. J. H. Vandeman.

The first imported case, a refugee, was taken sick August 17th; died August 21st. The first case among the residents of the city occurred over three weeks later (September 13th), and proved fatal on September 19th. The further progress of the epidemic, and the mean temperature for each week, are shown in the following table:

Epidemic at Chattanooga, Tenn., in 1878.

Week ending.	New cases.	Deaths.	Mean temperature.
September 27th	40	21	79.71°
October 4th	47	19	70.42°
October 11th	144	22	66.66°
October 18th	99	33	63.14°
October 25th	74	21	56.52°
November 1st	30	12	48.66°
November 8th	9	4	53.04°
November 15th	2	2	51.83°

Here we have an epidemic which was at its acme when the temperature was below the mean temperature of the winter months in Rio Janeiro, Havana, or Vera Cruz. The monthly mean temperature in the last-named city, and the mortality for each month, for a period of four years, are given in the following table:

Month.	1878.		1879.		1880.		1881.	
	Deaths.	Mean temp.	Deaths.	Mean temp.	Deaths.	Mean temp.	Deaths.	Mean temp.
January	16	69.5°	6	72.9°	2	73.2°	28	67.3°
February	5	72°	4	72.8°	0	75.3°	22	67.4°
March	0	76°	2	78.9°	1	78.1°	29	75.4°
April	1	80.5°	1	79°	1	80.8°	29	77.1°
May	7	84.3°	1	83.4°	0	84.9°	94	82.5°
June	58	86.9°	1	83.5°	0	86.4°	233	84.6°
July	114	85.6°	2	85.6°	1	87.6°	132	88.1°
August	110	84.6°	1	86.5°	3	86.2°	39	87.6°
September	62	83.4°	3	80.7°	9	83.3°	22	84.3°
October	45	81.2°	0	79°	42	77.5°	25	80.6°
November	24	77.3°	0	79°	92	76.7°	18	75.3°
December	7	70.2°	0	73.4°	98	74.7°	4	73.6°

An inspection of the above table shows that after an epidemic in the summer of 1878, which may be said to have lasted from June to December, two seasons of comparative immunity followed, which cannot be ascribed to a lower temperature. Indeed, the average temperature for the six months from April to September, inclusive, was somewhat greater in 1880 than in the epidemic year 1878. Again we see that in 1880, after an unusually healthy summer, yellow fever prevailed to a considerable extent during the months of October, November, and December, although the temperature was less than during the corresponding months of the preceding year. The epidemic impetus continued during the following year, attaining its maximum of intensity in the months of May, June, and July, although in two of these months (May and June) the temperature was lower than in the corresponding months of the preceding healthy summer.

Another factor of importance in the etiology of yellow-fever epidemics is atmospheric *moisture* and *precipitation*. Yellow fever is a disease of the sea-coast, and of the margins of great rivers, and it does not prevail in arid, desert places in the interior, although the elevation may be but little above the sea-level, and the temperature extremely high. There is reason to think that this difference is largely due to the difference as to moisture in the atmosphere and in the soil. Some authors have insisted especially upon the presence of moisture in the atmosphere almost to the point of saturation, as an essential condition for the development of an epidemic. But, on the other hand, epidemics have sometimes occurred in unusually dry seasons, as at New Orleans in 1841. In Martinique, according to Dutrouleau, yellow fever has sometimes committed its greatest ravages after and during the dryest season.

La Roche states that the epidemics in Philadelphia were "connected in most instances, at least, with a deficiency of atmospheric and terrestrial humidity—though in all instances of its occurrence it will be found that, prior to the accession of dry weather, the earth had been more or less saturated with rain." As pointed out by this author, "the coexistence of a clear atmosphere is often seen." The fact seems to be that, while a certain amount of moisture is essential, the limits vary considerably. In general, it may perhaps safely be said, that the degree of humidity and the temperature most favorable for the rapid decomposition of organic material, which forms the nidus in which the infectious agent multiplies, is the most favorable for the epidemic extension of the disease.

Heavy rains, by purifying the air and cleansing the streets and sewers of an infected city, exercise a favorable effect upon its sanitary condition, and in the tropics the commencement of the rainy season often puts an end to the prevailing epidemic. It is probable that the statement made by some authors, that upon the coast of Guiana, and elsewhere in the tropics, dry weather is favorable to the spread of the disease, is but another way of stating the fact that the heavy rains of tropical regions are unfavorable, the dry weather being only dry by comparison.

In the north temperate zone southerly *winds* are favorable to the progress of an epidemic, because of the elevated temperature which accompanies them, and, on the contrary, northerly winds have a tendency to arrest it. Fresh sea-breezes, and especially the trade-winds in the tropics, by reason of their constancy, are beneficial from a sanitary point of view. They dilute and carry away the poisonous emanations from the foul and narrow streets of infected cities, and refresh and invigorate the population.

There is no evidence that the infectious agent of yellow fever can be conveyed by the wind, in an active condition, to any considerable distance, and the wind has but little to do with the dissemination of the disease. In cities, the extension of an epidemic from centres, resulting from the importation of cases, or fomites, is usually quite gradual and independent of the prevailing currents of air. The Board of Experts appointed by Congress to investigate the epidemic of 1878 arrived at the following conclusion:

"We know of no instance, either from our own observations or from the published records of yellow fever, in which it has been established that the disease has been carried to any considerable distance by atmospheric currents, or by any modes or vehicles of conveyance other than those connected with human traffic and travel."

In the comparatively small and land-locked harbor of Havana, vessels which anchor some distance from shore, and which are kept in a good sanitary condition, do not suffer from yellow fever, unless unacclimatized members of the crew are permitted to go on shore. Vessels lying at the wharves, on the contrary, are very likely to become infected.

There are, however, numerous instances in which vessels have become infected from the shore, or from other vessels, or in which yellow fever has appeared in places lying to the leeward of infected vessels, in which the transmission of the disease has been ascribed to the agency of the wind. It is difficult to decide to what extent this explanation is correct, for we would have to be sure that no direct communication had occurred before accepting it; and the possibility that the infection may be conveyed to the shore by infected articles thrown overboard, in the case of infected vessels anchored to the windward of healthy places, must be borne in mind.

PROPHYLAXIS.—What has been said as to the etiology of yellow fever indicates clearly enough the measures of prophylaxis to be relied on in localities subject to invasion. These are: (a) Exclusion of the contagium of the disease by the sanitary supervision, at the port of departure, of ships sailing from infected ports, and their thorough disinfection at the port of arrival, when there is evidence, or a reasonable suspicion, that they are infected; (b) the establishment of quarantine stations, and, so far as practicable, in sparsely-inhabited places; (c) the disinfection of vessels, and of the clothing and bedding used by the sick, and of localities into which cases have been introduced, or which have become infected in any way; (d) depopulation of infected "localities," the removal of all susceptible persons whose presence is not absolutely necessary for the care of the sick.

The rigid quarantines of former days, which proposed to exclude the disease by detaining ships and passengers at a quarantine station for a fixed period of time after their arrival, irrespective of the sanitary conditions, and if yellow fever occurred on board, to quarantine the vessel for a further number of days after the occurrence of the last case, has been found unreliable, and has been generally abandoned. The modern method of exclusion, which relies upon the sanitary supervision of the ship at the port of departure, and, as far as practicable, while in transit, and upon isolation of the sick and disinfection of the vessel, when cases of yellow fever have occurred on board, at a quarantine station provided with the appliances for doing this in an effective manner, has proved far more successful. Reliance upon a time quarantine is unsafe, for the reason that the vessel may remain infected for an indefinite period of time after the occurrence of cases on board, or even independently of any case, if she has been at the wharves of an infected port. No more cases occur after all of the passengers and crew, susceptible to the disease, have suffered an attack, and it may happen that there are no susceptible persons on board; but the vessel is none the less infected and dangerous to the inhabitants of the port which admits her to pratique without a thorough disinfection. On the other hand, if we are to trust to the measures indicated, the sooner they are put into execution the better.

Depopulation of infected ports or towns, when yellow fever makes its appearance during the epidemic season, is a measure of great importance, which should be carried out, when practicable, under proper medical supervision. It has often happened, especially upon naval vessels, that the well are retained upon the infected ship, and the sick sent to a hospital on shore, under the idea that the chief danger lies in contact with the sick. This is a serious mistake, and has resulted in the loss of many lives. In the United States Army it is well understood that all susceptible well persons are to be removed to a locality actually as soon as yellow fever is known to have attacked an individual in quarters occupied by troops. It has been found by experience that a move into camp checks the progress of the disease among the garrison, although this may be established but a few miles from the infected barracks.

In the case of towns in a secondary position as to invasion by the disease, depopulation often occurs in a way which is most disastrous to other communities. It very often happens that the nature of the disease is not at first recognized by the physicians; and when recognized the hope is entertained that it will not become epidemic, until a considerable mortality, or the death of some prominent citizen, arouses the fears of the people and a general "stampede" occurs. The attempt has often been made to restrain the people of an infected town by means of a "sanitary cordon," composed of armed guards. This procedure is not only inhumane, so far as the susceptible inhabitants of the place are concerned, whom it is proposed to compel to remain within the infected area, but it is as a rule futile; for when a frightened man desires to escape from an unseen enemy, it is difficult to keep him in a place not surrounded by insurmountable walls, or by an impassable barrier of some kind.

At the International Sanitary Conference at Rome (1885), the following resolution was adopted, with a single dissenting voice—that of the delegate from Turkey:

"6. Land quarantines and sanitary cordons are useless."

This related, it is true, to cholera; but it applies as well to the case of yellow fever. Another resolution, adopted at the same conference, is to this effect:

"8a. The measures recommended against cholera are, in general, applicable to yellow fever and to other diseases which prevail in epidemic form, under the influence of bad sanitary conditions, and which are transmitted by human intercourse.

"The most effective measures for preventing the propagation of diseases of this class are:

"The sanitary improvement of cities and of vessels sailing from infected ports, isolation of the sick, and disinfection of infected or suspected articles and localities."

In yellow fever we require, in addition to this, depopulation of the infected localities, whenever it is practicable, and this should be effected systematically, and with due precautions to prevent the transportation of infectious material to other places.

Of all measures of prophylaxis those which relate to the sanitary improvement of cities and towns liable to become infected are perhaps the most important. Municipal hygiene has made great strides since the early part of the present century, and it is probable, to this fact more than to any other, that certain northern cities which formerly suffered severely from yellow-fever epidemics, owe their long immunity from such visitations—e.g., New York and Philadelphia.

Individual prophylaxis requires the individual, first of all, to avoid infected localities. If it is absolutely necessary for a susceptible person to visit a place where yellow fever is prevailing, or to remain in one in which it has effected a lodgement, he should observe the following precautions: Keep away from low-lying and filthy portions of the city; avoid the vicinity of the wharves, and all localities known to be centres of infection, especially at night; sleep as far from the ground as possible; avoid excesses of all kinds, and especially in the use of alcoholic drinks; keep out of the sun during the hottest part of the day, and be careful not to become overheated by violent exercise; avoid constipation.

With reference to the method of prophylaxis by inoculation, practised in Brazil by Dr. Domingos Freire and in Mexico by Dr. Carmona y Valle, the writer, after a careful examination, has reported officially that:

"There is no satisfactory evidence that the method of inoculation practised by Dr. Domingos Freire has any prophylactic value."

"The claims of Dr. Carmona y Valle, of Mexico, to have discovered the specific cause of yellow fever have likewise no substantial basis; and he has failed to demonstrate the protective value of his proposed method of prophylaxis."

THE PERIOD OF INCUBATION in yellow fever does not usually exceed four or five days, and may be less than twenty-four hours. Instances of a much longer period of incubation have been given by various authors—some as long as six weeks or two months—but we are satisfied that these are due either to error in diagnosis or to the fact that the cases result from the establishment of a new and unrecognized source of infection. Those who believe that the disease is only communicated by personal contagion naturally date the exposure to the latest date when such personal contact was possible. Thus, when a first case occurs on a ship at sea two or three weeks after leaving an infected port, the period of incubation is supposed to be at least this long. On the contrary, the attack is due, in all probability, to the fact that the ship is infected, and the first case will probably be quickly followed by others which have no direct connection with it, but result, as it did, from exposure on the infected vessel. Instances of an attack occurring within twenty-four hours after arrival in a city where the disease was prevailing as an epidemic, are numerous and well authenticated. Dr. Rush says, in his account of the epidemic of 1793: "The seeds of the disease, when received into the body, were generally excited into action in a few days. I met with several cases in which they acted so as to produce a fever on the same day on which they were received into the system." During the epidemic at Gibraltar, in 1804, strangers were in several instances attacked on the second or third day after landing, and some are said to have been seized on the first day. According to Drs. Pariset, Balby, and François, the period of incubation at Barcelona, in 1821, appeared very short. "We have," they say, "very strong reasons to suspect, and these reasons are founded on facts, that this period does not exceed twenty-four hours, or three days at most" (La Roche).

In the epidemic at Fort Barrancas, Fla., in 1875, the writer had an opportunity to fix the limits of the period of incubation. The whole garrison was exposed in the infected locality, and a number of cases had occurred, when the command was removed into camp in a healthy place across the bay—near Fort Pickens. On the day following the removal seven cases were sent back from the camp for treatment in hospital. The next day eleven cases came from the camp; the following day, two, and the fifth day, two. The remnant, consisting of forty-eight individuals, remained in good health until a month later, when two cases again occurred in camp. We do not believe that these two cases represent a prolonged period of incubation, but suppose that in the interval the camp had also become infected.

It is proper to state that several authors, who have had great experience, believe that the period of incubation may be extended to fourteen, or even more days—Blair, Rush, Féraud.

Clinical History.—As a rule, an attack of yellow fever is not preceded by any well-marked *premonitory symptoms*. The attack may occur at night in one who went to bed in his usual state of health, or in the early morning after an uninterrupted sleep, or during the day while engaged in ordinary occupations. In other cases there is a feeling of lassitude and discomfort for two or three days prior to the attack, with loss of appetite, slight pain in the back and loins, a feeling of giddiness or slight headache, flatulent eructations, constipation, a tendency to perspire at night, or upon very slight exertion, and more or less muscular debility, together with a disinclination for any mental exertion.

Dr. Wragg, who had charge of the Roper Hospital at Charleston, during the epidemic of 1854, made particular inquiries with reference to premonitory symptoms, and states that "out of a total of 225 cases the attack was sudden in 92; in 32 it came on insidiously, the patient complaining of malaise, etc., for a considerable time; and that 101 offered the usual symptoms characterizing the approach of fever."

The attack is commonly inaugurated with a more or less decided *chill*, which by its violence and duration affords some indication of the probable severity of the case. In certain grave forms of the disease, however, the onset is insidious, and is not marked by any perceptible chill. In a considerable proportion of the mild cases, also, especially in the tropics, there is no rigor, and the patient experiences, at most, only a slight sensation of coldness, which quickly gives place to that of heat. If a thermometer is placed in the axilla during the initial chill it will be found that the temperature is already considerably above the normal, and very frequently it reaches the highest point attained during the entire attack within a few hours from its inception.

Accompanying the chill are other nervous phenomena, similar in kind to those attending the onset of other specific febrile diseases. There is *cephalalgia*, often very severe, and located by preference in the forehead and supra-orbital region; the eyeballs also are painful, and there is intolerance of light in some instances. *Pain in the loins* is a very constant and early symptom, which occasions much distress, and sometimes extorts groans and cries from the patient. At the same time pain is usually experienced in the lower extremities, often of a very severe character, constituting the *coup de barre* of the French authors; it affects especially the calves of the legs, the knees, and the ankles. These symptoms continue, and are even aggravated, after the rigor has passed and the febrile stage is fully developed; in the meantime, the *face* becomes flushed, and sometimes deep-red and swollen in appearance; the *eyes* are shining and suffused, the conjunctivæ more or less hyperæmic and often deeply injected, in severe cases presenting a fiery, inflamed appearance which is accompanied by photophobia; the *skin* becomes hot and dry, and there is apt to be, especially in patients of a nervous temperament, great *restlessness* and *jactitation*.

Systematic authors have described numerous varieties of the disease, but these are for the most part simply different grades in the degree of severity, or depend upon individual peculiarities and complications. Yellow fever is the same in all parts of the world where it occurs, and every great epidemic furnishes examples of the several varieties which have been described. It will suffice here to mention the classification adopted by one or two standard authors. La Roche gives an account of the clinical history of the disease under the following headings: Inflammatory species, including three grades, intense, mild, and ephemeral; congestive species, including four grades, aggravated, adynamic, walking, and apoplectic. Bérenger-Féraud, in his elaborate account of the disease as it prevails at Martinique, classifies the cases as follows:

1st Degree.—Mild yellow fever.

2d Degree.—Yellow fellow of moderate intensity; A, cases in which the onset is frank; B, cases in which it is insidious.

3d Degree.—Grave yellow fever; A, ordinary forms, including the gastric, adynamic, ataxic, congestive, and typhoid forms; B, rare forms, including the hyperæsthetic, gangrenous, algid or choleraic, and hydrophobic.

4th Degree.—Yellow fever *sidérante*.

Different epidemics are sometimes characterized by the predominance of one or the other of the forms described, and the character of the disease, as to severity, often varies greatly during the same epidemic. The earlier cases are sometimes mild and the mortality small, while later the greater intensity or malignancy of the poison is shown by the occurrence of a large number of cases of the severest grade, and even of those rapidly fatal attacks denominated by the French *sidérante*.

It is evident, from the account given of the symptoms manifested at the outset of an attack, that these are not sufficiently characteristic to determine the nature of the disease, and in the absence of a prevailing epidemic its early recognition will depend largely upon other facts relating to the antecedents of the patient, etc. The complete clinical history of a case, however, gives a tableau which is easily recognized by one who is familiar with the disease. In this clinical history the thermometric observations form a very important item.

Yellow fever is a disease of a single febrile paroxysm, lasting from forty-eight hours to seven or eight days—more commonly from three to five days. The acme of temperature is reached at the outset, and from this time the temperature line is a descending one, interrupted sometimes by a slight evening exacerbation, up to the termination of the first period of the disease—*febrile stage*. The second stage is characterized by great prostration of the vital powers, and lasts from a few hours to two or three days—*stage of calm*; the temperature during this stage sometimes remains a degree or more above the normal, but more commonly it is normal, or even subnormal for a time. This is followed in severe cases by a *reactionary fever* of irregular duration which presents a more or less remittent character. These features are shown in the accompanying temperature charts.

Naturally the typical temperature curve is disturbed by complications—visceral congestions, abscesses, parotitis, etc. It is also disturbed by indiscretions in diet, over-active medication, and by moral causes (especially fright and grief). In mild cases the acme of temperature is reached during the first two or three hours of the attack. In more protracted and severe cases it is not reached until the second or third day, rarely later. In an analysis of [illegible] cases recorded by [illegible], and myself, the acme was reached on the first day in [illegible], on the second in [illegible], on the third in [illegible], and on the fourth in [illegible]. The temperature rarely, if ever, exceeds 108°. The highest temperature recorded by Faget was 107.2°. Thomson, in a total of [illegible] cases occurring at Memphis, noted a temperature of 108° in a single instance. With

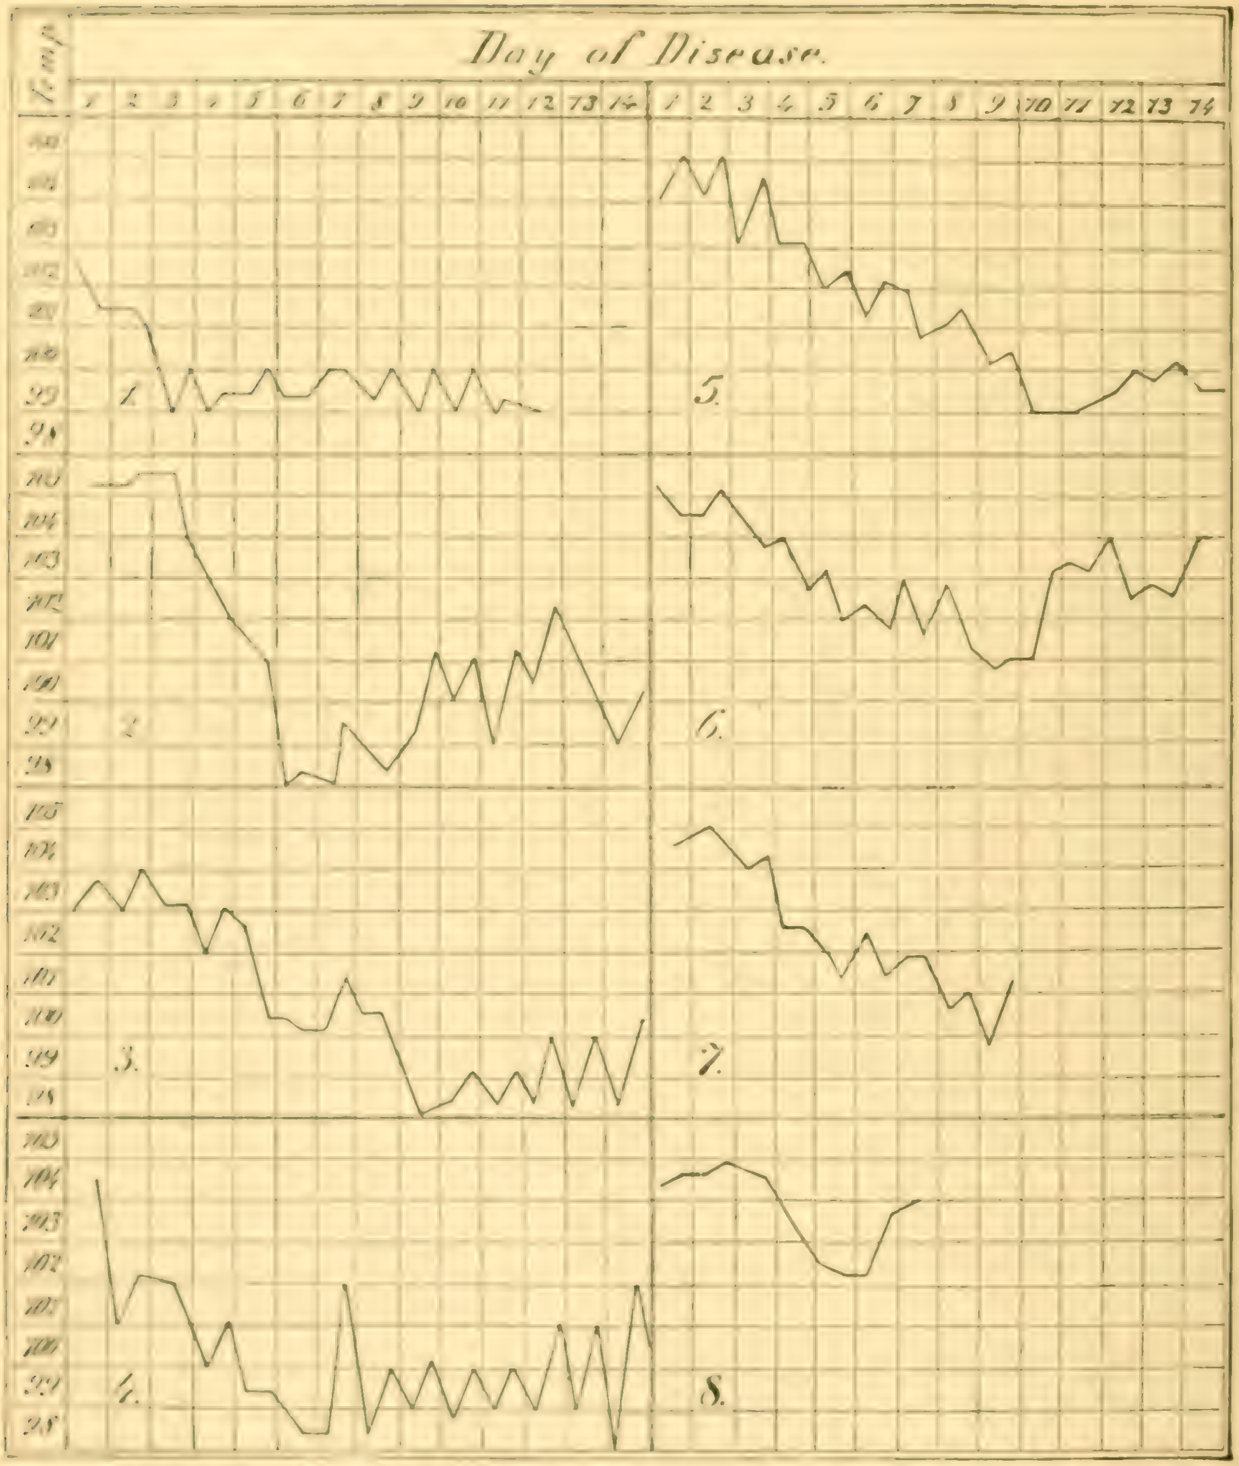

FIG. [illegible].—Temperature Curves of Yellow Fever. 1. Mild case ([illegible]); male aged [illegible]; Fort Barrancas, Fla., 1873 (Sternberg). 2. Typical severe case; recovery; male aged [illegible]; Fort Barrancas, Fla., 1873 (Sternberg). 3. Protracted mild case; recovery; male aged 27; Fort Barrancas, Fla., 1873 (Sternberg). 4. Typical case of moderate severity; recovery; male aged [illegible]; Fort Barrancas, Fla., 1873 (Sternberg). 5. [illegible] (Sternberg). 6. Typical severe case; protracted; death on [illegible] day (Sternberg). 7. Fatal case; death on [illegible] day; male aged [illegible]; Fort Barrancas, Fla., 1873 (Sternberg). 8. Fatal case; "*[illegible]*" (Sternberg).

this exception, 106.5° is the highest temperature recorded by him. In my own observations 106 has been the highest temperature noted. The temperature often rises rapidly just before death, and a very high post-mortem temperature (108° to 110°) is a common phenomenon.

In certain cases the initial paroxysm is divided, by a more or less complete remission, into two or more distinct periods of from two to four days' duration. These cases, which possibly depend upon a malarial complication, are not sufficiently numerous to require a modification of the general statement that yellow fever is a continued fever of a single paroxysm. In relapses, which may occur from imprudence at any time after the termination of the first febrile paroxysm, the characters of the initial paroxysm are repeated, but in non-fatal cases the duration is usually not so long.

The *pulse* in sthenic cases is full, strong, and hard at the outset of the attack, and may reach 120 or more pulsations in the minute, more commonly not more than 100 to 110. It diminishes in rapidity and force as the disease progresses, and this occurs even when the febrile heat is not reduced for two or three days, and is considered by Faget a valuable diagnostic sign. During the second stage of the disease, the pulse, however hard and accelerated it may previously have been, becomes preternaturally slow and soft. The feebleness of the heart, which seems to suffer especially from the action of the yellow fever poison, and which has undergone a certain degree of fatty degeneration, is shown by this very compressible and slow pulse, which is often reduced to forty, and sometimes even to thirty, beats per minute. This constitutes a very characteristic feature of the disease, and affords an important indication for treatment during the period of depression, or "calm."

The *tongue* is sometimes but slightly coated at the outset, and is usually moist ; generally it quickly becomes covered with a white coating, which may be in streaks ; the margins as a rule remain red ; very commonly the tongue is narrow and pointed, differing in this respect from the broad, flabby tongue of the malarial fevers. In the progress of the disease it often becomes dry, and the coating assumes a brownish color, or it may become very foul and loaded with sordes.

The *face* is at first flushed or bright red and swollen, or it may be of a dusky violet hue ; this, with the deep-red suffusion of the eyes in severe cases, is quite characteristic. The countenance often has an expression of anxiety or pain, or of dejection ; again it may appear dull and indifferent.

In the last period of the disease, in fatal cases, the features become shrunken—sometimes bloated and flabby—the brows are often contracted, and the eyes sunken, with ecchymosed lids.

The hyperæmia of the conjunctivæ in mild cases may be temporary, in the more severe ones it is apt to last through the first period, and in quickly fatal cases the eyes may be deeply injected throughout. Usually, by the third day a careful inspection will show that the conjunctivæ have a yellowish tinge which becomes more intense as the disease progresses.

The *skin* is hot and dry in some cases throughout the first period ; in others it soon becomes moist and there is a tendency to free perspiration, which is readily induced by covering with blankets, warm drinks, etc. Even in those cases in which the skin is hot and dry, the termination of the first period is marked by a soft, cool, and usually moist surface. In exceptional cases the skin remains hot and dry up to the fatal termination. When death occurs in the stage of depression, the surface becomes cold and often is covered with a clammy sweat. Many authors have spoken of a peculiar odor given off from the surface of yellow fever patients, and various attempts have been made to define its character by comparison with other known odors. Dr. Rush said that it resembled that of "the washings of a gun." Dr. Jackson describes it as "sickly and faint, and not unlike the smell of a fish-market."

The color of the skin, which has given name to the disease, is not always seen, but usually a yellow discoloration begins to make its appearance toward the end of the first period, and later becomes more intense, lasting for some time after convalescence is established. It varies much in intensity, from a slight yellow tinge to a deep orange or saffron color. In certain cases the skin presents a mahogany color, or that of bronze. In fatal cases the yellow color is developed immediately after death, even if it has not been very noticeable before dissolution took place.

The proportion of cases in which this yellow color of the skin is observed varies greatly in different epidemics, and even in different periods of the same epidemic. Dr. Rochoux states that in the West Indies it is absent in about half of the cases that recover. Bérenger Féraud, referring to this statement, says that there are in fact two kinds of icterus in yellow fever, the one due to blood pigment, denominated by Professor Gubler *hémaphéique* ; the other to bile pigments, and called by the same author *biliphéique*. The first is considered by Féraud to be constant and characteristic ; it occurs at a time when the urine is albuminous and free from bile, and manifests itself about the beginning of the second stage by a yellow tinge of the conjunctivæ, of the face, and of the skin over the great vessels. It coincides with the period during which the hæmorrhagic tendency of the disease manifests itself. The other form of icterus appears at the end of the second period, or during convalescence, at a time when the urine contains a notable quantity of bile pigments ; it gives rise to the deep orange or saffron color of the skin which is so striking, but which only occurs in a certain proportion of the cases, and cannot be considered an essential character of the disease. We are disposed to think that Feraud is quite right in this account of the icterus of yellow fever. A slight yellow discoloration of the conjunctivæ can commonly be detected during the second stage, even in mild cases in which no discoloration of the skin is perceptible.

Various skin eruptions have been described as occurring occasionally, but there is nothing characteristic about any one of them unless it is the erythematous eruption about the scrotum which Bérenger-Féraud believes to be pathognomonic of the disease. Other eruptions mentioned as occurring occasionally are petechiæ, vesicular and pustular eruptions, livid spots and vibices, erythematous patches about the knees and elbows, or a general erythematous eruption, papular eruptions, pustules about the mouth, furuncles, etc.

The *urine* in yellow fever, even during the first period, is reduced in amount below the normal standard. This marked reduction, and in fatal cases very commonly complete suppression, is a notable feature of the disease.

The presence of albumen in greater or less amount, is a symptom which is so constant that it has come to be generally accepted as one of the pathognomonic features of the disease.

The diminution in the amount of the urinary secretion in connection with the amount of albumen present is of importance in a prognostic sense, as it is to a certain extent an index of the gravity of the attack.

The most marked diminution occurs during the stage of depression, and the few ounces secreted in the twenty-four hours, in severe cases, are loaded with albumen to such an extent as to form coagula which occupy one-half to two-thirds of the contents of the test-tube.

In a series of observations made at Fort Barrancas, Fla., in 1875, to ascertain the amount and specific gravity of the urine in non-fatal cases of yellow fever, the writer arrived at the following results.

The *amount*, considered in connection with the *specific gravity*, is, of course, an index of the total solids excreted. In the table we have eliminated from the specific gravity column the constant factor, 1,000. The amount for the first day is no doubt too small, on account of the urine having been only partly collected. It will be noted that the amount increases, while the specific gravity diminishes, from the outset of the attack up to the time of complete convalescence.

Taking the average of eleven non-fatal cases, I obtained the following results:

	Amount.
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

It will be seen that the product of the amount, multiplied by the specific gravity, is tolerably uniform from the third to the twelfth day, and that this uniformity is preserved by a daily falling off of the specific gravity to compensate for the daily increase in quantity. To determine the product of amount multiplied by specific gravity in patients convalescent from yellow fever of a later date, I had the urine passed by sixteen convalescents, on full diet, who had been out of bed from ten to twenty days, preserved and measured. The result was that the average of amount, multiplied by the specific gravity for the sixteen cases, was 981—a product but little in excess of that obtained during the continuance of the fever when the patients were taking no food. The figures in the table may then be taken as representing, approximately, the normal quantity of urinary solids which should be excreted daily during the progress of an attack of yellow fever; and if the amount falls materially below these figures, defective excretion may be presumed, and treatment and prognosis governed accordingly.

In mild cases, only a slight trace of albumen may be found in the urine for a day or two, but usually the deposit is sufficiently abundant after the second day to leave no doubt as to its character. It becomes more abundant at the termination of the first stage, and in severe cases throughout the stage of calm, at which time suppression is very liable to occur, especially if, as a result of exposure, the cutaneous transpiration is checked. The early appearance and abundant presence of albumen is generally regarded as an evil prognostic. The reappearance of albumen, after it has once disappeared, indicates a relapse.

The amount of urea eliminated by the kidneys is less than normal, and in inverse proportion to the severity of the attack. According to Corlisle, the quantity is generally in proportion to the amount of urine secreted, and when the amount increases it is a favorable symptom. Uric acid is also said by this author to be present in diminished quantity, but in much less proportion than the urea. He says: "We have seen urine, containing only seven grams of urea per litre, give a relatively abundant deposit of uric acid." Bile pigments usually appear in the last days of sickness, and their presence is generally considered a favorable prognostic sign. In exceptional cases the urine may contain blood, from renal or vesical hemorrhage. The urine in yellow fever almost invariably presents a decided acid reaction.

The symptoms connected with the nervous system are varied. In mild cases the intellect remains undisturbed, and only a moderate amount of transient pain in the head and back marks the onset of the attack. In severe cases the frontal headache and rachialgia are most distressing, and may last throughout the first period of the disease. This stage is also one of great restlessness and jactitation; the patient sleeps but little, and his sleep is apt to be disturbed by distressing dreams; the mind often seems to be in a state of tension, the patient is watchful, excited, and anxious. In other cases the mind is calm, and in others, again, there is a condition of apparent apathy or indifference. Delirium is not a very common symptom in yellow fever, and the intellect often remains unclouded throughout, even in fatal cases. Some cases, however, are attended with incoherency of ideas, or hallucinations, and in some there is active delirium. More frequently the mind falls into a torpid condition; the patient is somnolent, and, when awakened, is disposed to be taciturn. A certain number of fatal cases are characterized by active delirium, followed by coma, and a greater number by coma gradually developed. In a limited number of cases death is preceded by convulsions, and occasionally tetanic symptoms of more or less general character have been noted. Among the nervous symptoms may be mentioned deep sighing respiration, sometimes of a suspirious character. Naturally the respiration is increased in frequency during the febrile stage. In the stage of calm it again becomes normal in mild cases, or rapid and spasmodic in those of a graver character.

There is complete anorexia during the first stage of the disease, but when the remission occurs patients are very likely to crave food, and even to insist upon having it. Thirst is a constant symptom during the febrile stage, and also in the second period, especially when there is frequent and copious vomiting—black vomit. The bowels are commonly somewhat constipated at the outset. In the second period of the disease there is apt to be more or less diarrhœa, and in fatal cases a dark fluid is often discharged from the bowels, resembling precisely that from the stomach. Occasionally there is a discharge of pure blood, the result of intestinal hemorrhage. A choleraic form of the disease is sometimes met with, in which there is profuse diarrhœa and collapse, similar to that in the algid stage of Asiatic cholera.

Symptoms connected with the stomach form a prominent part of the clinical history of yellow fever. The characteristic black vomit which has so much occupied the attention of medical authors, is for the vulgar the most striking feature of the disease, and even many physicians reserve their diagnosis in early cases during an epidemic until they have had ocular evidence that the vomited matter is black. The common name of the disease in Spanish countries—vómito—refers to this symptom. Yet in a majority of the cases there is no vomiting of black matter. Indeed, this is recognized as a very grave symptom, and although a considerable number of recoveries occur after the characteristic black vomit has been ejected, this may be considered an exception to the general rule.

Vomiting is a common symptom during the first period of the disease; sometimes the fluid ejected has a yellow color from the presence of bile, but more frequently it is colorless and consists only of the fluids ingested, containing, in suspension, a little mucus from the stomach; it is almost always acid. In favorable cases vomiting ceases with the first period of the disease; in those of a graver character, after an interval, perhaps, of twenty-four hours or more, during which there is more or less gastric distress—a feeling of weight and discomfort, vomiting again occurs, either of a clear acid fluid, or of one of the varieties of black vomit. At first the black material may be in the form of little flocculi suspended in a transparent fluid—"coffee-grounds vomit," and as the case progresses the amount of this material increases until the whole fluid appears to be uniformly black. Upon allowing it to stand, however, it will be seen that it still consists of a clear liquid with the black matter in suspension. Upon microscopic examination it will be found that the colored material is made up of little masses which are not black, but have a yellowish-brown color. A careful examination of recent specimens shows that these little masses contain decolorized and more or less deformed red blood-corpuscles, also granular leucocytes, and that the brown matter is diffused about these agglomerated cellular elements, and the matrix of mucus in which they often seem to be imbedded. There is no doubt that the black vomit is due to passive hemorrhage from the gastric mucous membrane, although this has been disputed by some recent authors—Freire, Carmona, others. Formerly it was maintained by some that the black matter was a secretion from the stomach, and by others that it was "altered black bile." I have myself repeatedly verified the fact by microscopic examination, that it contains the cellular elements of the blood. In certain cases there is vomiting of pure blood, resulting from more active gastric hæmorrhage. The black vomit is not always discharged during life, but it is extremely rare not to find it in the stomach after death.

The fact that the gastric mucous membrane is seriously involved in this disease is shown not alone by the vomiting, the passive hæmorrhage, and the post-mortem appearances, but also by the constant feeling of discomfort or pain in severe cases, and by a marked tenderness upon pressure over the epigastrium.

Hæmorrhage may occur not only from the mucous membrane of the stomach and intestine, but also from that of the mouth, nose, bladder, and uterus, and even from the eyes or ears. In some epidemics epistaxis is quite common; it may occur during the first period of the disease, but is more frequent during the second, at which time the general tendency to hæmorrhage is developed. Next to epistaxis, hæmorrhage from the buccal mucous membrane, and especially from the tongue, the gums, and the lips, is the most frequent.

In mild cases of yellow fever, *convalescence* is quickly established. Instead of the usual depression which marks the second stage of the disease, the patient, after a fever of three to five days' duration, may enter almost immediately into convalescence, and within a week may be ready to resume his usual avocations. But in severe cases, convalescence is often slow and may be interrupted by various *complications*—parotitis, buboes, furuncles, abscesses, hepatitis, diarrhœa. In the army, experience shows that but few of those attacked are able to resume their duties in less than ten days, and a considerable number remain in hospital from thirty to fifty days. Blair found the average number of days, during which patients were retained in hospital after convalescence was established to be 6.55 for mild cases, and 7.91 for grave cases.

Relapses occur for the most part during the early period of convalescence, or before it is fairly established; they are generally regarded as even more dangerous than the first attack. Occasionally a relapse, or second attack, occurs as late as from two to four weeks after the termination of the febrile period of the first attack.

PROGNOSIS.—The prognosis in yellow fever should always be guarded, for not only is it a very fatal disease in its severer forms, but cases which appear mild at the outset may suddenly assume a grave character. It is more favorable in the case of women and children than with men, and is especially unfavorable in those of intemperate habits, and in plethoric persons who have recently arrived in the infected locality. The principal guide in forming a prognosis at the outset of a case is furnished by the temperature observations. When the body heat does not go above 103° to 103½° F. during the first two days, a favorable result may be anticipated. Later, the amount and character of the urinary secretion is the most important prognostic indication. When this is scanty and heavily loaded with albumen, the case is very grave, although the general appearance of the patient may be favorable, and he may insist that he is "all right" and wants something to eat. On the other hand, hopes of a favorable issue may be entertained even in cases characterized by great prostration, and in which the hæmorrhagic tendency is pronounced, if the urinary secretion is tolerably abundant and the quantity of albumen small. The throwing up of black vomit is by no means a fatal sign, but as a rule the passive hæmorrhages which occur during the second stage of the disease are of grave import. Epistaxis occurring during the first stage has been considered by some authors a favorable event (?).

The early appearance of jaundice is an unfavorable sign; as is also frequent vomiting, and great distress and tenderness in the epigastric region. Intense and long-continued injection of the conjunctivæ, giving the eyes a fiery-red color, is unfavorable. Delirium, great restlessness and jactitation, and sighing respiration, are all symptoms which give reason for anxiety as to the result.

The prognostic indications as furnished by temperature observations are shown in the following table, made by the writer, some years since, from a series of cases in which a complete and careful record had been made:

Cases in which the temperature was	No. of cases.	No. of deaths.	[illegible]
107° and above	13	13	[illegible]
106° — 107°	9	9	[illegible]
105 — 106	[illegible]	22	[illegible]
104° — 105°	[illegible]	24	[illegible]
103 — 104°	[illegible]	6	[illegible]
102 — 103°	26	1	[illegible]
101° — 102°	15	[illegible]	[illegible]
Total	[illegible]	[illegible]	[illegible]

MORTALITY.—The mortality from yellow fever varies greatly in different epidemics and among different classes of the community.

Among the natives of cities in which the disease is endemic, or in which it has frequently prevailed as an epidemic, it may be as low as from seven to ten per cent. One reason for this comparatively small mortality is found in the fact that a considerable proportion of the cases in such a community are among children. Among unacclimated adults the mortality ranges from twenty to sixty per cent., and under certain circumstances even exceeds the latter figure. In the great Philadelphia epidemics of the last and the beginning of the present century, the mortality was from twenty to eighty per cent. In the French Antilles, according to Dutrouleau, the mortality during the years 1851 to 1857, inclusive, ranged from 12.9 per cent. to 50 per cent. Blair gives the mortality at the Seaman's Hospital at Georgetown (Demerara) in 1838 as 19.5 per cent.

At Vera Cruz the mortality for seven years (1875–1881), according to Dr. Molina's statistics, was 41.78 per cent. in the hospital for men, and 41 per cent. in the hospital for women. In Rio Janeiro the mortality for the year 1870 was 17.4 per cent. In the epidemic of 1873, it was 23.3 per cent.

The mortality among the Spanish troops in Cuba, according to the statistics of Dr. Bastarreche, was, in the year 1855, 24.31 per cent., and in the royal navy 17.8 per cent.

Dr. Bemiss gives the mortality-rate for the city of New Orleans, during the great epidemic of 1878, as 16.66, and classifying the cases according to age, has constructed a table which we have used on a preceding page (page 52).

The day of death is given by Bérenger-Féraud as follows, in a total of 1,059 cases occurring in the French Antilles:

Died on the second day, 16 = 1.5 per cent.; third day, 56 = 5.3 per cent.; fourth day, 141 = 13.4 per cent.; fifth day, 165 = 15.7 per cent.; sixth day, 177 = 16.9 per cent.; seventh day, 151 = 14.3 per cent.; eighth day, 89 = 8.5 per cent.; ninth day, 42 = 3.9 per cent.; tenth day, 35 = 3.3 per cent.; eleventh day, 28 = 2.6 per cent.; twelfth day, 34 = 3.2 per cent.; thirteenth day, 25 = 2.3 per cent.; fourteenth day, 21 = 1.9 per cent.; fifteenth day, 8 = 0.7 per cent.; sixteenth day, 7 = 0.6 per cent.; seventeenth day, 13 = 1.2 per cent.; eighteenth day, 6; nineteenth day, 6; twentieth day, 7; twenty-first day, 3; twenty-second day, 2; twenty-third day, 5; twenty-fourth day, 3; twenty-fifth day, 3; twenty-sixth day, 5; twenty-seventh day, 1; twenty-eighth day, 1; twenty-ninth day, 2; thirtieth day, 1; thirty-first day, 3; thirty-second day, 1; thirty-third day, 1; thirty-sixth day, 1. This table shows that sixty-seven per cent. of the whole number died during the first week, and eighty-two per cent. during the first ten days. In a similar table constructed by Dr. Clements, of the United States Army, out of a total of 111 fatal cases, death occurred, during the first week, in seventy-three per cent.; during the first ten days in eighty-two per cent.

DIAGNOSIS.—Notwithstanding the well-marked features of a typical case of yellow fever it very often happens that the early cases in an epidemic are not recognized, and even in fatal cases, with the assistance of an matoms, objections are practically common with the disease often called mild the diagnosis. At the outset of an attack, indeed, there is nothing sufficiently characteristic in the symptoms to enable one, as a rule, to decide definitely that the case is yellow fever, although there are certain indications which may give him a strong suspicion that it is. The frontal pain, flushed face, gastric distress, injected conjunctivæ, pains in the back, etc. When such a case occurs during the epidemic prevalence of yellow fever, in a stranger, or in one not acclimated, the inference naturally is that the individual has yellow fever; but this inference is sometimes mistaken, and more than one stranger is sent to the yellow fever hospital—himself who is, to his surprise, was later found to have some other febrile complaint, sometimes one of the eruptive fevers. A case in one of our own seaports, having with precisely the same symptoms occurring at a time when yellow fever was not prevailing, would almost infallibly be pronounced "remittent fever," or "bilious fever," or "congestive fever," as soon as it was evident that it was not one of the specific eruptive fevers. And that diagnosis would very probably be maintained, if no evidence could be found that the individual had been exposed to yellow fever, even if the further clinical history of the case corresponded with that of this disease. It is in this way that outbreaks of cases occurring in the practice of several different physicians at the outset of an epidemic are frequently called by some other name.

The fact that the early cases in an epidemic are sometimes of a mild character adds to the liability to error. A man has a chill followed by fever, and receives in the next forty-eight hours several full doses of quinine; at the end of this time his fever has disappeared, and, with the exception of a certain amount of debility, and perhaps an irritable stomach, he feels quite well. The inference is that he had an attack of malarial fever which was cut short by the treatment; perhaps it was so, but the inference is the same in either case. I have seen cases in the hospitals of Vera Cruz, for example, in which there was a slight amount of albumen in the urine, and in which the depression and slow pulse following a single febrile paroxysm of brief duration seemed to me to be characteristic of a mild attack of yellow fever, but in which the diagnosis was malarial fever, and the brief duration of the attack was ascribed to the full doses of quinine which had been administered. I have seen precisely similar cases during the prevalence of an epidemic of yellow fever, in which no quinine was given, and in which, notwithstanding, the febrile paroxysm was of brief duration and did not return. For example, the case represented by chart 1, in Fig. 5068. This case by itself would not have been diagnosed as yellow fever, but occurring as it did, with several others of the same mild character, side by side with severe and fatal cases of this disease, I did not doubt that it was due to the same specific cause, and was in fact a case of yellow fever. The occurrence, in a southern seaport, of a group of cases of so-called malarial fever, in a particular locality, especially among the colored population, should always arouse suspicion and lead to investigation. When in such a city, or in any place within the limits of yellow fever invasion, and during the summer months, we hear that a "malignant form of malarial fever" has appeared in a certain limited area, a single house or square, or district, we shall not be apt to go wrong in the inference that the disease is yellow fever. Malignant forms of malarial fever belong to the country rather than to the city, and cases do not occur in groups, within city limits, where the malarial poison is not prevalent in its most intense form, if at all. Formerly, very much uncertainty as to diagnosis arose from mistaken ideas as to the etiology of the disease. A considerable number of physicians in the United States maintained that yellow fever and the malarial fevers are closely allied, if not identical, diseases, due to the same general causes, and the idea was very prevalent that, under the influence of meteorological conditions, a mild form of malarial fever might be transformed into the malignant yellow fever. Under this idea, physicians felt justified in calling the mild cases in an epidemic malarial fever, and in reserving the name yellow fever for those in which a yellow skin, highly albuminous urine, and black vomit would make up the classical triad to which they gave the name yellow fever. Of these three prominent features only one is a constant character which can serve in establishing the diagnosis in mild cases. This is the presence of albumen in the urine. At some period of the disease, even in the mildest cases, there will be a distinct trace of albumen in the urine, as shown by the usual tests, and this will generally be sufficiently abundant to leave no doubt in the mind of the observer as to the nature of the precipitate. In sixty-one cases occurring during an epidemic in Jamaica, Jackson found albumen present for the first time, in 2 cases on the first day; in 11 cases on the second day; in 19 cases on the third day; in 14 cases on the fourth day; in 9 cases on the fifth day; in 4 cases on the sixth day; in 1 case on the seventh day; in 1 case on the eighth day. It will be seen that, in by far the larger number of cases, the presence of albumen was revealed on the second, third, or fourth day. The value of this test in the differential diagnosis of yellow fever is indisputable. It is true that a trace of albumen is sometimes found in the urine of severe cases of fevers of malarial origin, but in cases of yellow fever of equal severity, as compared with these, the precipitate would, as a rule, be very abundant on the third or fourth day of sickness, forming a deposit to the extent of one-fourth to one-half the contents of the test tube, or even more. At the same time a microscopical examination would show the presence, in the urine, of numerous granular casts from the tubuli uriniferi. These are found also, although in a smaller number, in the urine of the milder cases during the second stage of the disease. For diagnostic purposes the character of the febrile paroxysm, and especially the phenomena following this which mark the second stage of the disease, are the most important. The characteristics of the temperature curve are sufficiently shown by the charts of typical cases in Fig. 5068. It must be remembered, however, that while the stage of depression is commonly marked by a normal, or even subnormal, temperature, in a considerable number of severe and fatal cases the temperature still remains a degree or two above the normal when the cool skin and slow, soft pulse would indicate, if the thermometer were not used, that there was complete apyrexia; or again the skin remains dry, and the patient falls into a typhoid condition with a fluctuating temperature, without having had a complete remission of febrile heat. The second stage of the disease is, however, commonly well marked in non-fatal cases, and is its most characteristic feature; the remarkably slow and soft pulse, the evident prostration of the vital powers, although the patient may be comfortable, and even cheerful, and desirous of getting up, or of taking food; the yellow tinge of the conjunctivæ and skin—not always present; the tenderness on pressure in the epigastric region, and often a feeling of weight and distress in this region, attended with intense thirst and vomiting of a transparent acid fluid, or of the characteristic black vomit; the tendency to passive hæmorrhage from the mucous surfaces of the mouth or nose, oozing of dark blood from the gums, or lips or sides of the red and fissured tongue; the scanty urinary secretion, and the presence of albumen, usually in considerable amount; all of these symptoms constitute an ensemble that for the practised eye and hand is unmistakable.

The differential diagnosis from bilious remittent fever, with which yellow fever has frequently been confounded, is not always possible at the outset of an attack, but the contrast in the complete clinical history of the two diseases is sufficiently striking. Remittent fever, as the name indicates, is characterized by periodical remissions of the febrile heat; this is, however, in severe cases often not well marked, so far as exact thermometric observations are concerned, and is rather a remission usually occurring in the morning, of the general symptoms—headache, vomiting, heat of surface, rapidity of pulse—than a decided lowering of the body heat, as shown by the thermometer placed in the axilla. But, as a rule, an attack of remittent fever is made up of a series of paroxysms, each of which may be inaugurated by a more or less distinct chill; while yellow fever is essentially a disease of a single paroxysm, in which, as shown by our charts, the acme of temperature is reached early in the attack, and the remission is characterized by a descending line extending often through a period of three or four days. In remittent fever, on the contrary, the fall attending the remission is an abrupt one. The tongue in remittent fever is usually heavily covered with a yellowish or brownish coating, it is broad, and often marked upon the margins by indentations made by the teeth, showing that it is swollen. In yellow fever the tongue is usually narrow and pointed, often tremulous; at the outset of an attack it may be comparatively clean, or it is covered with a thin, white, or heavy cottony coating—occasionally yellowish. The yellow color of the skin in bilious remittent fever, does not differ from that of simple jaundice, and is very persistent when developed; it is, however, far from being a constant symptom. The same is true of the jaundice which is occasionally developed during convalescence from yellow fever. But, besides this, there is a more or less pronounced yellow tinge of the conjunctivæ and skin in yellow fever, which appears during the latter part of the first, or early in the second, stage, and which in convalescence quickly disappears. In fatal cases this yellow color is more pronounced, and may assume a dingy brown or mahogany color; the dependent portions of the body after death have a livid, mottled appearance, and the discoloration resembles that following a bruise which has produced an effusion of blood. In the malarial fevers the spleen is more or less swollen and tender, while in yellow fever it is not involved. In yellow fever the intellectual faculties are commonly unimpaired, at least during the febrile stage, and often up to the moment of the fatal termination; on the contrary, delirium is quite common in severe attacks of bilious remittent fever. In yellow fever vomiting of bilious matter is rare, and only occurs, if at all, at the outset of the attack; while later, the vomited matter consists of the fluids ingested, or of a transparent acid fluid containing flocculi of mucus, or of one of the varieties of black vomit; in remittent fever the vomited matters are nearly always colored with bile—indeed, bilious vomiting is commonly a marked feature of the disease. In remittent fever, according to La Roche, the quantity of uric acid in the urine is notably increased, being in some cases eight times as great as in health; in yellow fever it is diminished—the amount of urea is diminished in both diseases. Suppression of urine is extremely rare in bilious remittent fever, and extremely common in fatal cases of yellow fever; the uniform presence of albumen in the latter disease has already been noted. Finally, the marked hæmorrhagic tendency in yellow fever distinguishes this disease from bilious remittent fever.

There is a form of malarial fever, however—the so-called "hæmorrhagic malarial fever"—which is characterized by the periodical appearance of blood pigment in the urine, with sometimes a tendency to hæmorrhage from mucous surfaces. This is the *fièvre bilieuse mélanurique* of the French authors. The clinical history of this disease differs entirely from that of yellow fever. The distinguishing characters are given by Bérenger-Féraud as follows:

"Prolonged residence in a malarial country is the most powerful and, indeed, indispensible predisposing cause.

"The disease is always preceded by numerous attacks of malarial fever, simple at first, then more and more complicated, and taking in general more and more of a bilious aspect, producing a very decided anæmia.

"Icterus appears at the outset of the attack, and is never wanting; it gives from the commencement and throughout the attack a uniform yellow color to the patient, varying from greenish-yellow to a decided yellow ochre.

"The march is intermittent or remittent from the first, and the pulse, urine, and vomiting follow very exactly the variations of temperature. . . .

"The vomiting is bilious, of a decided green color; it is a constant symptom at the outset of an attack, it is arrested with the termination of one attack to reappear with the next.

"After the first, or febrile, period the vomiting continues, but preserves the same characters; it stains linen a bright green, and when collected in a basin it appears transparent, and is of a beautiful emerald green, or olive color.

"The tongue is moist, broad, covered at first with a heavy white fur, which soon receives a greenish tint from the vomited matters. The tongue is not red, either upon its tip or edges; it remains broad, heavily coated, and moist to the end of the malady.

"The urine is black from the commencement, and its color is characteristic, so that the patient himself is struck with it. It is usually abundant and frequently passed, and only has the melanuric aspect during the attack."

In malarial hæmaturia, as seen in this country, the urine varies in color according to the amount of blood pigment present, from a light red to a deep claret, or porter color. It is usually acid, and always albuminous. The presence of red blood-corpuscles has frequently been demonstrated by microscopical examination, and tube casts, made up of granular matter and red corpuscles, are often present in the urine. In the gravest form of the disease the patient falls into a typhoid condition, and at this time epistaxis is likely to occur, or there may be, in rare cases, hæmorrhage from the stomach or bowels.

The differential diagnosis between yellow fever and dengue will depend mainly upon the fatal character of the first-mentioned disease, the presence of albumen in the urine, and the hæmorrhagic tendency, as contrasted with the absence of these features and the skin eruptions and arthritic pains in the other. Dengue, like mild yellow fever, often terminates, after a febrile stage of forty-eight hours' duration, in complete apyrexia, and the patients are able to resume their ordinary occupations, although feeling stiff and sore when making any movement; more frequently there is a return of the fever, attended by a rubeoloid eruption, which ends in desquamation, and is accompanied with a return of the arthritic and muscular pains. This stage may last but three or four days, or may be of much longer duration; but in any case the disease is not attended with danger to life.

The *bilious typhoid* of Griesinger presents some points of resemblance with yellow fever, but the clinical and pathological features are sufficiently distinct to make it improbable that errors in diagnosis will occur when due care is taken.

Quite recently, Dr. Diamantopulos, of Smyrna, has given an account of a disease under the name *typhus icteroides*, which is said to be distinct from the bilious typhoid of the German authors, and which prevails upon the coast of the mainland, and upon the islands of the Ægean Sea. This name has frequently been applied to yellow fever, which the disease described resembles in many particulars, although no doubt distinct from it. It prevails in the summer and autumn. The attack begins with a chill, followed by fever, intense headache pain in back and limbs, jactitation, etc. The eyes are described as injected, glistening, and humid; the epigastrium is tender on pressure, the liver and spleen are more or less enlarged. There is a remission of the fever on the third or fourth day, and the second stage is inaugurated by a general improvement in the appearance and feelings of the patient; later (fifth or sixth day), icterus is developed; this is intense, giving to the whole surface a golden or orange-yellow color. Epistaxis is frequent in this stage, and hæmorrhage from the bowels, bloody urine, and petechiæ in certain cases, show that the disease has a hæmorrhagic tendency. It is said to prevail endemically, or as an epidemic, and to be miasmatic and not contagious. Perhaps this is the same disease as was epidemic on the island of Mauritius, in 1867, an account of which has been given by Pelleran in the *Archives de Médecine navale* (tome 36, 1881). This author, after stating that up to the year 1867, the opinion was generally entertained that malarial fevers did not exist in Mauritius, goes on to say that in 1807): "The effects were terrible, and so common that the sickness was ascribed to impregnation." One of the epidemics, quoted by Pelletan, gives the clinical features as follows: "The patient fell suddenly as when in perfect health, often after a full meal. The skin became hot, the face red, the eyes injected; the pulse mounted to 90 or 100; the skin became yellow, the tongue dry and glossy; precordial anxiety, accompanied by a small cough and exceedingly foetid pains; afterward followed intense prostration, with intolerable pain in the lumbar region and region of the liver. The poor patient, after twenty to thirty hours, died in a state of collapse closing a period of ... Another character of the fever was its tendency to relapse, to occur at all seasons of the year, in dry, elevated localities as well as in those which were low and humid, and to be accompanied by hæmorrhages."

It is evident that these fevers, if they prevailed in the same country as yellow fever, might give rise to confusion in the diagnosis, and also that our knowledge of the pathology of tropical fevers is far from being complete.

Many of the physicians practising in the French Antilles recognize a fever called by them fièvre inflammatoire, as distinct from yellow fever. Bérenger-Féraud has shown, however, that it is in fact identical with this disease, and only represents one of its grades of severity.

PATHOLOGICAL ANATOMY AND HISTOLOGY.—The exterior of the body of an individual who has recently succumbed to yellow fever presents an appearance which is quite characteristic. The icteric color of the skin, although often not too marked during the last hours of life, is developed in a large majority of the cases very soon after death. The color is that which is seen to follow a bruise in which there has been an effusion of blood, and the origin of the pigment is no doubt the same. The icterus from bile pigments, which occurs not infrequently during convalescence, and which may be seen in cases fatal from a relapse or at a late period of the disease, gives a uniform saffron-yellow color to the surface of the body and conjunctivæ. In the icteric discoloration of which we speak at present the color is not so intense and not so uniformly distributed. The depending portions of the body, and especially those subjected to pressure, have a deeper coloration, and are more or less livid and mottled from hypostatic congestion. Dutroulau has shown that this ecchymotic appearance of the back is due to position and pressure by placing the body upon the abdomen or side. In this case it is also the most dependent part which shows the livid mottled appearance referred to. The face and hands frequently appear congested, or the face may be livid and turgescent like that of one recently drowned. A little stream of black vomit is frequently seen trickling down from the corners of the mouth, or a similar fluid may escape from the nostrils, and the lips and gums may be soiled with dark blood which has oozed from them.

Cadaveric rigidity is quickly established and well marked.

The appearances observed upon removing the calvarium are usually those of hyperæmia of the brain and its meninges. The pia mater is almost always congested, and the vessels of the brain are commonly full of blood; the pons and medulla are generally in a condition of hyperæmia. There is more or less effusion into the subarachnoid space and in the ventricles; this is sometimes turbid and has a yellow color. The surface of the brain presents sometimes little hæmorrhagic points, and its substance, like the tissues of the body generally, has a more or less pronounced yellow tinge.

Dr. Schmidt, of New Orleans, has described certain pathological changes in the sympathetic ganglia, which he believes to be important. "In a majority of the cases examined by him the minute blood-vessels of the ganglia were found to be filled with blood-corpuscles. In two cases the ganglionic bodies of the first thoracic, as well as of the semilunar ganglion, had undergone granular degeneration. In the greater part of these ganglion-cells the nuclei had entirely disappeared, leaving no other trace but their outlines, which were very distinct. In the rest very faint outlines of the nuclei could still be observed. The bodies of all these ganglion-cells presented an indistinct appearance, and were characterized by a peculiar fatty lustre, even observed in specimens mounted in Canada balsam."

Usually the lungs present no evidence of pathological changes; occasionally they are congested and contain hæmorrhagic infarctions.

The fluid in the pericardium is often increased in amount and has a yellow color; in rare cases it contains blood. The heart is commonly paler than normal and, according to some authors, is often soft and friable owing to fatty degeneration of its muscular tissue (Riddell, Schmidt). This is denied by others (Crevaux, Guiteras, Gama Lobo). Woodward, who examined the material brought back by the Havana Commission of 1879, agrees with Guiteras that his sections did not present any decided evidence of fatty degeneration, but remarks: "This by no means proves that it does not occur in certain cases, perhaps in certain groups of cases."

Several of the most competent observers agree that there is a fatty degeneration of the walls of the small blood-vessels and capillaries of the various organs, and account in this way for the hæmorrhagic tendency of the disease. This is certainly a more rational explanation than the one so frequently offered, viz., that the hæmorrhages are due to the disorganized and diffluent condition of the blood. A moment's reflection should show that this explanation is insufficient, and that the blood, however diffluent, cannot escape so long as the vessels are intact. Ecchymotic points, or hæmorrhagic infarctions, are sometimes found upon the surface or in the substance of the heart, as well as in other muscles of the body and the organs generally. The cavities of the right side of the heart usually contain soft coagula or dark-colored fluid blood, and the right ventricle sometimes contains a more or less decolorized fibrinous clot.

The blood in yellow fever has been described by many observers as "completely disorganized" as to its histological elements. This is a mistake, as is shown by the numerous photo-micrographs made by the writer while in Havana, in 1879, from the blood of cases near a fatal termination. Both the red and the white corpuscles retain their normal appearance, and I have frequently seen the leucocytes undergoing their characteristic movements, even after twenty-four hours, in blood which had been preserved in culture-cells. In the days of bleeding numerous observers mentioned the fact that the blood does not coagulate readily, or forms a soft, loose coagulum, from which the serum does not separate. The same is true of the blood in the heart and large vessels after death; it is fluid and dark colored. Although there is no general destruction of the red corpuscles, it is probable that a considerable number of these elements perish in severe cases, for the serum contains free hæmoglobin, which gives it a yellow color, even as early as the third or fourth day. This yellow color is seen in the serum obtained from the application of blisters to the surface, and in blood drawn for microscopical examination. In blood obtained near the termination of a fatal case, and in post-mortem blood, this color is very pronounced, and increases in intensity by further solution of the hæmoglobin when the specimen is kept for a time; in the meantime the blood disks become paler than normal. In specimens kept in culture-cells I have observed the formation of beautiful crystals of hæmatoidin. This passing of the hæmoglobin into the serum, which is no doubt the cause of the yellow discoloration of the tissues in yellow fever, has been ascribed to the presence of bile. This view is not sustained by the chemical researches of Cunisset, a recent French author, who has arrived at the following conclusions:

"Yellow fever is not a poisoning by the bile; at the outset of the malady the biliary pigments are rarely found in the blood or in the urine. They appear generally only during the second period, and in a great number of cases they are not to be found at all.

"The biliary salts, to which the powerful action of 'cholæmia' admitted by certain authors might explain the disorders which the malady presents, do not exist either in the matters vomited, or in the urine, or in the blood, except, in certain cases, in very feeble quantity. In view of the profound alterations of the liver, this absence of the biliary salts is easily understood, and the defective depuration of the blood is to be looked upon as a complication rather than a determining cause of the malady."

Schmidt says: "The icterus in yellow fever is not owing to the presence of bile in the blood, as is believed by a large number of physicians, but to the presence of free hæmoglobin, and represents in truth the so-called 'hæmatogenous' jaundice. A 'hepatogenous' jaundice cannot take place, as the larger as well as the smaller hepatic ducts are found perfectly open, and as the secretion of bile during the disease, in the majority of cases, is rather diminished, or even suspended."

The white blood-corpuscles have seemed to the writer to be rather reduced in number toward the end of fatal cases; in specimens of blood mounted dry for microscopical examination they are frequently seen to contain one or more highly refractive granules, the exact nature of which has not been determined, but which I suppose to be fat. There are no micro-organisms present in the blood of yellow fever demonstrable by the usual methods of staining and microscopical examination, or by cultivation in the media commonly employed by bacteriologists.

The most important pathological changes in yellow fever are found in the organs contained in the cavity of the abdomen. The mucous membrane of the *stomach* is always found to be more or less hyperæmic; the congestion is commonly not general, but is confined to smaller or larger spots or districts, in which it is observed to proceed from one or more centres. From these centres it extends or radiates in a lesser degree, either gradually to be lost, or to pass over to another congested district. It is owing to this peculiarity of the congestion that it presents no uniformity of character, but is observed to spread irregularly over larger or smaller portions of the membrane (Schmidt). In addition to these congested patches, there are often to be seen small red patches resembling ecchymoses, but which, according to Schmidt, consist of "an unbroken network of minute vessels congested with blood, and identical with that network of large capillaries which surrounds the aperture of the gastric glands." Crevaux believes that a fatty degeneration of the cells which line the gastric glands and the capillaries of the mucous membrane is the most important lesion here. Other authors speak of an acute gastric catarrh as the process indicated by the appearance and histological examination of the mucous membrane; others again deny that there is any inflammation. My own examination of thin sections stained in various ways, shows that in a certain proportion of the cases there is evidence of inflammation, as shown by the presence of an unusual number of leucocytes in the submucous coat.

It has been asserted that the epithelium of the stomach undergoes fatty degeneration. This is denied by Schmidt. The dark fluid so often ejected during the last hours of life, known as *black vomit*, is almost always present in the stomach, in greater or less amount, after death. There is no question that the dark color is due to the presence of blood pigment, more or less changed by the acid secretions of the stomach. The best authorities everywhere are in accord on this point, which has, however, recently been called in question by Carmona, Freire, and Gibier. These gentlemen suppose the black pigment to be a product produced by the vital processes of a specific micro-organism. The two first-named authors base their opinion, that the color is not due to blood pigment, upon the negative results of their spectroscopic experiments. Dantec remarks with reference to this: "Every-one knows that the derivatives of hæmoglobin (hémaphéine, hématine, etc.) are insoluble in water; it is then not astonishing that MM. Domingos Freire and Carmona have not obtained any spectroscopic result, since the first condition is to examine the body in a liquid state. Upon dissolving the black matter with acidified alcohol, we have always obtained positive results." The author just quoted has repeated an experiment often made in this country, at a time when the question was whether the vomited matter consisted of "black bile," or derived its color from the blood. By adding some drops of hydrochloric acid to blood diluted with water, Dantec produced an "artificial black vomit" which resembled exactly that ejected from the stomach of yellow fever patients.

The small *intestine* commonly contains more or less black matter, either fluid and resembling that found in the stomach, or mixed with mucus and smeared over the mucous coating, especially of the ileum. This, no doubt, comes partly from the stomach, but in other cases is due to passive hæmorrhage from the mucous membrane of the intestine itself. This membrane presents arborescent patches of congestion, or portions of the canal may be uniformly red from hyperæmia of the mucous coat, the color varies from pale red to a reddish-brown, and is usually more marked in the lower portion of the ileum than elsewhere. The large intestine occasionally presents similar arborescent patches of congestion, but usually it has a normal appearance. Finally, we may say that the attention of pathologists has heretofore been so largely taken up with the pathological histology of the organs which present the most notable changes—liver and kidney—that the histology of the alimentary canal has been somewhat neglected, and further researches in this direction are desirable upon material obtained at the earliest possible moment after death.

The appearance of the *liver* in yellow fever is characteristic, at least so far as acute febrile diseases are concerned. Usually it contains less blood than in the normal condition, and is of a pale yellow or brownish yellow color, similar to that of new leather in its various shades; occasionally it is gorged with blood, and livid, deep blue, or dark purple in color. In the victims of chronic alcoholism, it often presents the nutmeg appearance of cirrhosis. The dimensions do not differ materially from the normal, but the consistence is modified by the fatty change, which gives the characteristic color, and the parenchyma is easily torn and more or less friable. On section it is found to be drier than in the normal state, except in the comparatively few cases in which it is hyperæmic; these are, as a rule, cases which have proved fatal at a very early period—a fact which indi

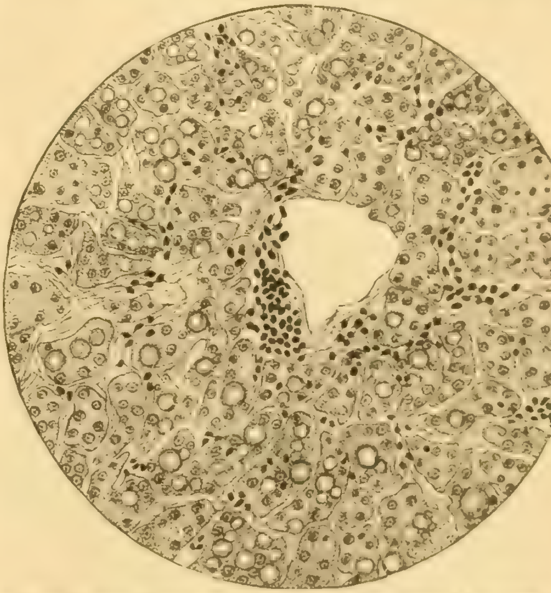

FIG. 4669.—Fatty Infiltration of the Liver Cells, with a Moderate Amount of Small-celled Infiltration, in a Case of Yellow Fever. Material from Havana.

quite free from it,—a stage of congestion antedating that of necrosis and fatty degeneration. According to Cunha, this congestion is limited especially to the portal radicles surrounding the lobules, and is attended with oedema of the intralobular connective tissue. Whether this primary congestion is a constant phenomenon or not, it is evident that in a majority of the examples the liver is found to be anaemic and to present more or less evidence of fatty change in the hepatic cells. This is not, however, a uniform process, but areas of greater or less extent are seen, in which the cells are infiltrated with fat globules (as seen in Fig. 4669), while in other places the cells appear normal. The fatty cells contain one or several fat-globules of varying dimensions and the protoplasm is reduced in quantity according to the extent of the fatty change. The nuclei very often remain intact in the cells infiltrated with fat, but according to Schmidt "a great number of the nuclei also undergo fatty degeneration." Often a circle of normal cells remains about the central vein, while those cells nearer the periphery of the lobule contain numerous fat globules.

In two of the livers brought back from Havana by the Yellow Fever Commission of 1879, in which there was evidence of cirrhosis, Woodward found that in addition to the fatty change described, "an abundant infiltration of cells resembling leucocytes was observed, not merely in the abnormally developed interlobular connective tissue, but also in the parenchyma of the lobules." I have also found an infiltration of leucocytes in two out of four cases which I have recently studied with care. In one, from which Fig. 4669 was drawn, it was attended with the usual fatty change. In the other it is far more pronounced, and the liver-cells to a considerable extent are atrophied and have lost both their nucleus and their protoplasm; indeed a complete necrosis of the cells has taken place (see Fig. 4670). This, however, is quite an exceptional picture, and probably represents a complication rather than an exaggerated degree of an inflammation common to the disease. Schmidt states that he has never observed any evidence of inflammation in the liver of yellow fever.

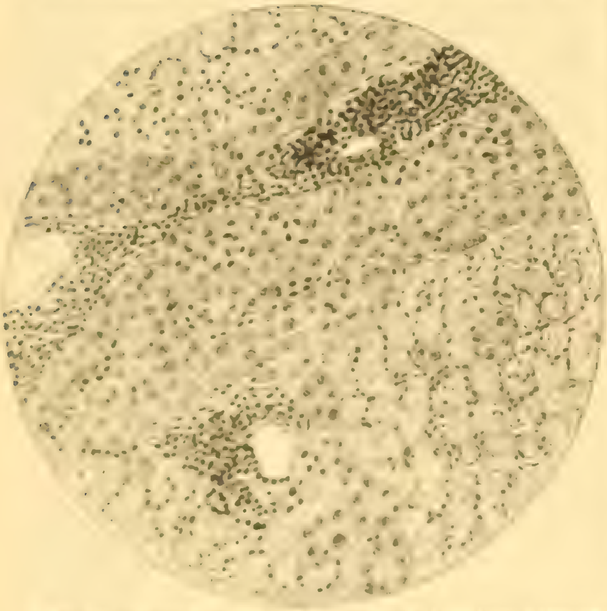

Fig. 4670.—Acute Hepatitis, with Necrosis of the Liver Cells; Leucocyte Infiltration. From a Case of Yellow Fever. Havana, 1887.

The kidneys are also the seat of important pathological changes in the disease under consideration. This consists essentially in a parenchymatous nephritis. Externally no material change is found in the organs. They do not vary greatly from the normal size, and usually are normal in appearance. When the attack has been brief, however, they may be hyperaemic and of a deep red color. Cunha believes that the changes found in the parenchyma of the organ are usually preceded by a stage of congestion; Schmidt agrees with him, and states that he has met with a limited number of cases in which death had occurred during this stage of hyperaemia. Ecchymosed spots and haemorrhagic foci are frequently seen beneath the capsule or in the cortical substance. In the latter situation little globular haemorrhagic points, the size of a pin's head, have been observed, which, upon examination, proved to be the distended capsules of the glomeruli. The change in the renal epithelium consists in a cloudy swelling, followed by fatty degeneration and desquamation. Every grade of change may be seen in the same section, from a slight degree of cloudy swelling to complete disorganization and desquamation of the cells. Whole bundles of tubes may often be seen which have been stripped of their epithelium and are entirely empty. In thin sections the lumen of the tubules is seen in places to be filled with infarctions of variable appearance. Some are homogeneous and translucent, and it may be more or less colored with blood pigment; these are composed of an albuminous material. Other infarctions are formed of the granular débris of the renal epithelium; or we may have a mixture of the granular and albuminous material, in which case the latter forms a matrix in which the granules are imbedded. These infarctions correspond with the casts found in the urine; those of a granular character are most abundant, and in them the granules often have a fatty appearance. There are also accumulations which differ from these in the fact that they are deeply stained by the aniline colors. They seem to be made up of the nuclei of the cells, sometimes intact, although swollen and compressed, more commonly massed together, or broken into irregular fragments. At least this seems to me to be the most probable interpretation of those infarctions which are stained by nuclear staining agents.

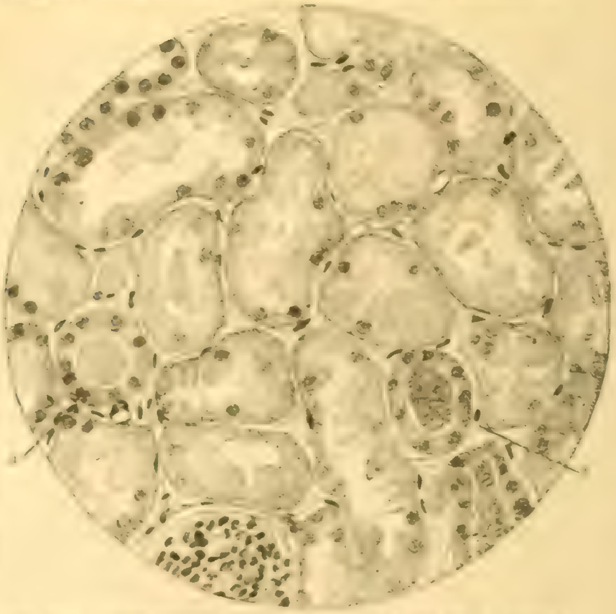

Fig. 4671.—Acute Parenchymatous Nephritis. a, Hyaline; b, granular infarctions. From a case of yellow fever. Havana, 1887.

The suprarenal bodies, according to Schmidt, undergo pathological changes similar to those observed in other organs, "consisting in the infiltration of fat and haemoglobin, derived from the blood and preceded by hyperaemia of the organ. . . . The infiltration or extravasation of haemoglobin absorbed by the cells is greater and more general here than has been observed in any other organ. Almost in every case examined it involved the whole medullary substance, from which it extended into the inner and middle layer, sometimes even into portions of the outer layer of the cortical substance. The degree of this pigmented infiltration is sufficiently great to be always distinguished by its brown color in sections of fresh specimens; in some cases, even, it appears dark brown.

The *spleen* does not undergo any marked alteration in yellow fever.

Treatment.—The unsatisfactory results obtained in the various methods of treatment proposed are shown by the fact that a majority of the physicians, in those parts of the world where yellow fever prevails, who have had an extended experience, agree that active medication is injurious, and have settled upon an expectant or symptomatic treatment, with careful nursing, as giving the most favorable results. Yet the records of the past show that a çertain proportion of the cases recover under all modes of treatment, even the most active and opposed to our present views. The famous Dr. Rush, of Philadelphia, was thoroughly convinced of the advantages of copious bleeding during the first stage of the disease, and ascribed the more favorable results obtained in the epidemic of 1793, as compared with those of 1741, 1747, and 1762, to the more liberal use of the lancet. Venesection was often repeated from five to ten times by Rush and other practitioners of his date, and the amount of blood extracted often exceeded one hundred ounces—one hundred and fifty and even two hundred ounces in some cases. This excessive bleeding was soon abandoned, but the propriety of drawing blood at the outset of the attack was maintained by many practitioners in the United States and the West Indies for many years after the "heroic" treatment of Rush had been abandoned, and the statistics offered in favor of this practice certainly compare favorably with the results obtained at the present day by expectant treatment. Thus Dr. Catel, who was in charge of a military hospital at Martinique, reports that, out of 176 patients treated during the first twenty-four hours by bleeding, 5 only died—a mortality of 1 in 35; of 108 treated on the second day, 11 died, or 1 in 9; and of 143 treated on the third day, 40 died, or 1 in 3. Dr. Lefort, a physician of the same place, also reports that 4 out of 5 of those bled on the first day recovered, and asserts that on the second day bloodletting affords six times less chance of success (La Roche).

The lancet has been entirely abandoned, in accordance with the changed views as to the pathology of febrile affections, but it may be questioned whether in the plethoric new-comers in tropical regions, who furnish so large a quota to the mortality list from yellow fever, a single bleeding at the outset of the attack might not still be practised with benefit.

Emetics were formerly considered an essential part of the antiphlogistic treatment. We speak of them only to condemn them, except in those cases in which at the outset of an attack there is evidence that the stomach contains undigested and fermenting material which is the cause of nausea and distress. In this case a simple emetic may be administered, with the sole object of unloading the stomach.

Purgatives have at all times been considered useful at the outset of an attack of yellow fever, and it is the standard treatment, wherever the disease prevails, to administer a cathartic of some kind as soon as the patient comes under observation. Opinions differ as to the best form of cathartic medicine; some prefer a mercurial, some a saline, and others a full dose of oleum ricini. On account of its prompt and thorough action and the absence of irritating properties, the last-mentioned medicine is a favorite in our own southern cities, in the West Indies, and in Brazil, especially in domestic practice among the creole population. The dose usually given might seem excessive to those who have not seen its favorable action; half a tumblerful, or even more, is the common dose for an adult—two to four fluidounces. Many physicians still prefer a mercurial purge, followed, if necessary, by a saline cathartic, and calomel is the mercurial usually selected. This was formerly given by some practitioners in enormous doses—forty to sixty grains—for its "sedative" effect, and by others in repeated small doses as a "salivant." Dr. Rush introduced the use of mercury as a salivant in the treatment of yellow fever in the epidemic of 1793, and "encouraged by the good effects observed on that occasion from a salivation, he was induced, the next year, to excite it as early as possible in all those cases which did not yield immediately to bleeding and purging. He was delighted to find that it immediately attracted and concentrated in the mouth all the scattered pains of every part of the body, checked nausea and vomiting, and gradually, when it was copious, reduced the pulse—thereby preventing the necessity of further bleeding and purging." He used mercury still more extensively in 1797, and during the memorable epidemic of 1798 a salivation was found by him to be the most certain remedy of any that was used in this fever; for he "did not lose a single patient in whom the mercury acted upon the salivary glands" (La Roche). It is scarcely necessary to remark that this treatment has been entirely abandoned, and when calomel is given to-day it is usually for its cathartic effect, or for its supposed action upon the liver. It may be, however, that it is useful in another way. As we have indicated in discussing the etiology of the disease, it seems extremely probable that it is caused by a microbe whose habitat is in the alimentary canal. If this is in fact the case, the indications are apparent, viz., to keep the *primæ viæ* as nearly empty as possible, so that the multiplication of the specific micro-organism may be restricted by want of pabulum; and also for the purpose of removing the microbe and its poisonous products; second, the administration of germicide and antiseptic remedies, with a view to the destruction of the germ, or at least of restricting its development. In carrying out both of these indications it will be necessary to avoid any measures which would induce gastric or intestinal irritation. For, as we have seen, the gastro-intestinal mucous membrane is in a hyperæmic condition early in the attack, and experience has demonstrated that this condition is aggravated by active medication, or by the presence of food—even the simplest—and that the gravest danger may result from the administration of anything which may add to the irritation of the stomach or intestine, the normal functions of which seem to be arrested as a result of the action of the toxic agent which gives rise to the morbid phenomena. For this reason it is necessary to administer cathartics with great caution, if they seem called for after the second day of the disease. As a rule, it will be best to spare the stomach, and to move the bowels by purgative enemata.

The prevailing opinion that yellow fever is closely allied to the malarial fevers, led many physicians, during the first half of the present century, to prescribe *quinine* in the expectation that it might prove a specific in this disease. This expectation was not fulfilled, but there are still a certain number of experienced physicians who think a full dose at the outset of an attack to be beneficial; others consider it injurious, and as a rule it has been abandoned. There is, however, much evidence in favor of the practice, although the benefits to be derived from it have no doubt been overstated. Dr. Fenner, in his account of the epidemic of 1849, states that the results obtained in the abortive method of treatment by quinine were entirely successful. The dose given was from twenty to thirty grains, with a moderate quantity of morphine or opium, after having unloaded the bowels with a purgative enema. Dr. Fenner says: "This would generally reduce the vascular and nervous excitement completely in the course of a few hours, throw the patient into a profuse perspiration, relieve all pain, and produce sleep." This is certainly a very desirable result, and while to-day it is generally admitted that quinine has no specific action in yellow fever, and that after the first day or two it is liable to do harm by irritating the stomach, the writer is disposed to think that, as an antipyretic and nervous sedative at the outset of the attack, it may often be administered with advantage. This was the conviction of some of our most experienced army surgeons who encountered the disease at Vera Cruz during the Mexican War, and subsequently in New Orleans.

Dr. Anderson, of Mobile, who, with his associate in practice, treated a large number of cases during the epidemic of 1858, says: "The marked and almost magic effect of a large dose of quinine at the outset was so apparent, that they [himself and associate] would have considered it little short of trifling with human life to have adopted any other treatment. They will not deny that there were cases in which it did no good; in fact, in those cases where there was at the commencement decided congestion of the brain, it may sometimes have done harm."

Blair, whose experience was very extensive, and whose treatment seems to have been eminently successful, gave twenty grains of calomel and twenty-five grains of quinine at the outset of an attack, and under certain circumstances repeated the dose several times.

Dr. Porcher, of Charleston, follows Blair's treatment so far as the first dose is concerned, but protests against a repetition of it. We think he is quite right in this, and that his remarks upon treatment are extremely judicious. In some of the new antipyretics and nervous sedatives we have agents which are probably superior to quinine for reducing the temperature and relieving the nervous symptoms. Favorable reports have already been made with reference to some of these. In the epidemic of last year (1887) at Key West, Drs. Porter and [illegible] used antipyrin, as they believe to the advantage of their patients. It has also been prescribed quite extensively in Havana; but I have seen no exact statements as to the results obtained. Nägeli, a German physician practising in Rio Janeiro, has given a very favorable account of results obtained by the use of kairin. According to this author, of 7 cases treated from the beginning, 5 of which were serious (had black vomit) all recovered. The course of the disease was not shortened, but the fever is said to have been controlled. The medicine was administered from the outset in doses of one grain every hour or oftener. This treatment is said to have quickly reduced the temperature—after three or four doses—to 38° (100.4° F.) or lower; at the same time abundant perspiration occurred and the pains were relieved. Doses of one-half a grain were given every hour after the temperature was reduced to the normal to keep it from again mounting. Iced drinks were given, but no food. After the fourth or fifth day it was sometimes necessary to increase the dose to 1½ to 2 grains, in order to control the return of fever. The urinary secretion continued during the use of the remedy, and Nägeli thought that less albumen was present than in similar cases not so treated. As the account of this method of treatment was published in 1884 and we have not heard that it has been adopted to any extent in Rio, the supposition is that, like many other methods, it has not stood the test of fuller experience. In the feeble condition of the heart in the second stage of yellow fever, we should anticipate that the large doses administered—as much as fourteen grains in the twenty-four hours—might be dangerous; but as all of Dr. Nägeli's patients are said to have recovered, we cannot urge this objection.

Many of the French physicians administer bromide of potassium as a nervous sedative, but we anticipate that antipyrin or one of the more recent remedies of this class will be found the most useful in meeting this indication, and for the reduction of temperature. There is no reason to expect, however, that they will prove to be specifics—they simply meet certain indications in the symptomatic treatment of the disease. Some of the physicians in Rio Janeiro have prescribed jaborandi and think well of it, without, however, claiming that it has any specific power. When the skin is hot and dry, it may serve a useful purpose, but it will be necessary to guard against the depressing effects of the remedy. Recently, Dr. Hebersmith, of the Marine Hospital Service, has given the muriate of pilocarpin in several cases, and he thinks with good results. Doses of ⅛ to ¼ grain were given hypodermically and produced profuse perspiration, with reduction of temperature. But as several of his cases were robust persons, and the initial temperature was moderate in all, we are not prepared to admit that recovery was due to the administration of this medicine.

Aconite, digitalis, and veratrum have been tested in the West Indies and elsewhere, in full sedative doses. [illegible] says of these medicines that "the attempts, although sufficiently numerous, have not yet furnished any decided results." After a careful trial of digitalis in doses of two to three grams (30 to 45 minims) of the tincture per dose, the author quoted arrives at the conclusion that in mild cases it seems to cause the fever to fall more quickly, but in intense cases it has not the same power. His general conclusion is, that aconite, digitalis, and veratrum are superior to quinine, and that in moderate doses they are useful in allaying nervous excitement and in moderating to a slight extent the fever. The writer has been in the habit of giving small doses of aconite, in combination with a mild diaphoretic, during the febrile stage of yellow fever, and has thought that some benefit was derived from the treatment, although it must be confessed that this has not been very marked.

Dr. Bemiss, of New Orleans, writes of this class of medicines as follows:

"It is the practice of some physicians to attempt the reduction of fever by large injections of cold water, which are said to prove very efficient antipyretics. Aconite, veratrum, tartrate of antimony, and ipecac are frequently exhibited. A cautious use of one or the other of the first two on this list may prove beneficial, but their injudicious or careless exhibition may do irreparable harm. *We have seen tincture of veratrum produce a most decidedly good effect in mitigating fever, and have often administered it in doses of thirty to sixty drops of the tincture every third or fourth hour.* It is best to give it in solutions of acetate of ammonia or potash.

Dr. Porcher, of Charleston, gives the following mixture as a gentle diuretic and diaphoretic:

℞. Acetate of potash .... ʒ j.
Citrate of potash .... ʒ j.
Morphine .... gr. j.
Camphor water .... ℥ vj.

M. A dessertspoonful to be given every two or three hours as long as there is heat of skin.

Some formula of this kind, which has a gentle sedative and diaphoretic effect, is useful so long as it does not disturb the stomach. Many practitioners refrain from giving any medicine at all, but permit the patient to swallow bits of ice, or small quantities of iced water, at frequent intervals. This we quite approve of, or iced carbonic acid water may be given. Others again give warm drinks to promote perspiration. This is the standard "creole treatment" in New Orleans, and in many parts of the West Indies. As the mortality among this class is small, they are well satisfied with the results obtained, but many strangers unacclimated, who have received the creole treatment die, in spite of the dose of castor oil, the hot pediluvia, and the orange-leaf tea. This treatment with careful nursing is, however, infinitely superior to the active medication of the novice in the treatment of this treacherous disease, for it is very easy to kill yellow fever patients.

Dr. Pardiñas, formerly director of the military hospital at Havana, gave full doses of the tr. ferri chlorid. throughout the disease, and, without claiming for it any specific virtue, he was convinced that the mortality was less under its use than by other methods of treatment with which he was familiar. The director of the Jurujuba Hospital at Rio Janeiro gave me the following formula, which, after trying many different modes of treatment, he has accepted as being, in his opinion, the best:

℞. Perchloride of iron (normal solution) grams iv.
Tincture of [illegible] .... gram 1.
Distilled water .... grams 400.

M. A tablespoonful to be given every hour.

Some physicians in the United States have also used the tincture of the chloride of iron in full doses, and have reported favorable results; but it has not come into general use, even in those places from which the favorable reports have come. In Savannah, during the epidemic of 1854, it was prescribed extensively by Drs. Wildman and Harris. The last-named physician reported that, out of two or three hundred cases treated in this way, he only lost six. La Roche, in commenting upon this report, says: "Unfortunately the remedy, though so advantageous when administered to the sufferers of Savannah, was powerless in the cases of those to whom it owed its celebrity, for both Dr. Wildman and Dr. Harris fell victims to the prevailing epidemic."

Baths of all kinds—hot, cold, tepid, medicated—have been given in yellow fever, and the evidence is varied as to their utility. The most judicious and experienced practitioners are, however, in accord as to the danger of disturbing the patient to the extent demanded by frequent baths, and, as a rule, content themselves with *hot pediluvia* at the outset of the attack, and with sponging the surface with cold water or evaporating lotions to reduce the temperature. Very hot or very cold baths are condemned by Féraud, on the ground that they are likely, even in the first stage of the disease, to produce visceral congestions, to which there is a great tendency in this disease. In the southern part of our own country, and in the West Indies, a *hot mustard foot-bath*, administered at the outset of the attack, is a standard method of treatment. The patient is wrapped in a blanket, and sits with his feet and legs immersed in a bucket of water as hot as he can bear, to which a liberal quantity of mustard has been added. This has a tendency to relieve cerebral congestion and headache, and often produces a free perspiration. It may be repeated several times during the first twenty-four hours. Cold applications to the head and repeated sponging of the hands, arms, and chest with cold water, give comfort to the patient, and are of decided benefit on account of their antipyretic effect. Some practitioners recommend the use of tepid water for sponging the surface; Féraud prefers a mixture of one part of aromatic alcohol with three parts of water; Dr. Peyre Porcher recommends "the assiduous and protracted applications of ice-cold water to the head, hands, and arms, as long as they are abnormally hot." This practice is justified by the results of his treatment, and we think it entirely safe and extremely useful. The knowledge that exposure to cool currents of air, or by removing the bed-covers at night when the weather has suddenly turned cold, is attended with the greatest danger, on account of the visceral congestions—especially of the kidneys—which result from such exposure, has led many physicians to refrain from making use of cold lotions to the surface. The same apprehension has also led to an excessive use of blankets, and the poor patient, who is burning up with fever, is sometimes smothered in blankets and carefully guarded, to prevent him from exposing hand or foot to the air.

Toward the end of the first stage, and throughout the second stage of the disease, this watchfulness to prevent exposure of the body to cool currents of air is very necessary; indeed, it is important at all times if the external temperature is low, and especially at night; but the object in view can be obtained without loading the patient with blankets. He should be lightly covered, but carefully guarded from exposure if the weather is cool. At the same time the body may be sponged under the blanket, and iced water applied to the head, face, hands, and arms, during the febrile stage.

Bérenger-Féraud speaks highly of the use of large enemata of cold water, frequently repeated, as a means of reducing the temperature. He has made extensive use of this mode of treatment, and has never seen any evil results from it.

The use of *sinapisms* and *vesicants* to relieve visceral congestion by revulsion to the surface, is approved by experienced physicians everywhere. We prefer sinapisms, and believe that, as a rule, they will accomplish all that can be expected from a blister. The feeling of weight, distress, or absolute pain in the epigastric region, attended with nausea, which is largely due to the hyperæmia of the gastric mucous membrane, is often notably relieved by the application of a sinapism to the epigastrium. The patient, who has been restless and uncomfortable, will sometimes quickly fall asleep after such an application. In the same way, cerebral congestion and headache may be relieved by revulsives to the extremities, and lumbar pain by the application of a large sinapism to the loins.

The scanty urinary secretion, and often complete suppression, in yellow fever, seems to call for the use of *diuretics*, but unfortunately experience teaches that the most reliable medicines of this class do but little good. The kidneys are best relieved by those means which promote perspiration, and by revulsants applied to the loins. Complete suppression is rarely, if ever, relieved by any plan of treatment. In cases with a hot, dry skin, and scanty urinary secretion, with lumbar pain, indicating congestion of the kidneys, we should expect benefit from the hypodermic administration of the muriate of pilocarpine.

Stimulants are rarely required before the fourth or fifth day, and must be given at first cautiously and in small doses, so as not to disturb the stomach; later, however, they are often absolutely demanded to sustain the feeble heart. During the second stage of the disease, when the pulsations of the heart often do not exceed 40 or 50 to the minute, there is always a tendency to syncope; this is especially manifested during the night, or toward morning, and many a patient, whose condition seemed satisfactory at the evening visit, has been found by his physician dead the next morning. This dangerous period may often be tided over by the use of stimulants. When the stomach is very irritable, a little iced champagne will often answer better than anything else; but perhaps the best form of stimulant is good brandy, given in teaspoonful doses, at intervals of half an hour, more or less, according to circumstances. It should be given ice-cold. Later, milk-punch, English ale, or porter, may be given in liberal quantities, especially to those who are in the habit of using spirits.

Blair, whose opinion in all that relates to this disease is worthy of attention, prefers hock to any other form of stimulant. He says: "Of all cordials the best is Rhenish wine. When of good quality it is retained when everything else is rejected, and it is universally liked by the patients. I have seen the most excellent effects from its use, and have often given it to the extent of two bottles in twenty-four hours. I believe it has saved many lives, and know of no substitute for it."

Medicines administered by the stomach to control vomiting, as a rule, are worse than useless. Minute doses of *morphine*, administered hypodermically, are sometimes useful in checking gastric irritability, but this is a dangerous remedy in yellow fever, and only very small doses are tolerated. Blair has seen stupor, prostration, and complete narcotism follow the administration of one-tenth of a grain. On account of the danger attending its administration, he thinks that it will be more judicious to place it in the *index expurgatorius* of yellow fever. Bemiss, whose opinion is of equal value, says, "Vomiting should be met with epispastics, blisters, ice, and small doses of opium, in combination with cherry-laurel water and sodæ bicarb." An effort should be made to arrest *hæmorrhage* by the use of ergot, the beneficial effects of which are sometimes well-marked. As it is not likely to be absorbed by the stomach, and may cause vomiting, it will be best to administer ergotine hypodermatically.

During *convalescence* the sulphate of quinine, in moderate doses, or citrate of iron and quinine, or the standard preparations of iron and of strychnine, will often be useful as tonics; and ale or porter, or a sound wine in moderate quantities, will be found beneficial.

The *alimentation* in this disease, as in the specific fevers generally, is a matter of prime importance. During the first part of the febrile stage no food is desired, nor is it required. It is best to give nothing in the way of food for the first three or four days of sickness; after this, if the stomach tolerates it, an ounce or two of iced milk or of chicken broth, may be given every two or three hours.

If the stomach is very irritable a smaller quantity at shorter intervals may be given; and it may be best to give the milk in combination with lime-water. If the stomach will not retain this, [illegible]. Do not push it further, but support the strength by nutritive enemata. Even when the stomach is quiet and the patient craves food, it will be necessary to give only liquid nourishment for two or three days, and then to allow nothing but the simplest and most digestible forms of solid food; for there is always danger of a relapse from imprudence in diet, even in the mildest cases.

Before closing this article, the writer ventures to refer briefly to a method of treatment which is still too recent to permit of a definite conclusion as to its value.

This was suggested by me during my recent visit to Havana, and is an attempt to formulate a specific treatment in accordance with our present views of the etiology and pathology of the disease. The intensely acid reaction of the urine and of the vomited matters, and the fact that I have usually found the contents of the intestine [illegible], has led me to believe that a very decidedly alkaline treatment might be beneficial; and, in view of the probability that the specific infectious agent is located in the alimentary canal, I have combined with the alkali selected an antiseptic agent which is known to prevent the development of micro-organisms when present in very minute quantity.

The formula suggested was as follows:

℞ Bicarbonate of soda .... grams 10 (150 grains)
Bichloride of mercury .... centigr. 2 (⅓ grain)
Pure water .... litre 1 (1 quart).

M. Sig.—50 grams (2 tablespoonfuls) every hour; to be given ice-cold.

A letter recently received from my friend Dr. D. M. Burgess, Sanitary Inspector at Havana, gives the following account of the results up to the present date. Dr. Burgess says:

"[illegible] cases have now been treated at Garcini by your alkaline and bichloride method and all have recovered—none subjected to that method have died. Three were treated successfully at another hospital here. Four are to-day receiving the treatment at Garcini, and about an equal number at each of two other institutions."

YELLOW SPRINGS. *Location and Post-office.*—Yellow Springs, Greene County, O.

ACCESS.—From Xenia, O., a station on the Pittsburg, Cincinnati & St. Louis Railway, by the Springfield branch of above road to the springs.

ANALYSIS (by Wayne and Locke).—One pint contains (52° F.):

	Grains.
Carbonate of lime	[illegible]
Carbonate of magnesia	[illegible]
Chloride of magnesium	[illegible]
Chloride of sodium	[illegible]
Sulphate of lime	[illegible]
Carbonate of iron	[illegible]
Organic matter	[illegible]
Total	[illegible]

These springs are located in Southwestern Ohio, on the Little Miami River, about sixty-five miles northeast from Cincinnati. The surrounding country is undulating, and affords many beautiful drives to the neighboring towns. Yellow Springs has a population of about 1,400. *G. B. F.*

YELLOW SULPHUR SPRINGS. *Location and Post-office.*—Yellow Sulphur Springs, Montgomery County, Va.

ACCESS.—By carriage from Christiansburg, Va., a station on the Norfolk & Western Railroad, three and one-half miles to the springs.

ANALYSIS (by Professor W. M. Gilham).—One pint contains (58° F.):

	Grains.
Carbonate of magnesia	[illegible]
Carbonate of protoxide of iron	[illegible]
Carbonate of lime	[illegible]
Chloride of potassium	[illegible]
Chloride of sodium	[illegible]
Sulphate of potassa	[illegible]
Sulphate of soda	[illegible]
Sulphate of magnesia	[illegible]
Sulphate of alumina	[illegible]
Sulphate of lime	[illegible]
Phosphate of magnesia	[illegible]
Phosphate of iron	[illegible]
[illegible] matter	[illegible]
Total	[illegible]

Gas.	Cubic inches.
Carbonic acid	[illegible]
Sulphuretted hydrogen	[illegible]

THERAPEUTIC PROPERTIES.—Marked calcic sulphur waters containing an active proportion of cathartic sulphates.

These springs are situated in the southwestern part of Virginia, on the southeastern slope of the Allegheny Mountains, at an altitude of over two thousand feet above sea-level. They are about sixty feet from the summit of the mountain on which they are located, amid beautiful mountain scenery, and possessing a cool, bracing atmosphere during the hottest months. All the modern conveniences for the comfort of visitors are furnished. *George B. Fowler.*

YERBA SANTA. "Consumptive's weed," "Mountain balm," etc. The leaves of *Eryodictyon glutinosum* Benth., Order *Hydrophyllaceæ*. A very pretty evergreen plant, growing on the western side of the United States and in northern Mexico, in gregarious clumps and patches in barren soils and among rocks. It has slender stems branching near the ground and simple above, a metre or more high, bearing numerous alternate or clustered, coriaceous, lanceolate, dentate leaves, five to eight centimetres (2–3 inches) long, and one or two in width. The upper surface of the leaves is smooth and shining, of a dark green color, completely varnished by a copious coating of resin, with which the entire plant abounds. The under surface is covered with a silver-white down, conspicuously netted-veined. Flowers small, something like "forget-me-nots," blue, pretty. Calyx five-parted, corolla funnel-shaped, regular, five-lobed, stamens ten, short, style two-cleft. Fruit, a one-celled capsule, with two placentæ, and one or two dozen seeds. Capsule semi-transparent from saturation with resin (Wellcome, quoted in "Proceedings of the American Pharmaceutical Association," 1876).

The principal constituent of this plant is the resinous compound. It also contains some tannin and a bitter principle. Yerba Santa, as one of its names shows, has a local reputation on the Pacific slope for coughs, colds, bronchitis, and phthisis, a reputation which is shared by many other resinous substances and has some foundation. It is also a pretty good vehicle for the administration of quinine, whose taste, like liquorice or glycyrrhizin, it covers pretty well. Of a fluid extract, three of four cubic centimetres (♏ xlv. ad lx.) may be given for coughs. A syrup as a vehicle for quinine is sometimes prepared.

Allied Plants.—This is a small order of plants, mostly American, containing none of much activity or importance. One or two *Nemophilæ* are cultivated for ornament.

Allied Drugs.—See Grindelia. *W. P. Bolles.*

YOLK-SAC. The vitelline sac, umbilical vesicle, or yolk-sac of man, is a pear-shaped bag of tissue about one-fourth of an inch in diameter, appended to the embryo by a long stalk, which is attached to the intestines of the embryo and runs the length of the umbilical cord, so that the sac lies a short distance from the placental end of the cord, in the space between the amnion and the chorion. These relations are well shown in Fig. 1276 (Vol. III., p. 112). This diminutive sac is always found in the early stages of development, and is said to persist up to birth; the stalk, however, aborts within the cord, and disappears during the first half of gestation.

The yolk-sac, as is shown in the accompanying diagram, is really an appendage of the intestinal canal, and is formed by the extra-embryonic splanchnopleure. During the third week of development, the sac appears very large in proportion to the embryo, but its growth ceases about the fourth week. At first, its connection with the embryo is broad and long (compare Fig. 652, Vol. II., page 144), but as development progresses, the neck becomes more and more constricted and lengthens out (Fig. 4673), so as to form a distinct stalk. Blood-vessels appear very early upon the yolk-sac, developing in the mesoderm of its wall, and forming a network over the sac; these capillaries communicate with two veins, the *omphalo-mesaraicæ*, which carry the blood along the stalk of the sac to the *septum transversum*, and so to the heart of the embryo. The arterial supply probably comes in man, as in the early stages of the rabbit, from small vessels connected with the aorta, but later there are, it is said, larger trunks developed which run out from the dorsal aorta. The arterial trunks disappear very early indeed; consequently in cross-sections of the yolk-stalk we find only the two veins, which pursue a somewhat contorted course. At first the two veins are nearly equal in size, but after the beginning of, say the fourth week, the *left* omphalo-mesaraic vein begins to abort.

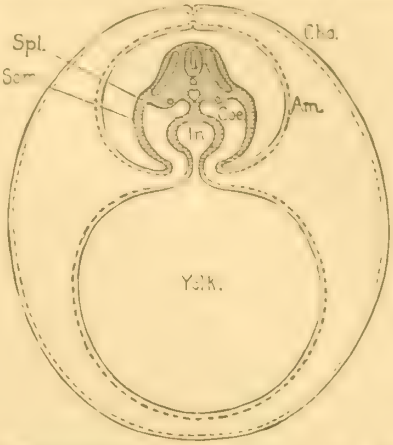

Fig. 4672.—Diagrammatic Cross-section of an Amniote Embryo and Ovum. The embryo is shaded; the extra-embryonic mesoderm is represented by a dotted line. *Som*, somatopleure; *Spl*, splanchnopleure; *Cho*, chorion; *Am*, amnion; *Coe*, coelom; *In*, intestine; *Yolk*, yolk-sac.

The yolk-sac is at first hollow, being lined internally by the entoderm, externally by the mesoderm. In that part of the stalk within the umbilical cord, the cavity disappears. In the vesicle itself the entoderm becomes fatty, and changes into a pavement epithelium, which is also thrown up into vascular villi at certain points (Kölliker).

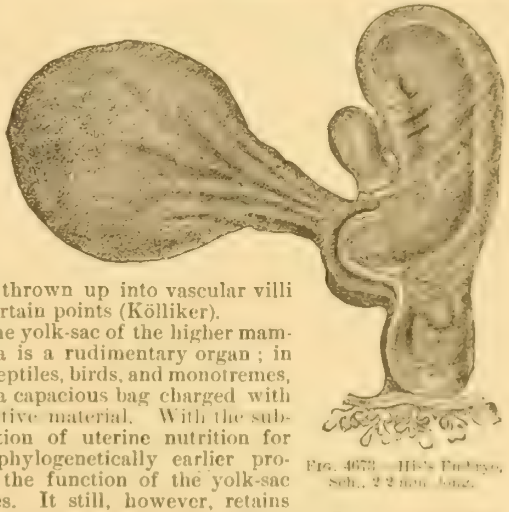

Fig. 4673.—His's Embryo, Sch., 2.2 mm. long.

The yolk-sac of the higher mammalia is a rudimentary organ; in the reptiles, birds, and monotremes, it is a capacious bag charged with nutritive material. With the substitution of uterine nutrition for the phylogenetically earlier process, the function of the yolk-sac ceases. It still, however, retains some yolk in certain cases (Rauber). In the anamniota the somatopleure (chorion) is also continued directly over the yolk-sac, as for instance in sharks, or in other vertebrates, the yolk-sac comprises entoderm (or yolk), mesoderm, and ectoderm. It may happen that the mesoderm fails to develop a coelom over the yolk-sac, and then it is incorrect to say that there are splanchnopleure and somatopleure present. Again, the mesoderm may fail to spread over the whole sac, in which case it is covered in one part by ectoderm lying directly on the yolk. As yet, however, there has been no comprehensive study of these and other modifications of the yolk-sac.

Charles Sedgwick Minot.

YUMA. (For an explanation of the chart and suggestions as to method of using it see article "Climate," Vol. II., pp. 186-194.)

The accompanying chart, obtained from the Chief Signal Office at Washington, represents the climate of the town of Yuma, Arizona, and may be profitably studied in connection with the brief article describing the climate of that Territory, which will be found under the title "Arizona" on page 404 of the first volume of this Handbook.

It is hardly possible to specify, in the case of this chart, which columns contain the data most worthy of attention: all, save perhaps columns J and R, are remarkable. But the extraordinary cloudlessness of the sky, phenomenally low rainfall, great dryness of the atmosphere, great nycthemeral range of temperature, and extremes of high temperature, are the features in the climate of this low-lying Arizona station, which are perhaps those most worthy of attention. *H. R.*

Climate of Yuma, Ariz.—Latitude 32° 45'; Longitude 114° 36'.—Period of Observations, October 1, 1875, to December 31, 1889.—Elevation of Place of Observation above the Sea-level, 139 (approx.) feet.

ZEDOARY (*Rhizoma Zedoariae* Ph. G.; *Zedoaire longue, Zedoaire ronde,* Codex Med.).

The rhizome of *Curcuma Zedoaria* Roscoe, Order *Zingiberaceae.* This is one of the numerous ginger-like plants which inhabit the warmer parts of Asia, and whose rhizomes or seeds are used as spices or condiments. Zedoary is indigenous in India and China, in which places it is also cultivated. It is introduced and cultivated also in Java and other Pacific islands. The rhizome is the part used, being dug up, washed or scraped, and then sliced and dried: the smaller branches, as is commonly stated, being the "long Zedoary," and the central tubercles or clumps the "round Zedoary." But, according to the French Codex and some other authorities, the latter is the rhizome of a related plant, *C. aromatica* Salisbury. Zedoary comes also occasionally mixed with curcuma. The long variety of Zedoary is of old occurrence in commerce, and was formerly a greater favorite than now, when its place is mostly taken by ginger, cardamom, sweet flag, etc. In this country, indeed, it is well-nigh obsolete, but on the continent of Europe it is still official in most countries, although but very little used.

It figures mostly in external applications as an ingredient of several proprietary liniments and "balsams." The French "*Baume de Fioraventi*" contains Zedoary along with fifteen other resins and spices.

Its composition resembles that of ginger and curcuma, so far as to its taste and flavor being due to essential oil and resin. Like these, too, it contains an abundance of starch.

Allied Plants and Drugs.—See Ginger.

W. P. Bolles.

ZINC. I. General Medicinal Properties of Compounds of Zinc.—Charging the blood with zinc affects nutrition in excess, developing poisonous symptoms, but the action is not as profound as with the majority of the heavy metals, and in medicinal dosage deleterious effects need not be feared. Therapeutically, the constitutional influence shows itself in a tendency—not very strongly pronounced, but still useful—to check spasmodic nervous disorders, such as epilepsy, chorea, hysteria, etc. Indeed, before the rise of bromides into medicinal prominence, zinc was a standard medicine for the relief of epilepsy and hysteria. At present it can only be said that among the heavy metals zinc combines more potency and availability as a constitutional nervine than any other—which is not saying much. Locally, the properties of the zinc compounds differ with the chemistry of the different compounds, mainly according to solubility, the soluble salts being caustic or irritant and astringent, and the insoluble compounds operating as absorbent, soothing, healing, and disinfectant dressings. Internally, the soluble compounds in moderate dosage determine prompt and thorough vomiting, after the manner of copper salts, though with less severity of action. In large doses they are corrosive or irritant poisons, according to the activity of the individual compound. The insoluble compounds in small dose allay gastric and intestinal irritability, but in large dose, probably through chemical conversion, may nauseate, and even vomit. Zinc-compounds are disinfectant, the soluble salts, especially the chloride, notably so, and since they do not stain they are the most generally available of metallic salts for the purpose.

The *therapeutics* of zinc consist of the following applications: *constitutionally*, as a medicine of second or third rate power to control spasmodic nervous disease; *in the stomach*, to allay pain or nausea, for which purpose an insoluble compound is commonly selected; *in the bowels*, to control diarrhœa, especially when the affection seems a reflex of nervous irritation rather than the expression of a catarrh; and, *externally*, the soluble compounds, to cauterize, or to perform the usual functions of a metallic astringent-irritant in the way of determining absorption of granulation-tissue, and abating catarrh; and the insoluble preparations to act as soothing, healing, or, applied dry, absorbent and disinfectant dressings. Solutions of the soluble salts are also available as efficient disinfectants of their kind for wounds, fabrics, floors, and all non-metallic receptacles.

II. THE MEDICINALLY-USED COMPOUNDS OF ZINC.—These are the *oxide*, *carbonate*, *chloride*, *bromide*, *iodide*, *sulphate*, *acetate*, *valerianate*, and *phosphide*, and, although not officinal, the *nitrate* and *oleate*.

Zinc Oxide (ZnO).—Zinc oxide is officinal in the U. S. Pharmacopœia as *Zinci Oxidum*, Oxide of Zinc. It is a "soft, pale yellowish, nearly white powder, permanent in the air, odorless and tasteless, insoluble in water or alcohol, but soluble in acids without effervescence (absence of carbonate). When strongly heated, the oxide assumes a deep lemon-yellow color, but turns nearly white again on cooling" (U. S. Ph.). Oxide of zinc is a commercial article, and impure and even fraudulent specimens are not uncommon. Oxide of zinc is the principal insoluble zinc compound. It may be used, given internally, for the constitutional effect of zinc, or to allay vomiting or diarrhœa; dose, from 0.06 to 0.30 Gm. (one to five grains), several times a day, in powder or pill. Externally, zinc oxide may be used, alone or mixed with powdered starches or gums, as an absorbent powder-dressing to excoriations and sores, or, in ointment, as a soothing and healing application, for which purpose it is very efficient. There is an officinal ointment, *Unguentum Zinci Oxidi*, Ointment of Oxide of Zinc, consisting of twenty per cent. of the oxide in benzoinated lard, which may be applied in full strength to sores or eruptions.

Zinc Carbonate.—Normal zinc carbonate occurs in the mineral *zinc spar* or *calamine*, which was formerly officinal in the U. S. Pharmacopœia as a medicine, but was dropped, because of its impurities, in the revision of the Pharmacopœia of 1860. In its place is officinal, now, the mixture of carbonates that results from precipitating a boiling solution of zinc sulphate by sodic carbonate. Such precipitate is entitled *Zinci Carbonas Præcipitatus*, Precipitated Carbonate of Zinc, and is assigned the formula $(ZnCO_3)_2 . 3\,Zn(OH)_2$. Precipitated zinc carbonate is "a white, impalpable powder, permanent in the air, odorless and tasteless, insoluble in water or alcohol, but soluble in acids with copious effervescence. When strongly heated, the salt loses water and carbonic acid gas, and leaves a residue of oxide of zinc" (U. S. Ph.). Zinc carbonate is substantially a duplicate of the oxide in medicinal properties, but its use is commonly confined to external application as an absorbent powder.

Zinc Chloride ($ZnCl_2$).—The salt, often commonly called *butter of zinc*, is officinal in the U. S. Pharmacopœia as *Zinci Chloridum*, Chloride of Zinc. It is "a white, crystalline powder, or white, opaque pieces, very deliquescent, odorless, having a very caustic saline and metallic taste, and an acid reaction. The salt is very soluble in water and in alcohol, forming a clear, or only faintly opalescent, liquid. This opalescence is removed by the addition of a few drops of hydrochloric acid When heated to about 115° C. (239° F.), the salt melts, yielding a clear liquid which, on cooling, congeals to a white or grayish-white solid. At a higher temperature it is partially volatilized and decomposed" (U. S. Ph.). The chloride is the most active of the zinc salts, being highly corrosive and antiseptic, both. It has little effect on the sound skin, but upon a raw surface or mucous membrane it disorganizes tissues, forming a white, tough slough. The action, though powerful, is not diffuse, so that it can be quite exactly regulated in area and depth. The slough remains odorless during its attachment, and, when finally cast off, as happens in a week or ten days, exposes an underlying surface presenting clear, healthy granulations, which rapidly proceed to cicatrization. Chloride of zinc thus makes an excellent escharotic, combining the features of being powerful, yet manageable, of disinfecting its own slough, of determining kindly healing of the resulting ulcer, and of being free from danger of producing constitutional poisoning. Its operation is, however, very painful. In solution, zinc chloride is a standard disinfectant, but, if strong, acts upon metallic surfaces. Internally, it is a corrosive or irritant poison, according to concentration.

For use as a caustic, patent lint may be soaked in a concentrated solution of the salt, dried, and then cut—with an old, worthless pair of scissors—into proper size and applied to the part, which, if covered with skin, must first have the epithelium removed by blistering. Much more convenient, however, is the plan of making the chloride into a paste with flour and water. Such paste can be applied moist, or may be dried and cut into pointed rods, which are then available for thrusting into any large mass requiring destruction, such as a cancerous tumor. This paste was devised by a Dr. Canquoin, of Paris, and often goes by his name. It is made by rapid admixture of zinc chloride and wheat-flour with a very little water—a few drops only to the ounce of paste. The strength in zinc salt will range from fifteen to thirty per cent., according to the character of the tissue requiring destruction.

As a disinfectant, zinc chloride can be prescribed in the officinal *Liquor Zinci Chloridi*, Solution of Chloride of Zinc. This is "an aqueous solution of chloride of zinc, containing about fifty per cent. of the salt." It is made directly from the metal by the action of hydrochloric acid, the resulting solution being purified from contaminating iron by a special procedure, and brought to standard strength by distilled water. The solution is "a clear, colorless liquid, odorless, having a very astringent, sweetish taste, and an acid reaction. Sp. gr. 1.555" (U. S. Ph.). In its pharmacopœial strength, this solution is entirely too strong for direct application, being, indeed, corrosive. As a general disinfectant, it should be diluted to three per cent. strength, and as a lotion for wound-surfaces or ulcers to one per cent. It has the merits of being deodorant and disinfectant, while at the same time it has no smell, does not stain, and, in the dilution enjoined, does not attack fabrics, or even practically injure metallic receptacles.

Zinc Bromide ($ZnBr_2$).—Zinc bromide is officinal in the U. S. Pharmacopœia as *Zinci Bromidum*, Bromide of Zinc. It is a "white, or nearly white, granular powder, very deliquescent, odorless, having a sharp saline and metallic taste, and a neutral reaction. Very soluble in water and in alcohol. When strongly heated it fuses, and, at a higher temperature, it is volatilized with partial decomposition" (U. S. Ph.). Because of its ready deliquescence, the salt should be kept in small glass-stoppered bottles. Zinc bromide closely resembles the chloride in general properties, being deliquescent and highly irritant. Its officinal recognition is, however, not for its duplicature of the chloride in uses, but for its internal employment in nervous disease, with the notion of getting the combined antispasmodic effect of zinc and a bromide. But in the small dosage which the character of the salt ceiving the quantity of bromine ingested is practically insignificant. The salt is given in doses of from 0.15 to 0.30 Gm. (two and a half to five grains), in syrupy solution.

Zinc Iodide (ZnI_2).—Zinc iodide is official in the U. S. Pharmacopœia as *Zinci Iodidum*, Iodide of Zinc. It is "a white, or nearly white, granular powder, very deliquescent, odorless, having a sharp saline and metallic taste and a neutral reaction. Very soluble in water and in alcohol. When strongly heated, it melts, and, at a higher temperature, it is sublimed with partial decomposition" (U. S. Ph.). Zinc iodide, like the bromide, resembles the chloride in qualities; but, like the bromide, is suggested for the purpose of getting the effects of the iodine salts along with those of zinc, in constitutional medication. But again the necessarily small dosage defeats the purpose. The salt is given in doses of from 0.10 to 0.20 Gm. (one and a half to three grains) in syrup. Locally, the iodide has been applied for the general purposes of the metallic astringents, in solutions ranging in strength from the one-fifth of one per cent. to six per cent., or as a twelve per cent. ointment.

Zinc Sulphate ($ZnSO_4 + 7H_2O$).—Zinc sulphate is official in the U. S. Pharmacopœia as *Zinci Sulphas*, Sulphate of Zinc. It is in "colorless, transparent, small, columnar, rhombic prisms, or acicular needles, slowly efflorescing in dry air, odorless, having a sharp saline, nauseous, and metallic taste, and an acid reaction. Soluble in 0.6 part of water at 15° C. (59° F.), and in 0.3 part of boiling water; insoluble in alcohol. When strongly heated, the salt melts, gradually loses water, and, at a higher temperature, it is decomposed, with evolution of sulphurous vapors" (U. S. Ph.). Zinc sulphate is the sulphate whose commercial impure variety is called white vitriol. The pure quality, official as above, is in the small crystals described, which look not unlike those of Epsom salt. Zinc sulphate is decomposed by alkalies and their carbonates, hydrosulphates, lime-water, soluble lead salts, and vegetable astringents. By heating, it can be made to part with its water of crystallization, forming what is called *dried zinc sulphate*.

Zinc sulphate is an irritant astringent, and, in the dried form, even caustic, though less powerfully so than the chloride. Internally, in moderate dose, it is emetic, in excessive quantity an irritant poison, though again less potent than the chloride. The salt is a favorite metallic astringent, being milder than copper or silver salts, as less irritating, and without staining property. It has thus a wide range of applicability, but yet, where a powerful action is wanted, it is distinctly inferior to nitrate of silver, or sulphate of copper. The crystals are too small to permit the salt to be used in solid form; it is therefore used mostly in solution, the strength ranging from the one-fifth of one per cent. to about four per cent. Dried zinc sulphate has been employed as a caustic, made into paste with one-eighth part of glycerin, or into ointment with one-fourth part of lard. Internally, the salt—preferably in pill form—may be given for the constitutional effects of zinc, in doses of from 0.015 to 0.06 Gm. (one-fourth to one grain), several times a day, or as an emetic in doses of from 1.00 to 2.00 Gm. (fifteen to thirty grains).

Zinc Acetate ($Zn(C_2H_3O_2)_2 + 3H_2O$).—Zinc acetate is official in the U. S. Pharmacopœia as *Zinci Acetas*, Acetate of Zinc. It is in "soft, white, micaceous or pearly, six-sided tablets or scales, somewhat efflorescent in dry air, having a faintly acetous odor, a sharp metallic taste, and a slightly acid reaction. Soluble in 3 parts of water and in 30 parts of alcohol at 15° C. (59° F.); in 1.5 part of boiling water, and in 3 parts of boiling alcohol. When strongly heated, the salt melts, and at a higher temperature it is decomposed with evolution of inflammable vapors, a residue of oxide of zinc being finally left" (U. S. Ph.).

Zinc acetate is practically a duplicate in its effects of the sulphate; but its use has been rather restricted by custom to local application for the purposes of the metallic astringents. Solutions may be employed of the same strength as of the sulphate.

Zinc Valerianate ($Zn(C_5H_9O_2)_2 + H_2O$).—This salt is official in the U. S. Pharmacopœia as *Zinci Valerianas*, Valerianate of Zinc. It is in "soft, white, pearly scales, permanent in the air, having a faint odor of valerianic acid, a sweet, afterward styptic and metallic taste, and an acid reaction. Soluble in 100 parts of water and in 40 parts of alcohol at 15° C. (59° F.), both solutions becoming turbid on boiling. When heated, the salt melts; at a higher temperature it gives off white, inflammable vapors, and finally leaves a residue of oxide of zinc" (U. S. Ph.). From its comparative insolubility, zinc valerianate is locally less active in every way than the salts typified by the chloride and sulphate. Its place in medicine rests upon the idea of combining in one drug the antispasmodic virtues of zinc and valerian; but since the effects of zinc are feeble at best, and valerianic acid is probably not the active principle of valerian root, there is little ground on which to rest a valid claim for the salt's efficacy. Zinc valerianate has also the positive disadvantages of disagreeable smell and taste and costliness. The salt has been given in doses of from 0.06 to 0.12 Gm. (one to two grains), several times a day, best in pill.

Zinc Phosphide (Zn_3P_2).—This salt, being of value solely as a means of giving phosphorus, has been described under the title Phosphorus.

Zinc Nitrate ($Zn(NO_3)_2 + 6H_2O$).—Zinc nitrate forms by the direct action of nitric acid upon metallic zinc. It occurs in colorless prismatic crystals which are soluble in water and alcohol, and are very deliquescent. The salt is fusible, and has been employed, although it is unofficial, in the form of sticks of the fused substance cast in paper moulds, for application to sores and ulcers. The action is caustic and healing, after the manner of silver nitrate. Sticks of zinc nitrate must be kept dry in well-stoppered bottles, else they will be destroyed by deliquescence of the salt.

Zinc Oleate.—An oleate of zinc is obtainable in the form of a fine, soapy feeling powder, of a pearl color. This powder proves to be a serviceable bland absorbent and detergent for local dusting upon the skin.

Edward Curtis.

ZYMOTIC DISEASES. It is somewhat remarkable that, with the evidences of organic changes constantly present on every side, the far-reaching observations and deep scrutiny of men of the past into the processes of nature should have failed to discover, or, at least, adequately realize what to us to-day seems so ordinary a process as that of fermentation, as also the causes underlying it. But observation had not failed to mark and, in some measure, accurately to note its results; for these, as seen in the leaven of bread and in the changes which the juice of the grape undergoes, have been known since the beginnings of history. Manifestly, therefore, it has been the means for accurate study and observation that has been wanting. A century ago, when one of the pioneers of chemistry made this memorable statement, "He that understands the nature of ferments and fermentations shall probably be much better able than he that ignores them to give a fair account of divers phenomena of certain diseases (as well fevers as others) which will, perhaps, never be understood without an insight into the doctrine of fermentations," it was beginning to be perceived that these fermentations, resulting in a transformation of the constituents of a substance, were due to processes which, while chemical in their nature, involved the agency of external influences which, as the oxygen of the air, acted directly upon the organic substances affected. Further for many years discovery did not go, until, as in the instance of the yeast plant, it was noticed that the chemical changes in beer wort were coincident with the free growth and multiplication of the cells of the plant. That the presence of the plant was the condition of this chemical change was for a long time slow to be believed; and even as late as 1882 Dr. Angus Smith inclined to the belief that nitrification may go on to some extent apart from the presence of microbes. The numerous investigations of the school, with Pasteur at its head, which adopted for its motto *omnis cellula a cellula*, have now for many years fully elucidated this "doctrine of ferments," and have thereby given rise to the new science of bacteriology.

But nothing better illustrates how difficult it is for the scientific mind to keep more than one idea before it than does this, for hardly had the bacterial theory gained a permanent basis, than the chemical side of fermentation began to be thrust into the background. For a time it was the microbe that was being sought rather than its effects; and not until the attempt to connect in every case a distinct species of microbe with a separate fermentative or pathological process had proved unsatisfactory, was it fully realized that, in the etiology and progress of a zymotic disease we have to hold a strict account with the elaborated products due to bacterial growth and multiplication. Said Dujardin-Beaumetz neatly, in a recent lecture on Prophylactic Hygiene, "Prophylaxis has entered upon a new scientific route, and the basis of modern preventive medicine is two great discoveries—that of the pathogenic micro-organisms on the one hand, and on the other, of the incessant production by the economy of toxic alkaloids, ptomaines, and leucomaines."

With the great improvements in the microscope, with the development of the theory of cell-growth in plants and animals, and with a knowledge of the cell-constituents of the blood and animal tissues, it was to be expected that observers should surmise that, as lower forms of cell-life were found to develop and multiply outside the body, so they might similarly do in the blood itself. On such a theory the formation of abscesses and the secretion of pus within the body might be explained. In such a direction Jenner's discovery of the protective value of the inoculation of vaccine lymph seemed to point; but systematic experimentation was needed along exact scientific lines before the broad facts underlying these phenomena could be properly understood. Before all experimenters must be placed Pasteur, as the one to cause this world to rise out of chaos. With his chemical class he undertook the study of the production of the alcohols, and by research disproved the generally received theory of Liebig, that such was due to fermentations dependent on albuminoid substances which became altered during the process. Pasteur found that the degree and kind of fermentation depended exactly upon a bacterium of a particular kind, thereby elaborating those remarkable conclusions as to the *aërobies* and *anaërobies*, which went far to explain the hitherto supposedly chemical nature of nitrification as being due instead to the action of microbes.

But these discoveries were soon to be extended in the scope of their application. Davaine had found certain rod-like bodies in the blood of animals dead from anthrax, and imagined that they played a part similar to the rods in Pasteur's alcoholic fermentations; and thereafter Pasteur was commissioned by the French government to investigate this disease, which was causing annually immense losses of both cattle and sheep. The zymotic nature of the fermentative action, both in the production of alcohols and in splenic disease, had been generally accepted for several years, when Tomasi-Crudeli aroused anew the interest in the new science by the publication of experiments pointing toward the discovery of the cause of malaria or intermittent fever. Other experimenters questioned the accuracy of these observations, seemingly lately confirmed by Cohn and his assistants. But an event of greater interest shortly after took place, when Koch published his experiments, which demonstrated that tuberculosis was a zymotic disease, having its origin not in tubercles of various appearance, but in a microbe, which in its growth and multiplication sets up the inflammatory action upon which the formation of tubercles depends. Said Professor E. J. Barker, F.R.C.S., recently, in his lectures on Tubercular Joint Disease: "But though all these facts seemed to point very clearly to the identity of scrofula and tuberculosis, it was not until the discovery of the bacillus tuberculosis, and its demonstration in the initial lesions of these two affections, that positive proof was actually forthcoming. Almost at the same time, Koch and Baumgarten pointed out that in typical tubercular and scrofulous nodules this organism could invariably be demonstrated by different methods of preparation. These researches were soon supported by a whole army of bacteriologists, both at home and abroad."

To have been able to explain the etiology of a disease so ubiquitous as consumption, was to give to bacteriology a practical value and impetus which must have long been wanting, had these discoveries been limited to anthrax and the vinous ferments. Since then the study has advanced with enormous strides, and its influence dominates the whole realm of medicine. Surgery has been revolutionized by Listerism, and asepticism has become the goal and condition of successful surgery. Therapeutics bases her hopes of progress largely upon the doctrine of ferments, and preventive medicine has as her battle-cry cleanliness as opposed to putrefactions, fermentations, sapræmias, and septicæmias. To state that in the latest tables by Cornil and Babes some one hundred and thirty species of bacteria have been described, is but to indicate the progress in the study of micro-organisms. We have only to recall the fact that rouget, chicken-cholera, enteric fever, Asiatic cholera, glanders, and many other diseases have been proved in all probability to be due to specific microbes, in order to understand what advances have in recent years been made in the etiology of disease.

But it were contrary to all experience to suppose that these demonstrations could long prove sufficient to satisfy the physician, who has chiefly to deal with effects; to know these facts could be of but little moment, should he not likewise be informed regarding the operations of micro-organisms. To the agriculturist a botanical classification has but little significance, if he knows nothing of those conditions which make the development of plant life luxuriant, in the case of his grains and grasses on the one hand, or which can minimize the growth of injurious plants and weeds, on the other. In fact, the life-history of micro-organisms must be, equally with the discovery of species, the work of the bacteriologist, but especially of him who would investigate zymotic diseases.

This the discerning mind of Pasteur early realized, and as early as 1881 he isolated and cultivated the microbe of chicken cholera, discovered by Peroncito in 1878, and applied its attenuated virus to the prevention of outbreaks of the disease. He had already indicated the distinctions between *aërobies* and *anaërobies*, and shown how, by alterations made in the culture medium, development might be aided or retarded. Such investigations led Davaine to conclude that the bacillus of cholera spored or fruited in the same manner as many known forms of cryptogamia. Then came the stage of the division of bacteria into sporing forms and non-sporing forms, and of the study of the conditions favoring sporulation. Temperature was found to be the factor whose influence, next to nutriment, was of importance in this development.

This was first investigated most thoroughly in the instance of charbon, when it was found that 35° C. (95° F.) proved most favorable to the growth and development of spores; that a temperature of 42° to 43° C. (107.6 to 108.4° F.) favored rapid growth of the mycelium, which was checked at a temperature two degrees higher still, while five degrees higher yet finally destroyed the plant.

Apart, however, from the mere fact of the discovery of the cause of tuberculosis, the next greatest step in advance in the study of micro-organisms was that made by Koch, who in his published investigations, in 1882, illustrated his methods of solid cultures. He then used gelatinized blood-serum, while to-day potato, gelatine, peptones, and agar-agar are constantly utilized as culture-media. The behavior of micro-organisms in their growth on these cultures, both as to their action on the constituent elements of the culture material and as to their macroscopic appearances as colonies and mycelial growths, is one of our chief means of differentiating between species and of obtaining pure cultures.

Such then, briefly summarized, are the steps by which ed have attained to our present knowledge regarding bacteria, and the agencies which it is now believed lie at the origin of zymotic diseases. How far any really distinctive classification of micro-organisms can at present be made it would be difficult to say; but a division into sporing and non-sporing forms will doubtless hold, since upon this quality some of the most important influences of those bacteria which cause disease depend.

We have already referred, in the beginning of this section, to the processes which [illegible] entered into the processes by which sugars became transformed into alcohol or acetic acid, and by which putrefaction of organic substances takes place in the soil. As to very distinct from these processes are those which go on in the growth and multiplication of microbes in the fluids of the body or in its tissues, except in the fact that, inasmuch as their presence is foreign to the well-being of the animal organism, their multiplication is opposed by the normal processes of the body; and that it is only when the resistance of the system is unequal to the task of destruction that the multiplication of these organisms proceeds to such an extent in the system as to cause disease. In every instance the growth and development of these micro-organisms of that zymosis give rise to products which belong to the normal physiological processes of vegetable plant life. The products of these physiological processes of bacteria have without doubt never been studied by Nencki, Gautier, and Brieger in so thorough a fashion, that some doubt suggest the multiplication of microbes in the human system produces such severe effects through their influences on the physical conditions of the person affected, has become possible. Says Dujardin-Beaumetz: "I shall show you, then, that the gastric disturbances—indigestion, and various intestinal troubles, and even the fatal phenomena which may supervene upon the ingestion of putrid foods—owe to their sole cause the presence, in greater or less quantity, in the digestive canal, of the alkaloids which I have just mentioned."

In this rapid review of the scientific basis upon which the theory of zymosis has been built up, it is made manifest that, as the science of "microbie," as Pasteur has recently named it, is but little more than well begun, so we must expect that as it advances many new facts will be learned regarding those diseases now called zymotic, which may cause us to some degree to modify our present views regarding them; while to the list of diseases now known to be of bacterial origin we may expect to add many more whose causation is now a matter of doubt.

Accepting zymosis as a fact, it becomes of importance to determine, with as much accuracy as possible, what those diseases are which with our present knowledge may fairly be classed among zymotic diseases. Until very recently, much discussion has taken place on the distinctions to be made between miasmata, infections, contagions, etc.; but with our present knowledge of zymoses it is easy to understand why no common basis for a classification could be accepted, or, indeed, be possible. Infections and poisons have similarly been confounded as a result of evidence gained from pathological phenomena. Bouchard has, however, clearly made the distinction between these, when he says that infection is produced by a particular poison, differing from ordinary poisons in that it reproduces itself indefinitely; he, in fact, regards it as a living body which multiplies. Again, Dujardin-Beaumetz says: "we shall . . . reserve the name of infection to designate the penetration of the economy by a living principle, capable of multiplying itself in the organism, i.e., of microbiotic origin."

According to this, Bouchard's distinction of a miasm as being an infectious substance which multiplies itself outside the organism can hardly be considered as the basis of a classification; many infectious, and hitherto considered miasmatic, are found to be capable, at least under artificial conditions, of multiplication outside the body. Of this fact, the bacillus of tubercle may be given as an illustration. Says again Dujardin-Beaumetz: "It seems to me that to-day, thanks to the incessant progress of microbiology, we may modify these divisions, and say with Bouchard, that every infectious disease is a function of microbes; not that science is in possession of the exact knowledge of all the pathogenic microbes, but the absolute similarity which exists between the microbe-diseases and the virulent diseases of which the microbe is unknown, is such that we may affirm that the cause which presides over these affections is the same in kind. It will not do to conclude from this affirmation that the infectious diseases—microbe-diseases—are all contagious, and you readily understand that there may be microbe diseases which are not contagious, or, at least, whose contagion is operative only under conditions which never exist in the ordinary or normal state." Clearly, then, we have to include under zymotic diseases those which, in their history, are found to have a period of incubation, whether or not their specific microbe has been, up to the present time, isolated; and which, during this prodromal period, produce such effects upon the animal economy as are known to be produced, in varying degrees, by those infections whose life-history has been investigated, and whose pathological phenomena are now well recognized, if not wholly understood.

Here, again, notable variations are observed, based, however, largely upon the special qualities of the disease, first as to those parts where its development primarily becomes possible, and second, as to the rapidity of its development within the system; or, in other words, according to whether the disease produces acute and rapidly developing symptoms, as in cholera and scarlatina on the one hand, or lepra and tuberculosis on the other. Yet clearly we have here variations not in kind but in characteristics of the development of the zymosis, since we know that, in such diseases as typhoid fever, the progress of its development varies greatly both according apparently to the amount of the virus received into the system, and, again, according to the degree of resistance which the system makes to its development, depending not alone upon the vital resistance of the constitution to the disease, but upon the favorable nature of the blood or culture medium to the multiplication of the specific microbe. Probably no better illustration can be given of this latter point than that of the negro of the Southern rice plantations. Living constantly in a malarial atmosphere, he is exposed with impunity to an infection which quickly affects a person not acclimated; while it is said that the American negro, returning to Liberia, becomes a ready prey to the deadly fevers of the African coast. From these statements regarding the progress of the disease in the system after the inoculation of any virus, it is evident that we cannot in any exact way fix the number of days at which after its invasion markedly acute symptoms will take place; and clinical experience has been forced to fix a by no means exact number of days at which invasion after inoculation takes place. For the same reason, viz., the resistance of the system to the poison, the point at which its inoculation takes place—whether by the digestive tract, the respiratory organs, abrasions of the skin, the vaginal mucous membrane, or the veins of the uterus—it will be plain that the intensity of the symptoms may vary indefinitely. It may further be pointed out that the qualities of the specific microbes of any disease, as regards the normal rapidity of their multiplication, will govern in a large degree the rapidity of the initial symptoms of the disease as well as the duration of the zymosis. Thus, taking the two diseases, cholera, whether Asiatic or cholera nostras, and enteric fever, we find the first short in its incubative period, intense in its symptoms, and, where not fatal, brief in the duration of its later stages; on the other hand, in typhoid fever we have a frequently very long incubative period, with an advancing severity of symptoms, and a frequently very protracted period, even months, before recovery takes place. Similarly, in carcinoma and tuberculosis we have even greater differences in the various stages of their development and progress.

What the special reasons are which cause these variations in zymotic diseases have not as yet been very definitely determined, but it is probable that they depend primarily upon the properties pertaining to the individual classes of these micro-organisms, *e.g.*, the micrococci and the bacilli, and, secondly, upon the suitability of the culture medium for the free development of any particular organism. Further, that the various organisms are capable of the development of special properties in certain directions, under variations of the culture media and of their environment, seems from various facts to have been proved beyond doubt. Thus typhoid has not hitherto been transmitted to animals, unless, indeed, certain recent experiments of Vaughan may have proved that dogs are not wholly refractory to it. Again, hares and guinea-pigs, readily inoculable with true anthrax, prove refractory to *charbon symptomatique.* Further, Gamaleïa, of Odessa, has recently shown, in a paper presented by Pasteur before the French Academy of Sciences, that the spirillum of cholera acquires an increasing virulence in its transmission from pigeon to pigeon. Finally, according to Loeffler, the individual resistance of rats to charbon inoculation varies, apparently, according to the physical resistance of the animal from day to day, due, it must be supposed, to atmospheric conditions or environment, or more probably, as suggested by Feser, to the character of the food upon which the animal had for some days previously been fed.

These latter facts have an extremely important bearing upon the whole question, not only of prophylaxis, but also of the treatment of the disease as regards its probable termination. We are aware that the probabilities of a favorable termination, in cases of scarlatina and diphtheria, for example, can, other things being equal, be in a very large degree measured by the hygienic and sanitary conditions under which patients are placed. Russell, of Glasgow, and Carnelley, of Dundee, have shown, from the mortality statistics of these two cities, that the rate per 1,000 of population progresses regularly as the number of rooms of a house decreases from four or five to two and one; while we are personally aware, in reports from time to time received from frontier settlements, of instances where large families crowded into cabins of one or two rooms, and having poor food and limited medical aid and comforts, have had every child carried off by diphtheria, while grown persons have, in too many instances, met with a similar fate.

In the foregoing paragraphs, we have endeavored to set forth the nature of the phenomena which may be said to belong to all zymotic diseases, rather than to discuss the clinical features and pathological peculiarities which serve to distinguish them one from the other.

In the present state of our knowledge, it is perhaps scarcely advisable to attempt any definite classification of these diseases, since such classification must vary according to the standpoint from which they are viewed, and, moreover, because each disease has some characteristics which would entitle it to a place in different classes. For instance, diphtheria might, according to some, be kept out of the class having symptoms of a constitutional character; according to others, it would be classed along with other septicæmias; while again, inasmuch as it may develop a rash, it might fairly be placed under the exanthems. Again, were we to make a class of those diseases in which the virus is apparently taken into the system by the digestive tract, *e.g.*, cholera, enteric fever, and diarrhœa, we could scarcely avoid classing diphtheria with them, since it is well known that milk and water are vehicles by which it is introduced into the system. For practical purposes, however, it seems desirable that, whatever may prove in the future to be the preferable basis of classification, there should be some arbitrary division of zymotic diseases. From the standpoint of prophylaxis, there are some leading points which may fairly be adopted as a basis for the classification of those diseases which are most prevalent, and whose characters are therefore best understood. Thus, under the heading of *Soil Diseases*, we may place (*a*) the indigenous fevers, as intermittent, congestive fever, mountain fever, swamp fever, coast fever, yellow fever, etc., since, in a very special sense, they are associated with the emanations from a decomposing organic soil of vegetable origin; (*b*) choleraic diseases, as Asiatic cholera, cholera nostras, cholera morbus, cholera infantum, dysentery, diarrhœa, etc.; for, while some of these are associated to some degree with decomposing animal matters, it is still true that the drainage from soils into rivers and streams, the water of shallow bays, etc., are peculiarly prone to produce these troubles. Again, we have *Filth and Crowd Diseases, par excellence*, under which we would place (*a*) typhus, and ship fever, dengue, famine fever, prison fever, etc.; (*b*) typhoid fever, with its modifications, remittent, typho-malarial, hog-cholera, rouget, etc.; (*c*) diphtheria, with exudative tonsillitis, membranous croup, strangles, and diphtheria in animals, as horses, cats, pigeons, etc.; (*d*) malignant pneumonia; (*e*) tuberculosis, scrofulosis, etc., since on the organic filth in atmospheres of houses must we place primarily the exciting conditions of this scourge; (*f*) septicæmias, as puerperal fever, erysipelas, hospital gangrene, etc.

As a better defined class, we have the *exanthems*, under which we may place (*a*) smallpox; (*b*) rubeola; (*c*) scarlatina; (*d*) Rötheln; (*e*) charbon, malignant pustule or carbuncle, charbon symptomatique, etc. This classification, purely arbitrary, not only indicates how impossible it is to draw hard-and-fast lines on any etiological basis, but also serves to point out the directions in which the work of prophylaxis must be begun and carried out. In the one class, the work is largely one of state medicine and municipal sanitation, including drainage, control of water-supplies, food supplies, etc. The second class, while also demanding municipal supervision, includes the work of household sanitation, and individual hygiene, covering the control of factories, workshops, and hospitals, as regards overcrowding, ventilation, overheating, etc.; while the third class is one which, while demanding household sanitation, makes especially prominent the duty of isolation of cases, and disinfection in its most complete form.

We have treated in a partial way a subject whose ramifications extend into the domain of medicine in all its branches, but what has been said will suffice to illustrate the problems which, not until within the last twenty-five years, have in any way seemed to approach a solution.

Peter H. Bryce.

APPENDIX.

ABSORBENT SYSTEM, DISEASES AND INJURIES OF THE. Anomalies of the Thoracic Duct.—Very many and remarkable instances of deviations in structure, form, course, size, and termination of the thoracic duct are to be found in the literature of the subject. It may begin at a higher or a lower point, consist of one or more branches, divide at one or several points, into two or several subdivisions which may reunite or separately join either the right or the left subclavian vein, or the vena azygos. In one case it terminated in eight branches, two opening into the left, and two into the right, subclavian vein, two into the right jugular, one into the external jugular, and one into the vertebral vein. Instances of double and triple ducts, and of transposition to the opposite side, are quite numerous.

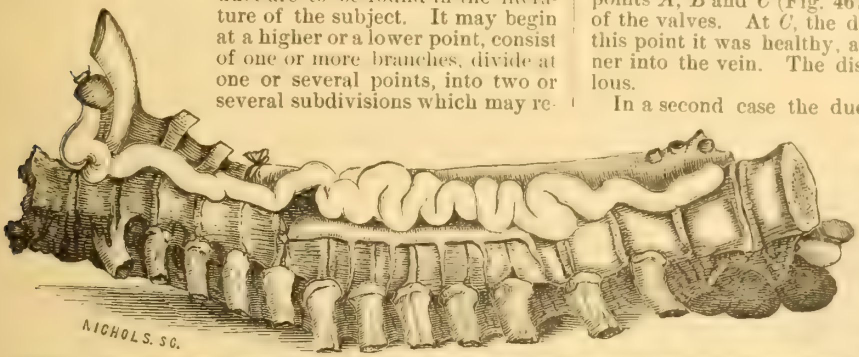

Fig. 4674.—Dilatation of the Thoracic Duct. The aorta, vena azygos, and lower portion of the left internal jugular vein, with that portion of the left subclavian vein which forms a right angle with it, are seen as half distended with course injection, and dried. The thoracic duct is little more than half distended with the injection.

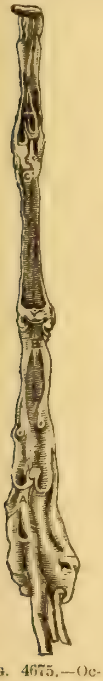

Fig. 4675.—Occlusion of the Thoracic Duct by Thickening and Fixation of the Valves.

Variations in size are equally remarkable. It may be uniformly enlarged from its beginning to its termination, or the dilatation may be irregular. Most usually the enlargement is at its terminus. In several instances, these enlargements have been so considerable as to appear like aneurismal tumors. Matthew Baillie cites an instance in which the duct was nearly as large as the subclavian vein, and Cruikshank asserts that he had seen it "as large as the carotid artery of an adult, or the barrel of an ordinary writing-pen." In most of the reported cases, the dilatation was associated with some morbid condition of the coats of the vessel, but in other instances it was a congenital malformation. The cases of Cruikshank (Fig. 4674) and Amussat (Fig. 4681), are illustrations of this class.

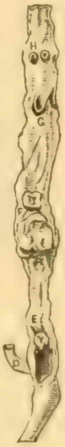

Fig. 4676. Occlusion of the Thoracic Duct by Fungous Growths.

In Cruikshank's case, the man was forty years of age. No obstruction or other cause to which the dilatation could be ascribed was discovered.

Diseases of the Thoracic Duct.—The reported cases of disease of the thoracic duct are not numerous. Cooper observed, in the cadaver of a person who died of phthisis pulmonalis, the thoracic duct occluded at the points *A*, *B* and *C* (Fig. 4675) by thickening and fixation of the valves. At *C*, the duct was obliterated. Beyond this point it was healthy, and emptied in its usual manner into the vein. The disease appeared to be scrofulous.

In a second case the duct was occluded by fungous growths (*E* and *F*, Fig. 4676). In this case the chyle reached the subclavian vein through an anastomosing branch, *D*. The mesenteric glands were enlarged, and the peritoneum was studded with tubercles.

A third case was observed in a laboring man, who had suffered for several months with an enlarged testicle, an abdominal tumor, and enlarged lymph-glands. The testis was a "pulpy mass, composed of broken-down coagulable lymph, and a blood colored serum." The thoracic duct was much altered; its coats were thickened and opaque, and its lumen was obliterated (Fig. 4677). Opposite the curvature of the aorta, the duct was lost in a large tumor, *L*, which differed only in bulk from the abdominal tumor. The receptaculum is seen at *I*; the thoracic duct at *K*; the duct emerging from the tumor at *M*, and the aorta at *N*.

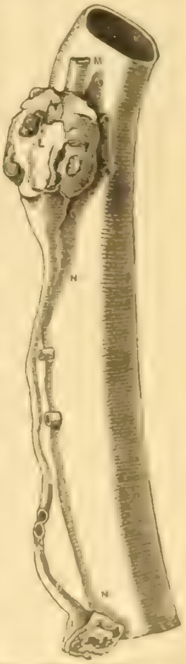

Fig. 4677.—Occlusion of the Thoracic Duct by a Tumor.

In another case the thoracic duct was completely obliterated at *L* (Fig. 4678). The communication between the receptaculum chyli and the subclavian vein was restored by the anastomosing duct *N*, which connected with the duct proper at *O*. This case, like the preceding, illustrates the effort of nature to prolong life by the formation of the anastomosing branch.

The duct has been found diseased in a variety of affections. In a patient dying of phthisis it was found transformed into a fibrous cord; in another dying of chronic nephritis, it was filled with pus, with marked inflammation of its coats; in a fatal case of croup, complicated with pleuro-pneumonia and gastritis, the walls of the duct were thickened, friable, and the lining membrane was inflamed; and in several cases of pelvic abscess the duct has been found diseased, and more or less filled with pus. These pathological conditions, somewhat analogous in character, have been found in association with tuberculous degeneration of the lungs and mesenteric glands, with gangrene of the lungs and abdominal viscera, with suppuration of the cervical glands, with abgans in the kidney and lumbar glands, with uterine sarcoma, pelvic abscess, and cancer of the testicle. It is impossible to adopt any exclusive view in regard to the primary or secondary nature of disease of the duct. It is evident that disease may originate in the tissues of the walls of the duct, but far more frequently it is secondary to some degenerative process taking place in other parts. In all the recorded cases of disease of the duct the lymphatic system has been involved; in some by extension from one part to another by continuity; in others by conveyance of infecting material through communicating vessels, or by contagion from diseased glands in close proximity. Worms has reported a case of idiopathic inflammation of the duct associated with disorganization of the [illegible], which ended in [illegible] by lymphatics filled with pus. The thoracic duct was obliterated at its outlet by a mass pressing upon its descending portion. The remaining portion was dilated to the size of a crow-quill and covered with pus. Its walls were thickened and opaque. The similarity of the morbid products found in the duct to the [illegible] degenerative changes [illegible] in other parts strongly supports the view that in such cases the lesions of the former were secondary, because they were in the line of the onward course of the current toward the venous system.

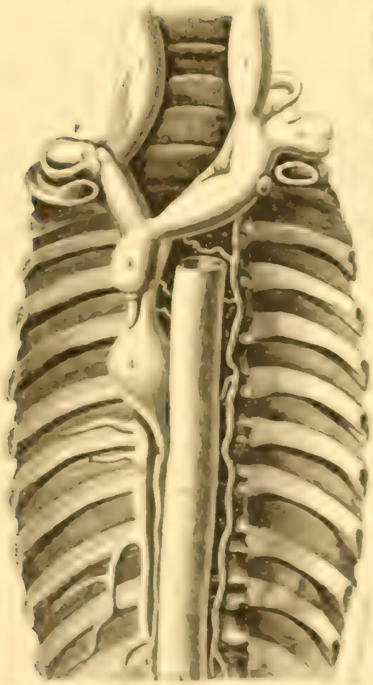

FIG. 4678.—[illegible]

Other kinds of contents of the duct have been observed. Besides blood, pus, bile, [illegible] worms and other extraneous substances, calcareous material has been found in quantities sufficient to completely fill the duct.

Lieutard found, in a scrofulous subject, the mesenteric glands "turgid with a chalky material," and the thoracic duct dilated to more than three times its normal size and filled with the same material.

Cheston reports a case of ossification of the duct (Fig. 4679). It was firm like a "piece of pack-thread," and was entirely plugged up with osseous matter from the receptaculum chyli. In some places the ossification [illegible] was firmly attached to the internal coat. The duct was totally impervious.

Cheston concludes the history of this case with the statement that the appearance of the patient was similar to those who had "[illegible] and been destroyed by slow inflammation of the viscera."

Ould reports the case of a woman who died of acute peritonitis supervening upon a chronic pulmonary affection, in whom the bodies of the last dorsal and five lumbar vertebræ were found destroyed, and the cervical, thoracic, bronchial, abdominal, pelvic, axillary, and inguinal glands were found filled with calcareous concretions. In another case, with an abscess in one of the iliac fossæ, and erosion and destruction of the os ilii, calcareous concretions were found in the bronchial, pelvic, and mesenteric glands.

These calcareous deposits most frequently occur in old persons, and generally consist of phosphate of lime.

In several cases calcareous material was observed in the receptaculum, but always in connection with similar depositions in other parts of the lymphatic apparatus. In a case (Fig. 4680) reported by [illegible], the deposit was found only in the receptaculum.

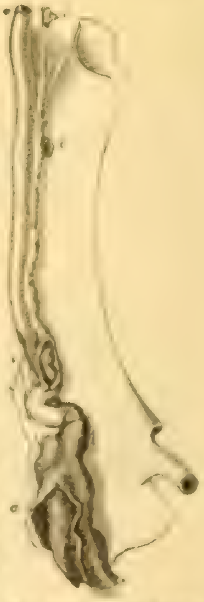

FIG. 4679.—Ossification of the Thoracic Duct. [illegible]

In order that a fuller explanation of the condition might be had, the thorax was opened, and yet the smallest trace of a thoracic duct could be found. It was apparent, however, that a foramen, indicated by the letter A, permitted the escape of the thinner portion of the chyle, by means of which the life of the man was prolonged. No communication of the chyle-conveying vessels with the venous system could be discovered. The coexisting dropsy was undoubtedly due to the interruption in the flow of the chyle.

WOUNDS OF THE THORACIC DUCT.—But few cases of wounds of the thoracic duct have been reported, and most of them are doubtful. In several cases in which an opening or rupture was found in the duct, from which chyle escaped into either the pleural or peritoneal cavity, such opening was the result of disease. There are, however, several cases which must be accepted as authentic. In one of Morton's cases the girl became hydropic "after too great an effort to raise a burden. From the frequent tappings there always issued "a chylous fluid, not unlike milk in color, taste, and consistency." Bartholin refers to a case in which the duct was wounded and the patient lived a long time. Glandorp reports the case of a woman who was wounded in the duct—"at least the mucus and liquid that escaped made it appear so. The patient was nearly cured, but relapsed and died." Hoffman relates the case of a woman who was wounded in the left side by a knife. From the wound a fluid escaped, which was milky during digestion, clear when the patient was fasting, and coagulated spontaneously. Monro reports a case in which lymph escaped through an external wound caused by a stab, and also into the pleural cavity. The case of Gulffart was somewhat similar.

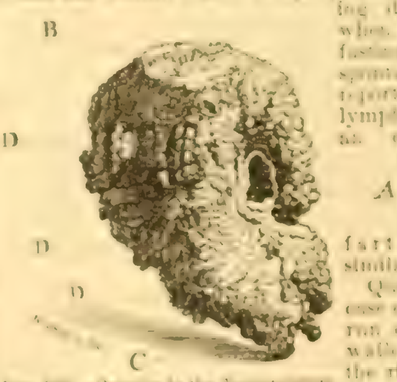

FIG. 4680.—Concretion in the Receptaculum Chyli. A, [illegible]; B, [illegible]; C, [illegible]; D, [illegible]

Quincke reports the case of a man who was run over by a wagon while lying partly upon the right side and abdomen. Dyspnœa set in on the third day after the accident, and increased from day to day until the tenth, when 1,800 cubic cm. of fluid were withdrawn. The fluid was whitish-yellow, resembled milk, and after standing, presented the appearance on its surface as of a white layer of cream about a millimetre in thickness. It exhibited under the microscope minute fat-globules. During the third tapping the patient expired. The right pleural cavity contained 7,000 c.c. of a milky, whitish-yellow fluid. The thoracic duct, from its mouth to the point of emergence from behind the right subclavian vein, was filled with coagulated blood. The lower portion could not be dissected out.

Lower ruptured the thoracic duct of a dog by introducing his finger between the ribs. The animal died after languishing a few days, and two pounds of chylous fluid were found in the right pleural cavity. Monro inflicted a wound in the receptaculum chyli of a pig, which recovered. The effusion of lymph was prevented by a coagulum.

Rupture of the Thoracic Duct, Receptaculum Chyli, and Lacteals.—Clinical and experimental observations have shown that rupture has occurred most often in the receptaculum, and least often in the duct. Post-mortem examinations of cases in which the communication between the venous and lymphatic systems was either partially obstructed or wholly obliterated, are not very numerous. The grouping of such observations is peculiarly instructive. There is no instance of the preservation of the life of the animal beyond a limited number of days, after the communication of the chyle-conveying vessels with the venous system has been completely and permanently obliterated. The free and unobstructed conveyance of the chyle into the blood is essential to the proper nutrition of the body, and to the preservation of life. Death is the result of inanition. This is conclusively shown by gradual wasting and progressive debility, which so markedly characterize such cases. Acute impoverishment of the blood is the inevitable result.

Effusion of Chyle into the Cavities: Chylothorax.—There have been reported ten cases, including the doubtful cases of wounds of the thoracic duct, of lesions produced by either disease or accident, either in the duct or in some of the larger lymph-vessels in the thorax. In five of the cases the chyle escaped from the duct. In one the aperture was discovered only after death; in the others the injury resulted from external violence.

In a number of the cases of chylous ascites, a chylous fluid was also found in one or both of the pleural cavities. In some of these cases, in consequence of obstruction to the escape of the chyle into the subclavian vein, rupture of some small branch of the thoracic duct may have occurred, but it is generally believed that portions of the fluid effused into the peritoneal cavity traversed the lymph-vessels of the diaphragm. The diagnosis of cases of effusion of a chylous fluid in the pleural cavities cannot be made except by withdrawing a portion of the fluid. In Quincke's case of injury by crushing of the chest-wall, the diagnosis was not made until after the evacuation of the cavity. All the cases belong to a class of casualties which do not admit of generalization, and are only instructive in suggesting the occurrence of an improbable contingency, which may happen under circumstances very various and unforeseen. The prominent symptom in such cases is dyspnœa, produced by the accumulation of a fluid in one or both cavities. The nature of the fluid can only be determined by its appearance and examination. In a single instance, a chylous fluid was emitted drop by drop from a puncture through the chest-wall.

Effusion of Chyle into the Peritoneal Cavity: Chylous Ascites.—There have been reported 37 cases of chylous ascites (27 in collection by Busey, and 10 additional cases in collection by Murphy). A number were not originally reported as cases of chylous ascites, but have been classified as such by collators, who have carefully examined the clinical reports.

The causes are various, but may be referred to conditions or some accidental circumstance which produced rupture of the thoracic duct, receptaculum chyli, or lacteal vessels. In a single instance it was due to the puncture of the filaria sanguinis hominis, and in another to "congenital occlusion of the thoracic duct, formation of a compound cystic tumor by distention of the lacteals at the root of the mesentery, rupture of one of the cysts during birth, persistence of this solution of continuity, and increasing effusion of chyle absorbed by the intestines." In most of the cases the chyle escaped through the ruptured wall of the receptaculum, or of one or more lacteal vessels. In several instances the walls of the receptaculum were found diseased, ossified or otherwise changed. In two instances, which recovered, the effusion was manifestly the result of accidental rupture of some chyle-conveying vessel. In much the larger number of cases the effusion was due to over-repletion distention, and consequent rupture of some chyle-conveying vessel, caused by obstruction to the current of the chyle. Such obstruction may result from compression by thoracic or abdominal tumors, enlarged mesenteric glands, peritoneal adhesions, inflammatory thickening of the folds of the mesentery, obstructed pulmonary circulation, interrupted cardiac circulation, stenosis of the thoracic duct at or near its junction with the left subclavian vein, obstructed subclavian vein, impenetrable and degenerated mesenteric glands, and dilatation of the right side of the heart, with stenosis of both auriculo-ventricular orifices. There are a number of cases in which dilatation and rupture of lymph-channels occurred in consequence of impediment to the lymph-stream, but the cases of Virchow, Friedberg, and Cholmely are perhaps the only instances of lymph-varices caused by congenital heart anomaly.

The milky fluid found effused into the serous cavities must be classed, according to its pathological aspects, as either a chyle-like or a fatty fluid. In cases of chylous ascites the effused fluid is chyle, but in other cases of a milk-like fluid found in the pleural or peritoneal cavity the fatty fluid is the product of the coexisting degenerative processes taking place, such as cancer or tuberculosis.

As the effusion of chyle into either the pleural or peritoneal cavity can occur only by transudation or through solution of continuity of some chyle-conveying vessel, its escape externally, or presence in either cavity, must be held as the essential element of differential diagnosis. When the emitted fluid results from transudation the quantity is small, and is usually rapidly absorbed by the peritoneum. When poured out through an aperture in the walls of a vessel the opposite condition exists. If no fluid escapes externally, then only the symptoms indicating the collection of fluid in the cavity will be exhibited, the character of which can be ascertained only by evacuation and examination. The accumulation of fluid can be recognized, and it can be determined whether it is free in the peritoneal cavity or in a cyst. Acute anæmia, with sudden and great prostration, loss of appetite, and rapid diminution of the quantity of urine, associated with a rapid accumulation of fluid in the peritoneal cavity, might suggest the presence of chyle. Dr. Murphy says, in uncomplicated cases due to rupture from violence the symptoms are well marked. "The patient, usually after exertion, is suddenly seized with sharp, localized pain, followed by rapid swelling of the abdomen, suppression of urine, nausea, and vomiting, which in some cases is milky and accompanied by milky diarrhœa." In most cases the loss of chyle by effusion and consequent accumulation is gradual, and the symptoms are more or less obscured by the causative condition. Gradual accumulation of fluid, with great prostration, marked and continuous emaciation, coincident with conditions which would suggest compression of the thoracic duct or interruption of the current of chyle, would suggest the nature of the fluid; but one could not safely assert the fact previous to the withdrawal and examination of a portion. Cystic tumors may usually be readily distinguished.

The prognosis is unfavorable. If the condition be due to the pressure of a removable tumor, recovery is possible by an operation, but in such cases the nature of the tumor usually precludes any hope. The cases of Nickerson and Murphy recovered. In both instances the effusion was the result of rupture of some chyle-conveying vessel caused by a trivial violence. Rest in bed, evacuation of the fluid, and a restricted diet resulted in recovery

I introduce the reports of the two cases following; the first was a case of very long duration with rupture of the umbilicus and discharge of the effused chyle; the other is of a doubtful nature.

Abdominal tumor with milky discharge, reported by Edward Amos, M.D. (Boston *Medical and Surgical Journal*, vol. vii., p. 16, 1832).

"Mrs. Hood, aged about forty, naturally of good constitution, enjoyed comfortable health until the year 1817. While pregnant with a pair of twins, a small umbilical rupture took place from the excessive distention of the abdominal parietes, not larger, as she says, than an English walnut, and which nearly disappeared after delivery. Soon after this period was discovered a tumor in the lower part of the abdomen, which gradually increased in size, became painful, and greatly impaired her general health. It possessed a soft but rather unequal surface, and circumscribed, with occasional paroxysmal pains, and not infrequently attended with some discharge. She, however, became anasarcous, which rendered her extremely large and, in appearance, very near her end. Her breathing became very laborious, and it was with difficulty that she could walk or lie down. But observing that the water exuded from her legs through the skin, I made several punctures with a lancet, which discharged freely for several days, and by the use of a few simple medicines the water unexpectedly subsided, and left her apparently free from dropsy, and so much relieved that she was able to perform the usual labors of her family with but very little help. The abdomen, however, remained much distended by the original tumor. The absence of the water led to the discovery of another swelling in her right side, extending from the spine of the ilium to the diaphragm. This last tumor was discovered about 1825-26, and both together caused her most extreme suffering from the pain of distention; and she several times sent for the neighboring physicians, and entreated them to open her side and give vent to what she believed to be a collection of fluid; but on examination, the tumor appeared solid and without any fluctuation, so that her requests were never complied with. After the above-mentioned period the abdomen began to be more distended, from what appeared to be an ascites, presenting a uniform surface, and the distinctness of the tumors became less apparent. As the disease progressed, the umbilical tumors protruded, and eventually formed a bag of an irregular shape, the apex, which was at the umbilicus, being elevated about five inches from the abdominal surface, and in the middle seven or eight inches in circumference, with two lateral processes resembling nipples about one inch in length. The existence of this singular tumor was unknown to anyone but herself, until an occurrence took place which I am about to mention.

"On the night of the 17th inst. (July, 1832) I was called upon to visit this woman in great haste, as a tumor had burst and was discharging profusely. On my arrival, a distance of four miles and a half, I found her sitting in her chair, with her clothes on, and her finger on the aperture to prevent any further discharge until my advice could be obtained. On inquiry, she told me she went to bed as usual, and about twelve o'clock she was awakened by a discharge from a tumor on her bowels, which had burst. She got up and dressed as quick as her situation would permit, with the assistance of her daughters, and had saved three pints besides what escaped. The friction from the pressure of the finger, for nearly two hours, had enlarged the orifice so much, that sufficient fluid to fill a common-sized pot would escape in a few minutes. About twelve pounds were drawn off while sitting in the chair, and being faint, she was laid on the bed, herself compressing the orifice with her finger; and after a while, three pounds more escaped, when she became too faint to bear any further evacuation, and the remainder was drawn off the next day—being twenty-five pounds in all. This fluid was discharged through an aperture in the umbilicus, which was at the extremity of the tumor. But what involves the whole subject in mystery is, this fluid was milk! and without any disagreeable odor, more than if taken warm from a cow.

"Although the woman is relieved from a great burden, and is able to walk about, she is still encumbered with two original swellings, one on each side, which I apprehend is an enlargement of the ovaries."

Fatal case of vomiting of a chyle-like fluid, reported by Dr. Lawrence Sprague (*New England Journal of Medicine and Surgery*, vol. xii., p. 4, 1823).

"On the afternoon of the 12th of October, I was called to visit a man on board of a schooner lying in the Kennebec River, who was attacked so suddenly, and severely with disease, it was feared he would not survive until I should arrive on board. When on board I was informed that he had done a seaman's duty from St. Bartholomew's to Hallowell, Me., and on the passage had enjoyed good health. One hour before I visited him he had been in the boat with other persons, employed in towing the schooner a short distance up the river, and while engaged in this duty he suddenly requested another person to take his oar, as he could hold it no longer, owing to a severe pain in his stomach and bowels, which so entirely prostrated his strength that he was immediately returned on board. I found him writhing under the most severe pain, which had passed from the abdominal across the lumbar region. Feeling for his pulse, there was not the least arterial action to be discovered at his wrists; and parts of his skin which had been most protected from the weather by the clothes which he wore, were of the same deathly coldness as the rest of the surface. His eyes had a glassy appearance, his countenance pale, and his whole aspect bore marks of immediate dissolution. On the outside of the berth in which he lay, I discovered the food which he had recently eaten and ejected from the stomach, mixed with a great quantity of chyle, it having the appearance of milk in a frothy state. On observing to him that he had puked, and inquiring of him whether he was now sick at the stomach, he replied that he had felt no sickness at his stomach, neither had he been exercised with puking, but that the same kind of fluid (with the exception of more food than had been already thrown up) had continued to flow from his mouth since the commencement of the attack, without the least nausea or act of vomiting. Considering this circumstance very extraordinary, and it having been corroborated by three individuals who had been constantly waiting upon him, my attention was arrested and particularly fixed on a fact, at the time, altogether to be unaccounted for. From the time of my arrival, the fluid resembling milk, which I can have no doubt was chyle, continued to flow so fast from his mouth—with but few seconds intermission, without the least exertion on his part, or the slightest action of vomiting to be perceived—that it was with difficulty he could at times keep from suffocating. It seemed as though it flowed through a channel without any perceptible effort to propel it, and no obstruction to its escape but completely closing the mouth. He was frequently inquired of whether he felt any nausea, and his uniform reply was, that he did not feel the least inclination to vomit; that the matter came up without his being sensible of the power which ejected it. This fluid of a milky appearance continued to flow from his mouth from the commencement of my visit until his death, which took place in half an hour after my arrival. After he was dead, and as long as I remained on board (which was half an hour), as he lay on his back on a board, the discharge from his mouth much increased, bearing the greatest resemblance to the purest milk in a frothy state, unmixed with any other substance. The quantity of fluid thus brought up is variously computed by three individuals who were with him from the commencement of the attack. One of the persons supposed the quantity to have been equal to a gallon measure, others a less quantity. For myself, I could not undertake to decide, but feel confident it was sufficient to produce the coldness which pervaded the whole surface of his body, the loss of pulsation at the wrists, and the fatal consequences which ensued."

The Relation of Obstructed Cardiac Circulation to Lymph Stasis.—Morton performed a number of experiments upon dogs by ligating the thoracic duct; in some the "receptaculum, and in others the lacteals, burst." In every case there was extravasation of chyle. In Sir Astley Cooper's experiments, when rupture occurred it took place at the receptaculum; and Dupuytren's experiments upon horses were followed by nearly similar results. Cooper says it is not necessary to tie the duct. If the animal is fed with milk, and the extremity of the duct is compressed one-half hour afterward, the receptaculum will rupture. Those and similar experiments prove that, under certain conditions involving an interruption or complete arrest of the current of the fluid through the thoracic duct, the resultant distention and dilatation may prove sufficient to produce rupture, which may take place either in the receptaculum or in the lacteals. In those cases in which rupture did not take place, the current of the fluid was re-established through anastomosing branches.

The clinical and post-mortem observations connect directly the process of gradual occlusion of the duct by disease with the concurrent development of a diffuse area of lymphangiectasis, which in some cases terminated in rupture and extravasation.

Monro cites the case reported by Morton of "hydrops ascites lactea," in which the rupture of the lacteals was occasioned by the compression of the thoracic duct near the subclavian vein by large indurated tumors.

Morgagni refers to the cases of Valsalva and Santorino, in both of which there was considerable dilatation of the lacteal vessels produced by the pressure of an aneurismal tumor on the thoracic duct. In Valsalva's case, the aorta, from the heart to the diaphragm, was dilated, and "the lacteal vessels presented the appearance of numerous white spots having a diversity of figure and magnitude."

In the body of a man who died after a large quantity of chylous liquor had been let out of his thorax, Bassius discovered an orifice, at or about the third dorsal vertebra, from which the chylous material flowed as from a fountain. Below this orifice the thoracic duct was pervious.

Cayley reports a case of obstructed thoracic duct and rupture of the receptaculum chyli. "On post-mortem examination some yellow fluid was found in the peritoneal cavity, and the peritoneum in front of the spine was bulged forward by the effusion behind it of a large quantity of milk-looking fluid. The receptaculum was much dilated, and on its anterior surface was a perforation two inches in length. The thoracic duct was immensely dilated throughout its course to its junction with the subclavian vein, where it suddenly became narrowed, and just at its mouth a fibrous vegetation was attached to the lining membrane of the vein which completely occluded the opening of the duct. The narrowed part of the duct was blocked by a firm, yellow, cylindrical coagulum."

Virchow refers to the case he observed in a new-born calf, in which, in consequence of thrombosis of the external jugular vein, the mouth of the thoracic duct was occluded, and nearly all the internal organs were dilated to the utmost with ectatic lymph-vessels filled with a slightly sanguinolent fluid. The intestines especially were covered with broad bead-like canals, arranged so closely together that the intervening tissue could scarcely be recognized.

Ormerod reports a case of chylous ascites in which, on several different occasions, large quantities of a milky fluid were removed. This fluid, Drs. Wilks and Marcet proved to be chyle mixed, more or less, with common serous peritoneal effusion. On post-mortem examination "the left subclavian vein and its afferent vessels were found plugged with a light-colored, ragged clot, evidently of long standing. It was soft in the centre, and at one point was firmly adherent to the walls of the subclavian vein. In the abdomen and chest were also found numerous nodular masses, consisting of an imperfectly fibrous structure."

The preceding citations establish the proposition that retardation or arrest of the current of the fluid in the thoracic duct, at or near its outlet into the subclavian vein, may produce dilatation, distention, and rupture of the lymphatic vessels, and consequent effusion of chyle and lymph into the serous cavities. When the impediment to the flow of chyle and lymph occurs at or near its outlet, the area of stasis and ectasis would necessarily depend upon the duration and extent of such obstacle, and hence, when the area of ectasis is extensive, the manifest inference is that the cause has been one of gradual development and protracted duration. In the case of Bassius, dilatation and rupture were caused by impermeability of the distal extremity of the duct; in Morton's case, the rupture of the lacteals was occasioned by the pressure of a tumor upon the duct near the subclavian vein. In Ormerod's case of chylous ascites, the interruption to the flow of chyle was caused by the "plugging of the left subclavian vein and its affluent branches with a light-colored, ragged clot, evidently of long standing." The resistance to the flow of the contents of the thoracic duct must have been derived exclusively from the interrupted venous blood-current. The heart was normal, and the duct was unobstructed. In Cayley's case of obstructed thoracic duct and rupture of the receptaculum, two factors were in operation, viz., the interrupted blood-current, occasioned by the fibrinous vegetations attached to the intima of the subclavian vein, and the partial obliteration of the lumen of the duct near its terminus. In Virchow's case of the new born calf, the condition existing partially exemplifies the obstructing forces operating in the cases of Ormerod and Cayley. The mouth of the duct was occluded by thrombosis of the external jugular vein. In addition to the slowing of the blood-current in the jugular and in the subclavian, produced by the projecting part of the thrombus, the exit of the fluid from the duct was also impeded.

The influence of partial obliteration or stenosis of the thoracic duct, at or near its termination, in the causation of dilatation or rupture of some part of the lymph vascular system, cannot be doubted. The effects of stenosis produced by the gradual encroachment from disease of the duct, or of surrounding and contiguous tissues and structures, have been shown both clinically and post-mortem. In this latter class of cases, the ectasis is gradual in its development, and more extensive. In those cases in which the lymphangiectasis was consequent upon the slowing or interruption of the venous blood current in the left subclavian vein, the relation of cause and effect seems equally well established. It remains now to show that such diseases of the heart as slow, impede, or stagnate the venous blood-current in the left subclavian or innominate vein, may also produce lymph-stasis. Petters reports a case of lymphangiectasis in which were found, upon the visceral peritoneum, "numerous cysts from the size of peas to that of filberts, some colored bright, and containing serum. Upon the small intestines numerous lenticular protuberances, transparent, and filled with wine-yellow fluid. . . . The glands of the right inguinal region were transformed into cysts of small walnut size, filled with wine-yellow fluid. From the inner wall of these cysts extended dilated lymph-vessels of crow-quill size, which connected the cysts with each other, so that a dilated vas efferens and afferens could be seen in each cyst. Upon puncture, a yellowish fluid spouted from these cysts in a jet of several inches. The lymph-vessels and cysts formed a mass which it was difficult to unravel. The lymph-vessels in the vicinity and the thoracic duct were greatly dilated.

"The heart occupied the entire anterior thoracic cavity. The enormous enlargement of the heart included the entire right side of the organ, so that the left ventricle with the auricle formed only an appendix. The muscular tissue of the left ventricle, which would not contain a hen's egg, was thin and flaccid. The left venous orifice, by the growing together of the apices of the bicuspid valves, was changed into a small crescentic opening, barely admitting the point of the little finger. The latter was callous and enclosing here and there a bony plate. Right ventricle largely dilated, with thinned walls. Columnæ carneæ of both ventricles very slender and insufficiency. [illegible] large as a child's head, [illegible] formed of a thin layer of peri-cardium. Aneurism of ascending aorta pressing [illegible]. Aortic valves incompetent. Right ventricle [illegible] enlarged."

This example [illegible] of the left venous out-flow and a moderate contraction of the right [illegible] opening. Powers concluded that the stasis of lymph, followed by the great dilatation of the lymph-vessels and glands, was caused by the organic disease of the heart. It cannot be doubted that the interruption of the current of blood by the narrowing of the orifices and dilatation of the right side of the heart retarded the movement of the contained fluid in the lymph-vessels. This influence, first demonstrating itself upon the movement of the contents of the thoracic duct, causing distention and dilatation of the vessels of the trunk, produced stasis of lymph in remote vessels. The [illegible] eminences, filled with a transparent fluid, grouped together on the mucous surface of the small intestine, were, probably, ampulliform dilatations of terminal lymph-spaces and the [illegible] on the peritoneum were of like [illegible] and nature.

At the conclusion of this report, Powers refers to the case of an old woman, "suffering with stenosis of the left orifices of the heart," upon whose right arm he found several semi-solid tumors, situated immediately under a [illegible], which he regarded as dilated lymph-glands.

J. Grainger Stewart reports a case of "dilatation of the lacteals," associated with hypertrophied and fatty heart, with diseased aortic valves and dilated auriculo-ventricular orifices. In this case the stasis of chyle occurred in the intestinal villi, producing dilatation of the central lacteal vessels of the villi, and arresting the further absorption of the chyle. To the incompetency of the aortic and auriculo-ventricular valves was added fatty degeneration of the heart. Here enfeebled action of the organ and regurgitation were co-operating factors in arresting the movement of the chyle.

In Rokitansky's case of chylous ascites, there was dilatation of the heart, "with thickening and shortening of the mitral valves." The cardiac affection not only interrupted the flow of chyle in the thoracic duct, but caused a stasis of chyle in the lacteals and mesenteric glands, and of lymph in the lumbar lymphatics, and an effusion of a milk-like fluid into the pleural and peritoneal cavities.

In Hughes's case of abdominal effusion of a chylous fluid, supposed to have resulted from the pressure of mesenteric tumors, "the heart was thin, pale, weak, and flabby," and "numerous lacteals—large, tortuous, varicose, and distended; some with milk and others with a clear fluid—were observed in all parts of the mesentery." The case was complicated with abdominal tumors, "consisting of several agglomerated mesenteric glands," believed to have been cancerous; but from a number of the enlarged glands "a cream-like fluid exuded," and hence it is not improbable that the morbid condition of the glands and lacteals was due to stasis of chyle and lymph, caused by the disease of the heart.

In this connection the case of mitral and tricuspid insufficiency, with granular liver, ascites, anasarca, and thrombosis, reported by Oppolzer, is interesting. The internal and external [illegible] veins were occupied at their [illegible] with pale, yellow, soft coagula. From the superior [illegible] the clot extended with a jagged end into the auricle, and continued into the right subclavian, as well as into the right internal jugular as far as the foramen lacerum. The left innominate and the beginning of the left subclavian were obstructed. The thoracic duct was plugged at its termination by a pale-red, fibrinous coagulum. Its walls were thickened, and its lumen, from the commencement to the [illegible] thoracic [illegible], was greatly dilated. The regurgitation of blood into the thoracic duct was caused by the obstruction to its entrance into the [illegible].

The explanation of this relation of cause and effect between cardiac disturbance and lymph-stasis must, in a general way, be sought in the varying conditions of blood-pressure. A potential, if not the predominant, factor concerned in the flow of the lymph is the difference between the arterial and venous blood-pressure; the greater this difference, the more rapid the movement of the lymph. In a normal condition of the heart, venous orifices, and great afferent and efferent vessels, the blood-pressure in the innominate veins and their affluent branches, during diastole, is at its minimum—represented in comparison with the pressure at the aortic summit as nil; so that, whatever may be the potentiality of the difference between the arterial and the venous blood-pressure as a force in promoting the movement of the chyle and lymph, it is at its maximum when the venous blood-current is flowing most easily and rapidly into the right auricle. Therefore, it must follow that any disease of the heart or any condition of its affluent veins which retards, impedes, or obstructs the free and rapid flow of the venous blood into the right auricle and through the tricuspid orifice will slacken, interrupt, and obstruct the movement of the chyle and lymph in the thoracic duct and its tributary vessels. This conclusion is not derived merely through inductive reasoning, but is illustrated and verified by clinical observation and post-mortem appearances.

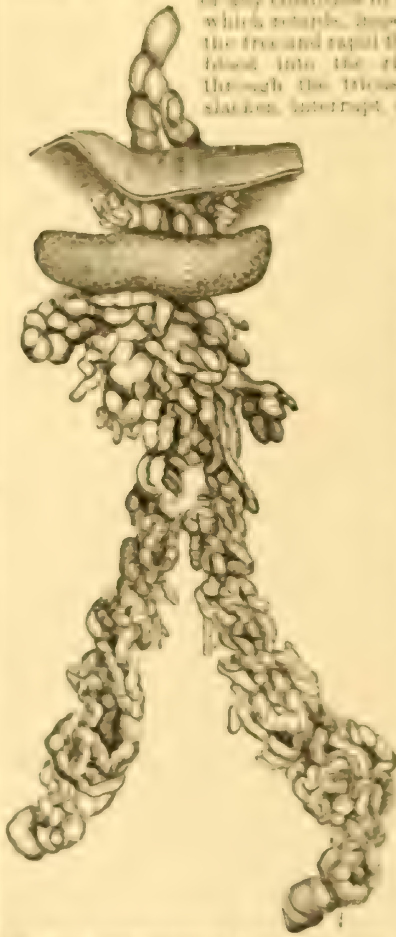

FIG. 4681.—Intra-abdominal Lymphatic Varices.

INTRA-ABDOMINAL LYMPHATIC VARICES.—But few cases of this nature have been reported, and most of them have been mistaken for hernia. The specimen shown in Fig. 4681 was obtained by Amussat, from the body of a youth, nineteen years of age, who during life had carried in each groin a large tumor which was supposed to be a double inguinal hernia, and for which he had worn a truss. Suddenly, after a long journey on foot, he was seized with acute pains under the right breast and in the folds of the groins, difficult respiration, dry cough, cephalalgia, fever, and lancinating pains in the tumors. After some hours of intense suffering he died.

After having turned out the thoracic viscera, the diseased lymphatic vessels were discovered. Some were as large as quills. The mass of dilated and twisted vessels extending to the iliac fossæ were dissected out.

The iliac and crural masses of lymphatics were blown up and macerated, when it was discovered that the hernial tumors were enormously dilated lymph-vessels.

The iliac chain of glands had disappeared, and seemed to have been replaced by lymphatic vessels. No direct communication with the veins was discovered.

The following case, reported by Drinkard, is somewhat analogous. The hernial tumor was discovered in the cadaver of a negro, on the dissecting-table. The tumor occupied nearly all the superior part of the groin, being situated rather more to its outer than its inner border. On dissection a thickened superficial mass was exposed. From the meshes of both of its layers protruded the cellulo-adipose tissue of the region. The tumor was not connected with either the crural or the inguinal ring, and appeared like a mass of cellulo-adipose tissue, interspersed with lymphatic glands undergoing fatty degeneration, and presenting here and there, through its substance, patches of a pale rose color, resembling cellular tissue, infiltrated with blood serum.

Nélaton operated upon a case, in which the diagnosis was uncertain, by making an incision over the mass in the groin, when a quantity of milk-like fluid escaped. The patient was seized with rigors and symptoms of purulent absorption, and died. A similar tumor on the opposite side, which had not been operated upon, was injected, and found to consist of a network of varicose lymphatic vessels.

In the following case, reported by M. Trélat, the tumors were mistaken by Trélat, Nélaton, and the physicians of l'Ile Maurice for hernial tumors. Their true nature was only discovered at the autopsy. The right tumor was situated, in greater part, under the cribriform fascia, in front of the aponeurosis of the psoas and abductor muscles, and consisted of lobes approximating each other; it was definitely bounded above, below, and at the sides, but behind it communicated with the deep lymphatic vessels. From it was discharged, in great abundance, a rose-colored fluid. No hernia could be discovered, but varicose lymphatic vessels occupied the inguinal canal and the superior portion of the cord. Upon removal of the peritoneum from the posterior abdominal wall, there was observed along the iliac vessels a mass of wrapped conduits rolled together, directed generally from below upward. This condition existed on both sides. Toward the columns of the diaphragm these two masses approached, and were probably blended together under the diaphragm. The masses were formed by dilated lymphatic vessels, and resembled exactly the illustration given by Breschet of the condition found in the case of Amussat.

In this connection I reproduce the cases of Petit and Aimé-David, in neither of which was the diagnosis of lymph varices verified. A student had noticed for a year, more particularly after fatigue, a swelling in each groin, which was accompanied with some pain extending down the thighs. Examination showed tumors in both groins, the integument covering which was unchanged in color. The tumors extended into the inguinal canals, and were painful to the touch; the pain extended along the saphena, which region presented the characters of angioleucitis. The boy left the lyceum and returned in eight days, wearing a double truss. The former condition returned, however; the tumors doubled in size, and the limbs became œdematous and benumbed.

The next case was that of a mulatto, about thirty years of age. In consequence of angioleucitis, a very extensive enlargement of the legs developed. At the internal region of the thighs there were present prominent tumors consisting of dilated lymph-vessels. The tumors were uneven, elastic, transparent, and under pressure receded into the abdomen.

Aimé-David refers to another case observed by M. Denis, in which the tumors present were analogous to those found in the patient of Petit. The patient also had a double hydrocele.

The tumor observed by Petters in the right inguinal region of his patient, equalled in size a small apple, and resembled a hernia. It "felt like a conglomeration of ascarides—like rebounding cords, which, upon pressure with the finger, became softer and more flaccid." Petters regarded this anomaly as a "venous plexus," but it consisted of the "glands of the right inguinal region transformed into cysts of small walnut size, filled with wine-yellow fluid. From the inner wall of these cysts trabecular projections extended into the cavity and it was possible to enter two dilated lymph-vessels, of crow-quill size, which connected the cysts with one another so that a dilated vas efferens and afferens could be seen in each cyst. Upon puncture, a yellowish fluid spouted from these cysts in a jet of several inches. Lymph-vessels and cysts together formed a conglomeration which it was difficult to unravel. The lymph-vessels in the vicinity and the thoracic duct showed considerable dilatation." This case was complicated with stenosis of both auriculo-ventricular orifices, enlargement of the heart, œdema, ascites, and cirrhosis, and it does not seem possible to have correctly diagnosed the true nature of the inguinal tumor, which was only recognized after paracentesis.

In view of the history of the foregoing cases, it becomes important to differentiate intra-abdominal varices from hernial tumors. Lymphangiectatic tumors may be confounded with reducible and irreducible tumors. Among the latter may be classed cold abscesses, cysts, and lipomata, which develop slowly, but may be distinguished from lymphangiectatic tumors by their reducibleness, transparency, and indistinct feeling of fluctuation, quite different from that of tumors containing fluid. Lipomata are fixed; they may be compressed, but cannot be reduced. They rarely develop symmetrically, while the inguinal glands on both sides may be affected. Of reducible tumors, lymph varices are most frequently mistaken for herniæ. Both develop slowly; neither changes the appearance or character of the covering integument; both increase in size during exercise and continued maintenance of the erect posture, and both usually recede in the horizontal posture. Hernial tumors do not, however, usually recede unaided, but glandular tumors do. The existence of dilated lymph-vessels in close proximity, the absence of any impulse on straining or coughing, the invariable size of the tumor, and the history of the case, are important data in determining its lymphatic nature. The cases of Trélat and Amussat presented the history and symptoms indicating hernia. In both cases the tumors were reducible and developed slowly. Aspiration and percussion offer the most certain means of differential diagnosis. The presence of a fluid presenting the chemical and microscopical characters of lymph would settle the diagnosis. A lobulated feel, or a sensation as of a congeries of twisted cords unattached and movable, which enlarge when the person is in the erect posture, should excite doubt as to the hernial nature of the tumor. The following case, observed by Fetzer, presented phenomena which should remove all doubt as to the character of the tumor.

"A girl, sixteen years of age, had—besides a double femoral hernia which had existed since her eighth year—upon her abdomen a ribbon-like stripe, commencing one inch below the navel, to the left of the linea alba, continuing to the left and upward, and passing between the false ribs and the ileum, proceeding thence, becoming lighter in color and narrower, as far as the vertebral column. Upon this band, anteriorly upon the abdominal walls, one inch below the navel and two lines from the linea alba, was a conglomeration of several, perhaps eighteen, wart-like tumors, from the size of a male to that of a female nipple, and of the same color as the surrounding skin. They were painless, flaccid, could be pressed into the abdominal walls, but rose upon the removal of the pressure. From two of the protuberances a milk-like fluid exuded continually, drop by drop. The flow issued from a small red spot in the centre of the tumors and was increased by pressure upon any of the unruptured bodies. After standing a short time, the fluid separated into a milky, turbid serum, rendered clear by ether, and a brighter, milky, large coagulum, which reddened upon exposure to the air." Fetzer removed with the scissors one of the protuberances, which was formed by a thin cutis, and immediately from the opening issued in a stream a considerable quantity of the milky fluid, and this was followed by great debility, languor, and a feeble pulse. The entire band was studded with minute raised points. Into the opening artificially made a probe might be passed to the depth of one inch. Chemical analysis of the fluid by Professor Kletzinsky, and microscopic examination by Professor Schlossberger, proved it to be lymph.

CHYLANGIOMA CAVERNOSUM.—In the summary of the causes of varicose lymph-vessels, attention was drawn only to the resulting [illegible] conditions. I will here present an abstract of the case of Quincke, in order to compare it with a case of chylangioma cavernosum, in which chyle retention in the mesenteric lymphatics was occasioned by a very different pathological condition of the mesentery. The following is a report of the autopsy made by Professor Langhans: "Intestinal serosa and peritoneum of parietes thickened and opaque, and covered by numerous fibrinous bands, which connect the intestinal convolutions with each other and with the mesentery and abdominal walls. Here and there these bands were infiltrated with chylous fluid, and consequently milky and opaque. About three metres above the ileocæcal valve, commenced a very dense injection of the chyle vessels, extending to the duodenum, with a perfectly chyle-like milk-white mass. The chyle-vessels were dilated, regularly and irregularly, and alongside of them were larger rounded, slightly prominent, milk-white spots, resembling extravasations. Chyle retention was found upon the villous mucosa of the entire small intestine in a marked degree, and also within the mucosa. In the latter was found an accumulation of chyle spots, and in the lower portion of the ileum the chyle could be seen to assume white flakes. The chyle-vessels were injected exactly to the root of the mesentery with the mesentery, not injected by the latter; mesenteric glands small, without chyle retention. The obstruction to the flow of chyle was caused by inflammatory thickening of both folds of the mesentery, by the transformation of the interposed adipose tissue into dense connective tissue, and by the adhesions along the surface, which glued the [illegible] of the mesentery to each other. The excessive capillary extravasation of chyle into the intestinal walls and peritoneal cavity was occasioned by the closure or compression of the lacteals by the inflammatory thickening of both folds of the mesentery."

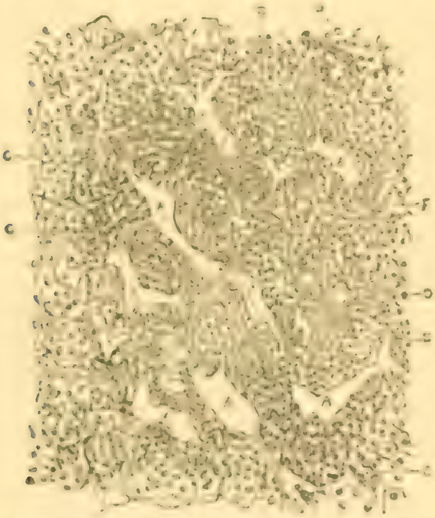

FIG. 992.—Cavernous Chylangioma. A, Fat lobules; B, cavernous [illegible]; [illegible]

Weichselbaum's case of cavernous chylangioma occurred in a man of eighty, who died of senility and pneumonia. Between the folds of the fatty mesentery of the upper ileum there was a tumor of fist-like size and 4 cm. in thickness, which looked like a lipoma. Upon incision into the tumor a watery-white milk-like fluid exuded. Fig. 992 exhibits a section through the tissue.

The tumor consisted of fat tissue filled with numerous caverns of varying size and form, which contained the milky fluid. The caverns formed the larger part of the tumor and [illegible]. The smallest cavern was lined with endothelium. Chemical and microscopical examination of the fluid showed that it possessed all the physical characters of milk.

In this case no extravasation or effusion took place, but the mesentery was transformed into a cavernous structure, the spaces of which were filled with chyle. The cavernous spaces were either dilated chyle-vessels or lacunæ.

In this connection the following case of lymphangioma cavernosum, reported by Hoffmokl, will prove interesting, because of its locality and the result of the treatment:

Adolf A——, aged two months; moderately nourished; anæmic; expression of face suffering. In the dorsal decubitus of the patient the entire right half of the thorax and lumbar region was seen to be occupied by a tumor, which extended upward to the crista ilii, forward to about one inch from the right edge of the sternum, and backward to the right transverse processes of the vertebræ. Length of tumor, 19 cm.; width, 16 cm.; height above normal level, 7 cm. The skin covering it was traversed by partly smaller, partly larger dilated veins and showed at the superior portion of the tumor several bluish, elastic places averaging three or four lines in diameter. Upon the external side of the tumor was seen a dark-red teleangiectasis, confined to the skin, and 1½ inch long by 1 inch in width. At the upper portion of the tumor the skin was retracted in an umbilicus-like manner in a place about one inch long, yet presenting no trace of a scar. The surface of the tumor appeared lobular, especially in the anterior upper and lower portions; the tumor itself was very elastic and fluctuating at the most prominent portions. It could be somewhat diminished by pressure. During the crying of the child it became tenser and more tense. Percussion of the tumor gave an empty (dull?) sound everywhere. No other alteration in the thoracic and abdominal organs. The tumor at its upper portion appeared somewhat transparent. Exploratory puncture gave exit to about two ounces of clear, yellowish, lymphoid fluid, when the tumor collapsed somewhat, and then showed still more distinctly that it consisted of numerous caverns, which perhaps communicated with one another by several canals. The fluid itself was feebly alkaline, coagulated after about a quarter of an hour, and after a time the fibrinous cake expelled the serum, similarly to what occurs in a bloodclot. The specific gravity of the serum was 1.020. Microscopically, a small number of lymph-cells could be demonstrated; 100 grammes of the fluid contained: serum albumin, 2.585 Gr.; fibrin, 0.085 Gr.; globulin in small quantity; and salts of the blood serum. No lymph-vessel epithelium could be discovered.

Six days after the puncture the tumor was nearly as full as before. Dr. Hoffmokl again punctured at another place, and obtained the same fluid, but scarcely two drachms. Three days afterward erysipelas was developed in the seat of the entire tumor. The tumor became tense and painful, and the child seemed to be much debilitated. Cooling applications with the addition of lead water were made, and by the end of a week the erysipelas had almost wholly disappeared, and the tumor was much smaller, and presented at many places a distinct hardness, caused probably by coagulation of its contents. The appearance of the child was improved.

Twenty-six days after the second puncture the erysipelas had disappeared entirely, the tumor was flat, smaller by two-thirds, solid in the lower, but fluctuating in the upper, portions. The appearance of the child had by that time very much improved.

SIMPLE LYMPHANGIOMA.—Simple lymphangioma, which is exclusively a congenital form, may be illustrated by the following cases of macroglossia and macrocheilia.

"A child, two years of age, had, from birth, a thick tongue, which had greatly increased during the preceding two weeks. The tongue protruded from the mouth in a broad, thick, hard mass, and was closely encircled by the stretched lips.

"Upon the posterior under-surface lay, in partly bead-like rows, bluish transparent vesicles, varying from very fine, just visible bodies, to the size of large flaxseeds.

"Upon longitudinal section through one lateral half of the ablated portion, the cavernous tissue was found principally in the middle part corresponding to the region of the transverse muscle, as shown in Fig. 4683.

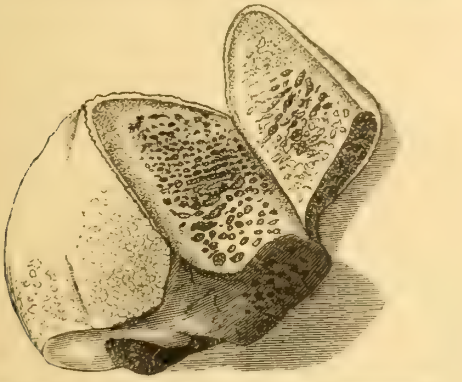

FIG. 4683.—Lymphangioma of the Tongue (Macroglossia).

"Upon the top could be distinguished the whitish, tough layer of the mucous membrane and the papillæ; below it a longitudinally striated, very tough, and whitish layer; next, the cavernous mass, and below, again, a more longitudinally striated layer, which continued beyond the apex. The same result was found upon transverse section, and the cavernous structure appeared in the centre in very coarse meshes, while toward the lateral portions it became fine, and toward the periphery the mesh cavities became smaller and smaller, in such a manner that bead-like vesicles could be traced up to the papillæ. The cavities were elongated perpendicularly, and varied in size from the smallest, barely visible points, to over a line in their greatest diameter. The width of the trabeculæ varied. Many of the cavities communicated by narrow openings; many, however, appeared closed, and the adjacent vesicles could be seen shining through at the bottom; the trabeculæ and partition walls which bounded them were sharply defined, more or less smooth, and pale."

"C. R., fifteen years of age, was born with a thick upper lip. He often suffered with swelling of the glands of the neck during childhood, without suppuration ever taking place, and several times the upper lip had been inflamed and much swollen, which had subsided, leaving only an increased enlargement of the lip.

"The excised portion collapsed very much, and showed to the naked eye a distinct cavernous trabecular tissue, and a lymphoid serous fluid could be pressed from the deeper caverns, while coagula were formed in the smaller caverns. The trabeculæ were formed in part of connective tissue only, in part also by fibres of the orbicularis oris; the largest cavities were of the size of small peas, the smallest microscopic."

"E. S., aged seven months, suffered from congenital macroglossia, which, about every four weeks, was attacked with some inflammation attended with difficult deglutition, dyspnœa, and considerable enlargement of the neighboring lymphatic glands. The volume of the tongue was increased after each attack, finally attaining the size of an ordinary apple, felt very tense to the touch, was dark red; its surface was covered with a thick, white coating. The strongly developed papillæ gave to the surface a thickly villous, furry appearance.

"The protruding portion was amputated, and on examination its parenchyma was found to have degenerated into a cavernous meshwork, whose trabeculæ were partly formed of white, firm, connective-tissue cords, partly by muscle-bundles. The fluid within the meshes of the cavernous tissue coagulated into very white coagula, which looked like fibrin coagula, and consisted of lymph-corpuscles."

Virchow insists that the "bead-like, bluish, transparent vesicles, which varied in size from just visible bodies to the size of hempseed," found on the under surface of the ablated portion of the tongue, were dilated terminal lymph-spaces, and communicated by very fine apertures with deeper-seated vessels, or with the cavities of the cavernous tissue of the parenchyma. For, although this connection could not be demonstrated, it could be shown that the cystoid spaces, probably dilated lymph-canaliculi, became smaller and smaller toward the surface, and, finally, bead-like vesicles could be traced up to the papillæ. The characteristics of the cavities with which the hypertrophied portions of the tongue were interspersed, can only be explained upon the supposition of the primary ectases of lymph-channels. In Billroth's case of macrochilia, cavernous trabecular tissue, from which a lymphoid fluid could be pressed, was distinctly visible to the naked eye; and in the other case, he found a cavernous transformation of the parenchyma containing a lymphoid fluid. Neither Billroth nor Virchow succeeded in establishing a direct continuity between the caverns and lymph-capillaries, but the microscopic character of the fluid was sufficient. In one of Billroth's cases of macrochilia, it was not possible to distinguish the fluid from lymph, and in the other it consisted of lymph-corpuscles and fibrin. Virchow maintains that the cystoid formations found in the nodes of congenital hypertrophies, are formed by the dilatation of the lymph-spaces, though their communication with lymph-vessels may not be recognized. Billroth, though holding that congenital macroglossia and macrochilia may be either solid or cystic, concedes that the cysts owe their origin to occlusion and dilatation of the lymph channels; and O. Weber asserts that congenital lymph-angiectases of the tongue and lip find their cause in dilatation of the terminations, or, more correctly, of the calibre of the lymph-vessels.

CHYLOUS HYDROCELE; GALACTOCELE; CHYLOCELE; LYMPHOCELE.—Cases of effusion of a milky fluid into the tunica vaginalis have been reported by Vidal (de Cassis), Ruthman, Ferguson, and others. The cases of C. H. Mastin, and W. M. Mastin occurred in the city of Mobile.

The fluid in the case of Vidal was composed of water, a substance analogous to albumen, and fatty matter. It was alkaline and coagulated spontaneously. Under the microscope there were seen a multitude of small globules having the appearance of the globules of butter. In the case of Ruthman the contents were the color of milk with a greenish-yellow tinge, and they thickened and coagulated spontaneously. In Ferguson's case the fluid was indistinguishable from milk, and emitted a peculiar odor.

The cases of Mastin and son, of Mobile, Ala., have been more carefully observed and studied, and seem to have determined the nature and cause of the effusion, as well as a proper method of treatment. The first, by C. H. Mastin, occurred in a man twenty-two years of age; five feet and eleven inches in height; weight, one hundred and fifty-seven pounds; of robust health, and bilious temperament; brunette. Eight years previously he had noticed an enlargement of the scrotum, which gradually increased for four years, when he was tapped, and a quantity of "white fluid" was drawn off. The same operation was repeated three times, and when seen by the reporter, the sac exhibited every appearance of a hydrocele. It was tapped a fourth time, and eight ounces of a thick, milky fluid evacuated. The sac was dense, firm, and elastic. Testicle slightly enlarged, but no evidence of disease of the gland. The fluid was alkaline; specific gravity, 1.015; highly albuminous; and composed of innumerable molecules, and some small granular cells resembling colorless blood corpuscles, floating in a ser one pint. The fluid in its chemical and physical qualities was comparable to chyle. The patient had refused again until one year had elapsed. The tumor was then opened by an incision three inches in length, and eight ounces of the same kind of fluid were discharged. The sac was found [illegible]. The cavity was smooth, polished, and pearly white, and, at the junction of the cord with the testicle, a small, round, glandular-looking mass, about the size of an English pea, was seen. This was snipped off, and at its base were observed the patulous orifices of three or four small vessels, which did not bleed. These vessels were dissected back, and being found to pass into the cellular tissue around the cord, were tied en masse with a silk ligature, the ends of which were brought outside. The front wall of the vaginal tunic was excised, its edges [illegible] with a drainage-tube by silk sutures, and the cutaneous wound was closed by the pin suture. Recovery was rapid. Five years afterward the patient was seen and carefully examined. There had been no return of the disease.

To Dr. C. H. Mastin is due the honor of first having observed a lymphatic varix on the surface of the tunica vaginalis, though Lebert,[1] as early as 1855, had suggested the possibility of its occurrence in cases of chylous hydrocele.

The second case occurring in Mobile is reported as follows by Dr. W. M. Mastin: H. E. A., aged twenty-two, white, American, a decided blonde, somewhat below medium stature, a carpenter, and a resident of Mobile. Four years previously he had noticed that both testicles were enlarged, firmer than natural, and the seat of considerable and dull pains. At the time of examination the right tumor was the size of a man's fist, pyriform in shape, opaque, somewhat elastic, with slight fluctuation, and at its posterior and upper parts, in the region of the cord, filled with irregular, tortuous, worm-like masses, resembling a varicocele. The left tumor was much smaller, with no perceptible fluctuation, not transparent, but marked by similar convoluted and tortuous masses, which were somewhat diminished by the recumbent position. By aspiration three ounces of a milky fluid were withdrawn from the right sac, which exhibited the usual chemical and microscopical characteristics of similar fluids. Upon opening the sac there was found on its upper and front surface a smooth and rounded lump. This nodule was pedicled and oozing, and after its removal a milky fluid oozed from the patulous mouth of the vessel, nearly as large as a knitting-needle, in the stump. Previous to its removal it had been transfixed at its base with a needle armed with a double catgut ligature, each ligature being tied separately and cut short. Recovery was complete.

The appearance of the varices in these two cases differed only in that in one there were visible the orifices of three or four ducts after the varix was snipped off, and in the other the mouth of a single vessel only. In both cases the varix was located on the anterior surface of the sac, at the junction of the cord with the testis.

The third is reported in abstract as follows by Dr. W. M. Mastin, and is the first in which the filariæ have been discovered.

J. F. M., a [illegible] by occupation, twenty-two years of age, born in Mobile, of Irish parentage, [illegible], of slender frame but moderately robust, came under observation on September 27, 1887, suffering from an enlargement of the left testis. Inquiry elicited these points in his history: There is no evidence or history of either hereditary or acquired disease. His father died of acute cerebral congestion at the age of fifty-three, but his mother is still living in the enjoyment of good health, as are the other members of his family, consisting of five brothers and two sisters. His own health has always been excellent, and, with the exception of the usual diseases incident to childhood, and a short attack of malarial fever in the fall of 1885, he has never suffered from fever, or, indeed, from serious or wasting illness of any kind. His bowels are [illegible]. His appetite and digestion are good, but he complains of nervousness and disturbed sleep, the result, probably, of irregular hours consequent upon his occupation of night-watchman. His habits are good and he is not a drinker, although he indulges in an occasional glass of beer. His residence is located in a [illegible] portion of the city. He has never been out of Mobile and its immediate vicinity. The water ordinarily consumed for drinking purposes by himself and family is supplied by the "City Water Works," but is occasionally derived from a drove well, the former being pumped up from a clear running stream into an open reservoir, from which distributed to the town. He does not remember to have drunk cistern or tank water, or any standing uncovered water. Eight years ago his right testicle passed up into the inguinal canal, where it has since lodged; this he attributed to immoderate exercise, although he has no recollection of any injury connected therewith.

The left testicle began to enlarge three years ago, but was without pain, and, indeed, the only discomfort experienced therefrom is the inconvenience resulting from its bulk.

Examination shows him to be fairly nourished and apparently in good general health. The right testicle is atrophic, insensitive, and occupying a fixed position about the centre of the inguinal canal. The left testis has the dimensions of a medium-sized pear, is pyriform in contour, fluctuating, semi-transparent (by transmitted light), and painless—in a word, presenting the characteristic features of an ordinary hydrocele.

The glands in both inguinal spaces are moderately enlarged and in chains—each gland being easily outlined and traced to its association with another. There are also a few enlarged glands in the right axilla and the right cervical region, but no other lymphatic enlargement is discernible, and, in fact, there is no evidence of any other disease whatever. The left tunica vaginalis was tapped, and four and a half ounces of milky fluid withdrawn. The testicle was neither enlarged nor painful. This fluid was alkaline in reaction, albuminous, of a yellowish-milky color; and, as shown microscopically, contained numerous fat granules, some leucocytes, casts, epithelial scales, and embryonal filariæ in active motion.

The sac slowly refilled and was retapped twice. The first time was on November 7, 1887, when about one-half ounce was removed; three slides were examined, with the result of finding fourteen of the embryo nematodes. The final tapping was on May 19, 1888, and resulted in the removal of one ounce of fluid and a "find" of five embryos in three slides. These were all active and vigorous, and remained alive until the desiccation of the liquid medium.

Repeated blood examinations were made, but always with negative results, although great care was observed in conducting them, due regard being had for diurnal migration and inversion of this periodicity.

VARICES OF THE LYMPH-VESSELS OF THE PENIS.—The varying forms of varices of the lymph-vessels of the penis are shown in the following cases. Dubois reports the case of a man aged thirty years, who a year previously had contracted a urethritis, the acute period of which was complicated with lymphangitis of the prepuce and [illegible]; resolution took place, but there remained on the anterior surface of the penis little knots, [illegible] near the raphé. On the left side a reddish, nipple-like pimple was to be seen, terminating at its summit by a grayish point, alternately opened and closed. From this there passed a subcutaneous knotted cord parallel to the median raphé of the penis; the skin was not adherent, and had not changed its color. At its posterior extremity the cord terminated in a nodosity, adherent to the skin, and on which existed two grayish openings resembling the one before described. Pressure being made upon the knotted cord, a sero-purulent fluid escaped from the openings; a stylet introduced into one opening penetrated the cord and passed out through an opening of the other extremity. Between the openings described there existed another in the middle of the cord, at which the cord adhered to the subcutaneous cellular tissue, which was the point of anastomosis of the affected with the healthy lymphatics."

In this case the valves, though incompetent, were present, hence the characteristic knotted condition. When entirely absent, such portion of the vessel will expand uniformly.

Huguier reports the case of "a man, aged thirty-nine years, who had a right inguinal hernia, and for two years had used a bandage. On the penis, at the base of the glans, was seen a congeries of transparent vessels, hard, tortuous, and three or four millimetres in diameter. These vessels seemed to arise from the frænum of the prepuce, from whence each could be seen dividing into three or four branches, a little smaller, but quite as hard and tortuous, crossing toward the root of the penis and dipping into the fibrous tissue of the envelope. Through a puncture a dull, almost colorless fluid escaped, followed by collapse of the vessels."

Huguier's case was characterized by great dilatation, transparency, and thinning of the vascular walls, due to the incompetency of the valves, as shown by the complete evacuation of the fluid and collapse of the vessels.

The following case of Friedreich exhibits the rosary and cylindrical forms of dilatation in combination:

"A youth, aged eighteen, had a simple, non-indurated chancre upon the external end of the penis. When nearly healed, the lymphatic glands in both groins began to swell and to pain, followed by turgescence and a painful swelling of the whole penis. Simultaneously was observed a vessel surrounding the corona glandis like a ring, having its beginning on both sides of the frænum, running thence upward in the furrow behind the corona, and continued above in a thicker second vessel, which extended along the median line to the root of the penis, but receded gradually inward, escaping more and more from view, and finally could only be discovered by the touch. These vessels were very prominent above the surface; felt full, elastic, painless, and were recognized as dilated lymph-vessels by their whey-like, dull-white contents, as well as by their rosary-like arrangement. From the circular vessels radiated numerous thinner vessels of the calibre of knitting-needles, which carried the same contents, but being dilated equally, did not present the same rosary-like arrangement, and which, receding after a short course upon the glans into the deeper tissues, soon escaped from view. The periglandular abscesses in the groins were incised and a quantity of pus was discharged. With the gradual disappearance of the inguinal tumors and healing of the wound the dilated lymph-vessels were reduced to their normal size."

The varying form of ectasis, which was cylindrical in the smaller, and irregular and rosary-like in the larger, proves conclusively the incompetency of the valves in the former, and their competency in the latter. The gradual disappearance of the lymphangiectasis with the cure of the periglandular abscesses, and removal of the compression of the inguinal glands, established the relation of the stasis of lymph in the vessels of the penis to the impermeable groin-glands.

Causes.—The most frequent cause is coition. Balanitis, chancre, urethritis, periadenitis, impermeable inguinal glands, and congenital defects which interrupt the current of the lymph, are also occasional causes.

Diagnosis.—To obtain a good view of the lymphatic varicosity the folds of the prepuce must be obliterated by drawing down and making tense the skin of the penis, when it appears in the form of a little rounded cord, resistant and hard to the finger, in which has accumulated a limpid, aqueous liquid, which cannot be expelled through either of the extremities. The varicose vessel being confounded with the folds of the prepuce, and directed from behind forward, and from above downward, there is a dorsal extremity situated near the median line, and a frænal extremity bordering upon the frænum of the prepuce. The cord presents intersections which mark the localities of the valves. If with a needle a slight puncture be made in the dilated cord toward the frænal extremity, that portion is emptied which is situated between the puncture and the intersection; but if made in the dorsal extremity, the whole cord will be emptied. The course of the lymph is toward the dorsal extremity, in which direction the valves open. When the varices are confined to the superficial vessels, the diagnosis may be made by the hard, knotted, flexible cords along its course. When ampullar, they are usually small rounded tumors, reducible by pressure, but resuming their form upon removal of the pressure. Sometimes the fluid discharged through a fistula or puncture is dull and colorless, in other cases it is milky. In some cases collapse of the vessels follows puncture. When the varix is caused by coitus, it is at first intermittent, but after frequent recurrence becomes permanent.

Treatment.—Beau varies the treatment according as the affection may be intermittent or permanent. In the first form he employs local applications of cold water and astringent solutions. But when continuous, he operates by passing a needle armed with a thread through the frænal extremity, and along the vessel for a short distance, then out through the wall of the vessel. He then ties the two ends of the thread traversing the dilated vessel, and conceals them in the cul-de-sac of the prepuce. As soon as inflammatory action is set up, as evidenced by slight pain and swelling, the thread is removed. The swelling disappears in a few days, and in the course of a few months the hard and knotted vessel has entirely disappeared. It is not necessary to traverse the entire vessel with the thread, but it is important to introduce it at the frænal end. When the varix is caused by enlarged, compressed, or impermeable glands, the cause of the interruption to lymph-flow must be removed by an operation.

Samuel C. Busey.

[1] Narrowing, Occlusion, and Dilatation of Lymph-channels, Acquired Forms, by Busey. p. 86.

ANTIFEBRIN, or ACETANILIDE. The popular name of this new antipyretic is as much open to criticism as are those of drugs in general which are called from the clinical effects that they are expected to produce rather than with reference to their chemical constitution. We shall soon exhaust the possible combinations of Greek and Latin words in describing the particular symptoms produced by drugs of this class if chemistry continues to be prolific. We have already antipyrin, antifebrin, and antithermin; and a recent writer informs us that we still can dispose of such names as contrapyrin, contrafebrin, contrathermin, and contracalorin, after which we shall be forced into new directions to keep pace with the activity of chemistry.

Antifebrin was first made by Gerhardt, and is chemically an anilin in which one atom of hydrogen has been replaced by the acid radical acetyl. It is made on a large scale by boiling (with arrangement for condensation and reboiling of vapor) one hundred parts of chemically pure anilin with one hundred parts of anhydrous acetic acid. This process of boiling is kept up until the product, when treated with a weak solution of caustic soda, no longer allows the precipitation of any free anilin. At this stage the process of fractional distillation is resorted to. At 120° C. the acetic acid passes over, at 295° C. the acetanilide distils from the retort. This solidifies on cooling, forming a crystalline mass, which is subsequently purified by recrystallization with animal charcoal from distilled water.

It occurs in the shape of colorless, odorless, silky, rhombic crystals, having a fatty feel. When placed upon the tongue it causes a slight burning, and it is of mildly bitter and not unpleasant taste.

It is soluble in 189 parts of cold water, and is freely soluble in hot water, in alcohol, and alcoholic fluids like wine; also in chloroform and in ether. Its chemical formula is $C_6H_5NH(C_2H_3O)$.

It melts at 112°–113° C., forming a clear fluid, which boils at 292°–295° C. It is of neutral reaction.

The therapeutic properties of antifebrin were first discovered by Cahn and Hepp, and their results have been very frequently confirmed in all parts of the world.

Its uses are numerous. Locally it has been found to be a bland and unirritating antiseptic in the treatment of wounds.

Given internally to a healthy man, it is not likely to cause a fall of the temperature, but if it be given to a febrile patient it causes a decided diminution in the fever, accompanied frequently by a lessening of the frequency of the pulse and an increase in its force. The power of this drug to cause effects of this kind seems to be at least two or three times as great as that of antipyrin. The maximum effect is produced in the third or fourth hour after the dose has been taken, and it is continued between three and ten hours, depending upon the size of the dose. Defervescence is often accompanied by a general reddening of the surface of the body, with more or less profuse perspiration, and is followed by a subsequent elevation of temperature which is sometimes accompanied by a pronounced chill. Occasionally, especially if large doses are given, there may be alarming symptoms of depression, approaching even to a condition of collapse.

During the apyretic period there is often diuresis and quiet, refreshing sleep. The drug is well borne by the stomach and there is, indeed, no danger attending its use other than the condition of depression just referred to, which is often accompanied by cyanosis.

The blood shows the spectrum of methæmoglobin. Occasionally, but not often, it has caused an eruption of an itching character, which manifests itself especially in the development of dark-red spots upon the face and forehead. Mydriasis, deafness, and ringing in the ears have been noted among its effects.

The fall of temperature does not seem to be dependent upon the sweating, for the latter phenomenon can be prevented by the administration of atropine without preventing the antipyretic effect.

Experimentally it has been found, if given in enormous doses, to cause death, preceded by loss of reflexes, tremors, convulsive movements, great fall of temperature, frequent, irregular, and superficial respiration, retention of urine, coma, and general paralysis.

Prolonged action of the drug has produced fatty degeneration of the heart, liver, and kidneys.

Its influence over fever has been shown to be especially marked in typhoid, intermittent, and hectic fevers, that effect being distinctly less pronounced in pneumonia, puerperal fever, and measles.

It has been found of value in the treatment of acute rheumatism, as a specific, its effect being often quite similar to that of salicylic acid. It has also proved of value in the treatment of neuralgia of various kinds, including facial neuralgia, migraine, and the lancinating pains of tabes.

ADMINISTRATION.—It can be used pure upon wounds as a powder, or to impregnate gauze. For internal administration the dose is from five to ten or fifteen grains. Larger doses have often been given, but they are not unlikely to produce unpleasant symptoms of collapse as already noted. It can be given in wafers, or in alcoholic solutions, if the patient is taking stimulants of that class, or it can be given in pill form. Collapse is much more likely to be caused by it if the fall of temperature induced by it coincides with a normal remission in the course of the disease. Opinion is divided as to whether it produces more lasting results if given in a single full dose, or in very frequently repeated small ones.

George L. Peabody.

ARTIFICIAL FEEDING OF INFANTS. When the natural means, wholesome maternal milk, the only perfect nourishment of infants, is wanting, it becomes a serious problem how best to substitute a suitable food. The importance of the problem will be appreciated when we consider the dire results which generally follow attempts made in ignorance, or with imperfect knowledge, to hand-feed infants. The enormous death-rate which, in all countries, occurs among those deprived in early days of maternal milk is sufficiently startling, while among those that survive, the too frequent defective health, stunted growth, and even actual deformity, plainly attest the failure.

The problem also gains greatly in importance from the frequency with which it confronts us, and it would appear, from recent writers, that the number of American-born mothers who, for one reason or other, are unable to nurse their infants is on the increase. I am, however, unable to give any statistics relative to the subject.

Important recent advances have, however, been made in our knowledge both of the causes of failure and of our means of combating them, and a satisfactory solution of the difficulties can, in the majority of cases, under good home management, be now assured. But it involves unremitting care. Minute instructions must be intelligently and efficiently carried out by the mother or trustworthy nurse, under frequent medical supervision, and all in charge must feel that no point is too insignificant to receive the closest attention. A recent writer goes so far as to say: "There can be no doubt, though the statement is a bold one, and seemingly contrary to nature, that, among the average, infants properly brought up by hand are better developed and enjoy more perfect health than those completely breast-fed." My own experience does not accord with this, except in the cases where lactation has been unduly prolonged, or where the mother's health is defective. Bottle-fed infants are not as strong on the average as those fed with wholesome maternal milk, even when all their surrounding circumstances are most favorable. On the contrary, I believe they feel the influence of unhygienic conditions much more quickly, and more severely, than do those fed at a good breast. Doubtless, in many of the infants for whom bottle-feeding is necessary, congenital debility, as Dr. Parker, of the East London Hospital, has pointed out, may have much to do with the results. "It does not need any long experience," he says, "to enable one to pronounce that if the mothers are weakly, the offspring likewise will be weakly, and in estimating the causes and treatment of marasmus and other kindred diseases in infancy, it seems to me that too little stress is laid on the congenital debilities under which numbers of children labor." Certainly the task of rearing an infant by hand, even with all the knowledge and skill we can command, will be found one of very varying difficulty. If the powers of digestion are naturally strong, and especially if the infant has received the advantage of maternal nursing for some weeks, until its gastric and intestinal secretions have become somewhat developed, our task of supplying a suitable food may be a comparatively light one, requiring only care. But if the infant inherit a weak constitution, with feeble powers of digestion and assimilation, still worse, if it must be bottle-fed from its birth, great difficulties will be experienced, and in large cities, especially during the summer season, the prospects of such cannot be said to be favorable. In all cases we must recognize the necessity of such infants enjoying the powerful tonic and stimulating effects of pure, fresh air, plenty of sunlight, and careful general hygiene. When these, for any reason, cannot be supplied, our chances of success are much diminished.

We must remember, also, that an infant is not nourished by what it swallows, but only by that portion of its food which is digested and assimilated. A proper dietary, therefore, must be adapted to the infant's age, constitution, and digestive powers, so that, as far as possible, everything swallowed may be digested and absorbed. "And as children differ as much in constitution as in features, it is impossible exactly to formulate a food that will be applicable in every case." As age and strength increase, there is a corresponding development of the gastro-intestinal functions, and a call for more and stronger food. On the other hand, should the system be reduced by disease, the digestive, sympathizing in the general debility, loses somewhat of its power, and assumes that of an earlier age. In such cases the impaired strength must be sustained and increased by giving only such food as may be completely assimilated, and not by forcing down strong food merely because it is strong, for the latter, when not vomited, passes through the bowels undigested, and the little creature starves to death in the midst of plenty, or dies from the ill effects of the constant presence of fermenting food in the alimentary canal. On these accounts many changes in diet, as to quality and quantity, must be anticipated and made." That this may be done intelligently, it is desirable at the outset to have clear ideas on the principal physiological facts connected with infantile digestion.

PHYSIOLOGY OF INFANTILE DIGESTION.—We notice, first, that the *secretion of saliva* during the first few weeks of infant life is very small in amount, and its diastatic effect is slight and slow in action. This is due to the imperfect development of the glands of the mouth. The parotid is the most developed. Keating detected distinct but very feeble amylolytic action in the secretion as early as the seventh day, but the quantity secreted is very small compared with what it afterward becomes. The submaxillary and sublingual are still more backward in development. About the end of the second month the amount of saliva increases considerably, and its diastatic power becomes greater. In infants of large size and good development the secretion is stronger and more abundant than in delicate infants of the same age; while in infants weakened by disease the secretion is apt to remain defective. According to Korowin, the diastatic effect of the saliva of a baby of eleven months was found to be as strong as that of an adult. During these early weeks any uncleanliness of the mouth renders the secretion acid and interferes with its action.

Different varieties of starch are found to vary in the rapidity of their transformation into sugar under the action of the ferment. The starch of barley, oats, and potatoes are among those that are more rapidly changed. It is said that the effect of the saliva on the food persists for some time after its introduction into the stomach, but ceases as soon as the secretion of hydrochloric acid takes place. This, Uffelmann found, was not till after the first half-hour of digestion. Before this, lactic acid only is present. In the older infant this may be important, for although no mastication takes place, probably a considerable amount of saliva, which may have a very distinct action in the stomach, may be swallowed shortly after, or along with, the food.

As far as we know at present, there are no essential differences in either the digestive processes or the secretions of the infant's stomach as compared with those of the adult. At this early age the shape of the *stomach* is somewhat cylindrical, its position is almost vertical, and its muscular structures are little developed. Its capacity is variable and difficult to estimate. Frowlowsky's investigations indicate a rapid growth for the first few weeks, and a more gradual one afterward. The rate of growth, as evidenced by the capacity, may be represented in ratio, according to him, by the following figures: 1 for the first week, $2\frac{1}{2}$ for the fourth week, $3\frac{1}{5}$ for the eighth week, $3\frac{1}{8}$ for the twelfth week, $3\frac{4}{7}$ for the sixteenth week, $3\frac{3}{5}$ for the twentieth week.

The *secretion of pepsin and acid* would appear to be fairly active within the first few days after birth. In digestion the absorption of the watery and saline constituents of the milk begins at once in the stomach. The casein is coagulated by the pepsin, to be dissolved again after a little while. The presence of acid appears to aid the coagulation, but is not absolutely necessary. The secretion of the pepsin is stimulated by the absorption from the stomach of such liquid elements as are capable of being thus treated. The secretion of acid is augmented when the contents become more solid. Hence hard curds increase acidity, while the addition of water affects the amount of pepsin. In the artificial digestion of casein, when the action of the pepsin has ceased, it has been observed that it may be re-established by the addition of water simply; but in the stomach, not only does the supplying of water have a similar effect to what it has in the retort of the chemist, but in addition it stimulates the secretion of more pepsin, and assists the exit from the stomach of what has already been digested. As a rule, water is not supplied sufficiently to infants. Even in breast-feeding, it has been noticed that any cause rendering the milk more concentrated than normal interferes with its digestibility. In artificially fed infants there is a strong tendency, during gastric digestion, to the development of acid in excess. This is owing partly to the liability of the sugar to undergo acid fermentation, and partly to the fact that cow's milk is apt to form hard, firm clots, which favor excess of acid secretion. This excessive acidity may have a disastrous effect on intestinal digestion, and may alter nutrition generally throughout the body. The *secretion of bile* takes place, as we know, even during utero-gestation, and after birth it appears to be found in considerable quantities. During the early months its function is probably principally eliminative. The *secretion of the pancreas*—the gland associated with the salivary in the conversion of starch into sugar—is during early life in a still more undeveloped condition than that of the salivary glands. It remains very feeble in action till after the sixth month. Under the influence of the bile and pancreatic juice, the fats of the food are emulsified and become fit for absorption. It appears, however, from the investigations of Wegscheider that, even under the most normal circumstances, when no food but mother's milk is given, a considerable amount of fat is eliminated with the fæces, partly as a soap, partly as a free fatty acid, and a portion in an unchanged condition. From this Dr. Jacobi infers that care should be taken not to give too much fat, lest we thereby derange both digestion and assimilation through the formation of fat acids in large quantities.

In reference to *intestinal digestion* in the infant our knowledge is still very imperfect. Absorption is rapid through the numerous and large villi whose capillaries are said to be larger than similar capillaries in the adult. The special glands are few in number and only slightly developed. Of the amount of the *intestinal secretion proper* we have no exact knowledge. The large intestine does not aid in digestion. It will absorb water and soluble substances, but whatever is absorbed in this way, such as albumen or sugar, unless it be predigested, is soon eliminated by the kidney. The formation of acids in the intestinal tract is very liable to take place, especially in artificially fed infants. Reference was made above to the same tendency in the stomach. We have, in addition, in the intestinal tract, the presence of a large amount of mucous secretion, along with the possible presence of undigested material, both of which easily undergo acid fermentation. The alkaline secretions of the liver, pancreas, and intestines are easily neutralized, and new acids are formed from material which ought to have been digested by them, giving rise to irritation, and, possibly, diarrhœa. But, besides this, an excess of free acid in the infantile intestines is injurious by breaking up the combinations of phosphoric acid with lime and the alkalies so needed by the growing tissues, and thus allowing their elimination from the system. Hence the tendency of such infants to suffer from rachitis, and the necessity of maintaining an alkaline state of the upper bowel to avoid its development.

A *suitable food for an infant* must contain all the elements required for its nutrition. Nitrogenous material it must have to supply waste and the wants of its growing tissues. Without it starvation of the tissues will surely ensue, but the amount required is small compared with the proportion existing in adult food. Carbohydrates must also be present. On them we depend for the production of heat in a being whose muscular activity is comparatively slight, yet in whom the activity of the vital processes would be greatly impaired were its body-heat lowered in any degree. More than that, they are found to be essential to nutrition and to the chemical changes that take place during the activity of the several tissues. Fat especially appears to be intimately associated with new cellular growth. The carbohydrates, however, must be in an assimilable form, and we notice that little or no provision is made by nature for the digestion of starch during the early months of life. Possibly the secretion of the intestinal glands may have some amylolytic action, but it is probably only slight. It is asserted that several forms of bacterial life, which are found in the intestinal tract of infants, have a distinct effect in this way, but the exact influence of these micro important enzyme at present very problematical. Carbohydrates must be supplied, therefore, in the form of some sugar, and of these milk-sugar appears to be the most acceptable. The fats must be in the state of a fine emulsion. There can be little question that the administration of starch in any quantity, during the early months of infancy, is opposed to the conditions of normal infantile physiology; and practically we find that a food containing much farinaceous food, when supplied to young infants, results sooner or later in defective nutrition, and gives rise to acute diarrhœa and marasmus. It is requisite for the food to contain mineral matter also. Phosphate of lime is required for the hardening bones, and chloride of sodium and iron for the blood daily increasing in amount. Sodium salts also undoubtedly do much service in the vital processes of digestion, absorption, and nutrition, processes for which a full and sufficient supply of water is also required.

HUMAN MILK COMPARED WITH OTHER MILKS.—Having thus briefly considered the distinctive features of infantile digestion, we require the supply of a suitable food; and this, according to the consensus of all, must correspond as closely as possible, in chemical composition and general properties, with healthy breast milk. With this end in view, many careful analyses of mother's milk have been lately made to find out its exact composition, and to discover wherein it differs from the milk of the several domestic animals to which we naturally turn for an efficient substitute.

One of the most thorough analyses recently made is that of Professor Leeds, of Hoboken, who in a very able paper on the subject of Infant Foods, read before the College of Physicians of Philadelphia, gives the following results:

Analyses of Forty-three Samples of Woman's Milk, Reaction Uniformly Alkaline.

	Average.	Minimum.	Maximum.
Specific gravity	1.0313	1.0[illegible]	1.0[illegible]
Water	86.73	[illegible]	[illegible]
Total solids	13.266	10.92	16.93
Fat	4.13	2.11	6.89
Milk sugar	6.987	5.40	7.92
Albuminoids	1.996	1.06	4.86
Ash	[illegible]	0.138	[illegible]

He adds: "Not only was the reaction alkaline when the samples were fresh, but, with one exception, in which it was neutral, the alkalinity was found to remain for at least twenty-four hours afterward."

Baginsky quotes the following as the result of very numerous analyses by Pfeiffer:

Result of analysis.	1st day.	6th day.	8th day.
100 parts contain:			
Water	86.82	86.92	87.72
Total albuminoids	2.[illegible]	1.[illegible]	1.[illegible]
Casein	1.[illegible]	1.[illegible]	1.[illegible]
Albumen	[illegible]	[illegible]	[illegible]
Non-nitrogenous substances	[illegible]	[illegible]	[illegible]
Fat	[illegible]	[illegible]	[illegible]
Sugar	[illegible]	[illegible]	[illegible]
Salts	[illegible]	[illegible]	[illegible]

Both of these are particularly interesting as, in part, explaining the wide divergence in the results obtained by chemists in their analyses. All analyses, however, agree in asserting that human milk contains all the elements necessary to constitute a perfect food—proteids; carbohydrates in the two forms of fat and sugar; salts, and water. On examining these tables, however, we find that we have by no means a constant combination of these materials. All of them appear to be more or less variable. The most striking peculiarity in woman's milk, says Professor Leeds, is not the constancy, but the great variability in its composition. According to his analyses the proteids are the most changeable constituents, with a maximum of 4.86 per cent., and a minimum of 0.85. Then come the fats and salts, whose maximum is about three times the minimum. The sugar shows comparatively little variation. Pfeiffer finds that the period of lactation has also much influence, and that during the first days of nursing, human milk contains more proteids and salts than it does later on. These both decrease rapidly, while the percentage of sugar at the same time rises.

We have here, then, to do with a fluid which, while containing all the elements necessary for the perfect nutrition of the infant, contains them in quantities which are liable to considerable variation according to the period of lactation, to the age and temperament of the mother, and perhaps to some special condition, which we are unable to appreciate, in the mammary glands themselves. Being drawn direct from the gland into the infant's mouth, it may be said to be absolutely free from germs. In the great majority of cases infants digest and assimilate it easily. It would appear, therefore, that in our substitutes we can may allow some slight variation, provided that we retain the great qualification of being easily digested and assimilated, to which, undoubtedly, the aseptic state of the food is a necessary condition. In seeking a substitute for mother's milk, the attention is naturally directed toward the similar products of the mammary glands in other mammalia, and of these the milk of the cow, goat, ewe, ass, and mare, are more or less available for our use. Careful analyses have been made of these, with the following results:—

	Cow.	Goat.	Ass.	Mare.	Ewe.
Water	87.7	85.50	90.5	90.[illegible]	82.0
Albuminoids	3.42	4.50	1.[illegible]	1.[illegible]	7.9
Fat	3.[illegible]	4.[illegible]	1.3	1.[illegible]	5.8
Sugar	4.[illegible]	4.[illegible]	6.2	6.[illegible]	4.9
Salts	0.[illegible]	0.[illegible]	0.[illegible]	0.[illegible]	0.7

Of these the nearest analogues are the milks of the ass and mare, but they can never become generally available, although an attempt is now being made at the Hôpital des Enfants Assistés to use that of the ass in the case of those infants suffering from hereditary contagious disease.

Goat's milk is more frequently available, but possesses no advantages over cow's milk. It appears to be rich in fats and its peculiar odor is often objectionable to the infant. Kraus says that the coagula which form from goat's milk under the action of rennet and acid are less dense than those of cow's milk, and more like the coagula of human milk; but this assertion has been denied, and on making the experiment one's self, there appears to be little difference between the curd-forming elements in the milk of the two animals. Routh, however, states that these qualities of the milk may be much controlled by the food given to the goat, and that, when it is fed on beet-root, as opposed to straw and trefoil, the amount of the casein and fat are both lessened by more than one-third. He also says that the peculiar smell is not essential, and may be greatly diminished if the animals are kept clean, washed from time to time, and not allowed to associate with the rams. In certain cases this milk may have the very important advantage of being obtainable fresh. Where good cow's milk is not available it may be carefully tried, care at the same time being given to the feeding of the animals. In the preparation of it for infant feeding it will be noticed that it generally contains a larger proportion of fats, albuminoids, and salts than does cow's milk, while the percentage of milk sugar is less.

Cow's milk has many advantages. It is plentiful everywhere, and is easily and cheaply obtained. Next to ass's milk, it most nearly corresponds in chemical composition with human milk, and it should have no objectionable properties in the way of taste and smell. The formula of its chemical composition is thus given by König, and for the sake of ease of comparison we place the result of his analysis of it side by side with his analysis of woman's milk:

	Mean.		Maximum.		Minimum.	
	Woman's.	Cow's.	Woman's.	Cow's.	Woman's.	Cow's.
Water	87.09	87.41	90.90	91.50	83.69	80.32
Total solids	12.91	12.59	16.31	19.68	9.10	8.50
Total albuminoids	1.94	3.76	4.25	12.44	0.57	1.58
Casein	0.63	3.01	1.90	7.40	0.18	1.17
Albumen	1.31	0.75	2.35	5.04	0.39	0.21
Fat	3.90	3.66	7.60	7.09	1.71	1.15
Milk-sugar	6.04	4.92	7.80	5.67	4.11	3.20
Ash	0.49	0.70	?	0.87	0.14	0.50

On comparing these tables we notice much similarity between the two fluids. Both exhibit considerable variation in the albuminoids and fats, and constancy in the amount of milk-sugar, while the amount of difference between the two averages is in no case so great as the variation between the maximum and minimum of each. Yet on closer examination we shall find important differences which demand careful study and correction, if we would successfully utilize the cow's milk in the preparation of food for infants. These differences may be stated as follows :

1. While human milk is always alkaline, and remains so for many hours, the reaction of cow's milk is in general acid ; especially when the cow is stall-fed. When pasture-fed it is more or less alkaline at first, but quickly becomes slightly acid. This acidity is in part due to the preponderance of potassium biphosphate in the milk, and probably in part also to the presence of more or less lactic acid.

2. While albuminoids are present in human milk in only half the quantity that they are in cow's milk, the two are found to differ essentially in their curd-forming properties. Cow's milk, according to Leeds, on the addition of a coagulating acid yields up nearly four-fifths of its albuminoids as a rapidly forming and firm coagulum, very slowly dissolved by gastric juice ; while, on a similar treatment of human milk, only one-fourth of the albuminoids are coagulated in the form of a flaky and easily digested curd, while the remaining three-fourths do not undergo alteration.

At first this difference was but imperfectly appreciated. Lehmann thought it was principally due to the more alkaline reaction of the human milk, and says : "I have found woman's milk, when acid, yield a much thicker coagulum than when alkaline, and cow's milk, when alkaline, a much looser coagulum than when acid ; facts which are of the greatest interest and value in relation to dietetics." Biedert insisted on a much more radical difference in the caseins ; and more recently numerous chemists have made investigations of the properties of the two. Radenhausen says that the proteids in woman's milk exist as albumen, protalbumen, and peptones, and that there is little or no real casein in it. Struve finds in woman's milk about one-sixth the quantity of insoluble casein, twice the quantity of soluble casein, three times the amount of albumen, and one-third more peptones than he finds in cow's milk. Simon found that after complete desiccation the proteids in woman's milk are freely soluble in water, while those of cow's milk are largely insoluble. Bouchardat and Quevenne, Meggenhoffen and others, state that the casein of woman's milk forms soluble compounds with small amounts of acids, while the casein of cow's milk is coagulated by the same. Thus, although there is still disagreement as to the exact nature of the albuminoids in each, all admit the much greater digestibility of those contained in woman's milk as compared with those of cow's. Dr. Brush has explained this property of forming hard curds as belonging to the milk of all cud-chewers, in contradistinction to the softer and more flaky curds of the milk of those animals which are not cud-chewers. He says : "The young of the former all chew the cud soon after birth, therefore the milk designed for their use contains a variety of casein which coagulates into a mass sufficiently hard and consistent to be regurgitated and chewed." This statement appears probable, though I am not aware of its having been corroborated. There can be little doubt that this difficulty in the digestibility of the proteids forms our chief obstacle in utilizing cow's milk. The excess of the proteids, even supposing they were equally digestible, is, however, not unimportant. In the case of two children, one nursed from the breast, and the other fed upon undiluted cow's milk, each taking the same quantity of milk per day, the second will obtain nearly double the amount of proteids obtained by the first ; but as the latter generally drinks more than the former, the excess becomes even greater. Escherich has found that an infant thus fed took, on an average, a litre of undiluted cow's milk per day, containing 34.64 grams of proteid, while a child of the same weight, nursing from the breast, took only 774 grams of milk, containing 12.93 grams of proteid, per day. Even if all this excess were digested it cannot be assimilated, and can therefore do no good, but only harm.

3. The amount of the carbohydrates, even in pure cow's milk, falls below that in woman's milk in most of the analyses published ; while if we compare the ratio of the proteids to the carbohydrates in the two milks, the slight deficiency becomes a considerable one. In woman's milk the proportion of albuminoids to milk-sugar is as 1 to 3.11, while in cow's milk the relation between these food-stuffs is as 1 to 1.31. Hence if the milk be reduced to avoid excess of proteids, a very marked deficiency both in fats and in carbohydrates will occur.

4. An analysis of the saline ingredients in the two milks shows a considerable difference in the relative amounts of the sodium and potassium salts.

The following is the result of Bunge's analysis as given by Hoppe-Seyler. One thousand parts contain :

	Woman's milk.	Cow's milk.
Potassium oxide	0.7799	1.766
Sodium oxide	0.2315	1.110
Calcium oxide	0.3281	1.599
Magnesium oxide	0.0636	0.210
Ferric oxide	0.0039	0.0035
Phosphoric acid	0.4726	1.974
Chlorine	0.4377	1.697
Total amount ash	2.2186	7.977

The proportion of the potassium salts is thus greater in woman's milk than in cow's milk : the lime salts are in excess in cow's milk, but the latter contains a slight deficiency in the amount of iron. The differences, however, appear too slight to require much correction.

THE PREPARATION OF COW'S MILK FOR INFANTS' USE.—With the above facts before us, our study must be directed to the means at our disposal to correct, if possible, these differences between the two milks, and the first point which demands our consideration is the prevention of the dense indigestible curds which are a constant source of irritation. *Simple dilution* will to some extent hinder this, both by diluting the acid of the gastric juice and by lessening the amount of casein. It favors also, to some slight extent, the secretion of the pepsin by promoting the absorption of the soluble substances in the milk. Hence, in all our methods it should be more or less employed, but the effect is too slight to be depended upon without other means. Lehmann was one of the first to point out the effect of *the addition of an alkali* in rendering the curd less dense. The alkali also acts by partially neutralizing the acids met with in the stomach, so that coagulation takes place more slowly. Lime-water, and sodium or potassium bicarbonate, are frequently employed for this purpose. When lime-water is used, it is, I think, advantageous to add it in somewhat larger quantities than is frequently directed. As it contains only half a grain to the fluid ounce, it may be added to the extent of one-fourth or even one half of the amount of milk employed. An efficient substitute for lime-water is the liquor calcis saccharatus of the British Pharmacopœia, which is made as follows: Take of slaked lime, one ounce ; refined sugar in powder, two ounces ; distilled water, one pint. Mix the lime and sugar by trituration in a mortar ; transfer the mixture to a bottle containing the water, and, having closed this with a cork, shake it occasionally for a few hours. Finally, prepare the clear solution, with a syphon and keep it in a stoppered bottle. From five to fifteen drops of this solution may be added to each half pint of milk mixture. Should constipation be present in the infant, the carbonate or bicarbonate of potassium may be used in the amount of four or five grains to the pint of milk. [illegible] recommends [illegible] as an occasional diluent. In this method, it should be remembered, the use of alkalies in too large quantities may weaken the digestive juices and render the infant flatulent. It is, moreover, only partially effective, and in young infants and those of weak digestion is insufficient to prevent much gastric difficulty, although it may be more often employed in addition to other methods. Another plan, more efficient than the previous, is the one frequently referred to as mechanical, in which, instead of plain water as a diluent, a solution of some substance is used which, by its physical consistency, is apt to diminish the density of the coagulum. This method is an old one, as we read that Van Swieten, in the fifteenth century, used decoctions of wheat or barley for this purpose; but its utility has of late years been very strongly urged by Dr. Jacobi. Its practical advantage has also been proved by Professor Leeds, who, in a series of careful experiments, showed that the coagulum precipitated under such circumstances was a far more friable material which, by incorporating therewith, acts as an attenuant. The coagulation will also in such cases take place much more slowly—a very positive advantage, as it affords the digestive fluids and the peristalsis of the stomach a better opportunity for action. Many substances have been used for this purpose. Dr. Jacobi appears to favor a decoction of gum arabic as the diluent in the case of very young infants. It is, he says, absolutely indifferent from a chemical and physiological point of view, as it is not acted on by the digestive fluids and is not absorbed, but acts mechanically only. I have myself more frequently used a solution of gelatine in such cases. A good method of preparation for this is as follows: Put a piece of plate gelatine an inch square into half a tumblerful of cold water, and let it stand for three hours; then turn the whole into a teacup; place this in a saucepan half full of water and boil until the gelatine is dissolved. When cold this forms a jelly, of which two teaspoonfuls or more may be added to each half pint of food. For older children well-boiled decoctions of barley or oatmeal form a highly recommended diluent. Dr. Jacobi writes: "I have always preferred barley when an article for steady diet was to be recommended, for the reason that oatmeal, on account of its containing fat and mucin, tends to relax the intestines sooner than barley meal. Otherwise the chemical composition of both is so nearly alike that it would make but little difference upon which the choice would fall. . . . . In the case of very small children it will pay well to allow the barley-corns to boil for hours, in order to let the outer layers burst and yield their contents, as in this way the largest part of the starchy matters in the centre will be got rid of by straining. Otherwise it is better that the people should grind the barley themselves in a coffee-mill reserved for that purpose, and thus shorten somewhat the time required for boiling." When the ordinary pearl barley is used, he says that much of the gluten is lost in the husk. Dr. Eustace Smith recommends the following as a convenient mode of using the barley: "'Two tablespoonfuls of washed pearl barley, with a pint and a half of water, are put into a saucepan and boiled slowly down to one pint. It is then strained and the liquid allowed to set into a jelly. A few teaspoonfuls are used in the preparation of each half pint of food.' It is better, however, when practicable, to prepare it freshly every time. In this case one or two teaspoonfuls only of the barley are used in the above recipe, and the resulting decoction is added directly to the milk." Dr. S. C. Busey urges the advantage of arrowroot, substituting this, prepared in a similar way, to the barley, and says that he has often witnessed its beneficial effects in cases of diarrhœa and vomiting. I have myself found it to agree when the others had failed.

The disadvantage of all these diluents, however, for very young infants is that they introduce a material quite foreign to milk, and with which their digestive powers are unfit to grapple until their salivary and pancreatic secretions become more fully developed. It must, therefore, be clearly understood that the introduction of the starchy elements in this method is not intended for nutritive purposes, but simply as an attenuant of the casein, and used in this way Dr. Jacobi thinks that a small quantity may be introduced into the intestine without giving rise to disturbance. It is very necessary, however, that the percentage of starchy matter should be small, and that it should be very thoroughly boiled. Dr. Smith recommends several hours, so that a portion may be changed into its soluble form. If thus carefully used, I have no doubt that in infants of fair digestion this method is very frequently of practical advantage, notwithstanding theoretical arguments against it. Dr. J. Lewis Smith has recently urged the claims of *dextrine*, a partially digested starch, as a distinct advance on these previous methods. He writes to the Secretary of the Sub-committee on Infant Feeding of the American Medical Association as follows: "According to my observations babes can digest dextrine readily—even those under the age of three months, who digest starch with difficulty." His plan of preparing it is the following: Take from five to ten pounds of well-selected wheat flour (that made by the Hungarian process is the best); put this dry into a bag and tie firmly. Boil it for several days, preferably five or six, then take it out and scrape off the rind of dough carefully. The hard, dry inside must then be grated and sifted, and placed for two days in pans in an oven at a temperature of about 180° F. The starch, by this process, is largely converted into dextrine, but not into glucose. It is thus only partially digested, and, in his opinion, conduces to a better and more healthy condition of the infant than when fully digested. When kept for use it is also more stable than the glucose preparations made from Liebig's formula, and it acts better as a mechanical diluent. I have myself frequently used this formula with great satisfaction.

In addition to this mechanical method of preventing the coagulation of the casein, we can have recourse, especially in infants of weak digestive power, to the *partial digestion* of it, thus rendering it more or less the physiological equivalent of the albuminoids in human milk. There are several ways in which this may be accomplished. One of the first proposed was that of Professor Frankland, in which the casein of a portion of the milk is first peptonized by fresh calf's rennet. The directions for this are as follows: Allow one-third of a pint of new milk to stand for about twelve hours; remove the cream and add this cream to two-thirds of a pint of new milk as fresh as possible. Into the skim-milk put a piece of rennet about an inch square (this can be obtained from the butcher). Set the vessel in warm water till the milk is fully curdled, which will be in from five to fifteen minutes, the rennet being removed as soon as curdling commences, and put into an egg-cup for future use, as it can be employed daily for a month or two. Break up the curd thoroughly and separate the whole of the whey; then heat it rapidly to boiling, when a little more casein will separate and must be removed by straining. One hundred and ten grains of milk-sugar is now to be dissolved in the hot whey, and the whole mixed with the milk and cream mixture previously made. This gives us one pint of artificial human milk, which should be used within twelve hours after its preparation. All vessels and apparatus concerned in the manufacture must be kept scrupulously clean. Instead of this fresh rennet some liquid preparation of pepsine and acid would doubtless answer the purpose equally well, and would appear to be free from the objection associated with using rennet kept for some time. This method has the strong recommendation of the Sub-committee on Infant Feeding.

In this country Professor Leeds has strongly recommended the use of pancreatin, and a firm in New York has made a preparation of it suitable for the purpose of predigesting milk. The directions for its use are thus given: "Put into a clean quart-bottle five grains of extractum pancreatis, fifteen grains of bicarbonate of soda, and four fluid ounces of cool, filtered water; shake thoroughly together, and add a pint of fresh cool milk. Place the bottle in water so hot that the whole hand may be held in it for a minute without discomfort (120°–130° F.), and keep the bottle there for exactly thirty minutes. At the end of that time put it on ice to check further digestion and keep the milk from spoiling." The fluid obtained, while somewhat less white in color than milk, does not differ from it in taste. If, however, an acid be added, the casein, instead of coagulating in large, dense curds, forms small, soft flakes, resembling the curd of human milk. At this stage the casein is only converted into peptone; but, if the heat be continued, the liquid becomes grayish-yellow in color, has a distinctly bitter taste, and shows no coagulation whatever on the addition of an acid. The peptonization is now complete, but it is undesirable, for many reasons which we shall refer to presently, that this stage should be reached. To seize the proper moment for arresting the process, the person in charge must taste the milk frequently, and, as soon as the least bitterness is appreciable, the bottle must be removed from the hot water and placed on ice, so as to be immediately cooled. In my own practice I find it generally desirable to stop before the bitterness is detected, and to judge the effect by the time rather than by the taste, otherwise the later portions of the digested food are apt to become very bitter. To facilitate this process, a "peptogenic milk powder" has been prepared containing pancreatin and bicarbonate of soda, along with some milk-sugar. When the food is wanted, milk, water, and cream are added to some of the powder, and the whole heated over a brisk flame to a temperature of about 130° F., and kept at this heat for six minutes. When properly prepared the resultant, so-called humanized milk, presents the albuminoids in a minutely coagulable and digestible form, has an alkaline reaction, a not unpleasant taste, and contains about the same amount of proteids, carbohydrates, and fats as exist in human milk. When the necessity for predigestion passes away, an ordinary milk diet can be gradually resumed by regularly diminishing the time that the artificial digestion is allowed to progress. These processes are reported by many as having given excellent results in their hands. In my own they have not proved as successful as I at first anticipated. In their employment some skill and intelligence are requisite, and these qualifications are not always at our command. Scrupulous care must always be exercised in the selection of the pancreatin, as it is very liable to become decomposed, and the use of the stale, foul-smelling preparations sometimes met with in the market, for the peptonizing of infants' food, can only be condemned as liable to introduce impurity.

It is very doubtful also, to my own mind, whether the addition of the large amount of alkali apparently necessary for this process is not decidedly injurious. After the peptonizing process has proceeded sufficiently, I prefer to have the milk boiled, so as to insure, as far as possible, sterilization, and to check further action of the ferment. The cases in which complete digestion of the proteids is requisite are very few. On this point Professor Vaughan gives a necessary warning. He says the employment of completely digested foods may be admissible for a short time in case of extreme weakness, but their continued use is not to be recommended. In the first place, the digestive organs may be weakened if the food used for any length of time be completely digested before its administration. Like other parts of the body these organs need exercise, and, if relieved of their physiological duties, are liable to atrophy and become less efficient in action. Moreover, the use of wholly digested proteids in quantity is not free from danger. Albertoni and Schmidt Mühlheim have shown that if peptones be injected directly into the blood they are poisonous. Normally it is a function of the liver to arrest and alter the products of proteid digestion in the stomach and intestines; but if a great quantity of ready-made peptones be poured into the stomach they may be absorbed so rapidly that the liver will fail to perform this function fully. Again, Breiger has shown that the artificial digestion of proteids is accompanied by a poisonous base, to which he has given the name peptoxine. Whether this substance is found in normal digestion or not, we do not know; but if so, it must be altered or eliminated by the liver. Certainly it cannot be altogether safe to pour a large quantity of this poisonous base into the stomach of a child. Hence, while the partial artificial digestion of the casein may be not only admissible but desirable, its complete digestion demands much caution in its employment. Before leaving the subject of the coagulation of the casein it may be stated that, by simply boiling milk we remove a small amount of casein, and the coagulation of the remainder is rendered somewhat less dense.

Besides having to get rid of the hard casein curds, we have in our conversion of cow's milk into an infant food to deal also with the excess of proteids, which by most analyses amounts to about double the quantity found in woman's milk. This can be corrected by simple dilution with water, in which case the quantity of the fats and the carbohydrates will require to be increased by the addition of cream and cane- or milk-sugar. It may also be very effectually accomplished by removing the casein altogether from a portion of the milk, as in Frankland's process, and then adding the whey with the cream to the remainder. The amount of the proteid that should be allowed to remain has been a subject of discussion. Dr Biedert recommended, as the result of his experience, that in children of weak digestion the amount of the proteids should be reduced to not more than one per cent., and more recently Dr. A. V. Meigs, of Philadelphia, has insisted that in our preparation of cow's milk the albuminoids should not exceed this amount. He further says that the direction generally given, to increase the strength of the dilution as the child gets older, is of doubtful propriety, for human milk twelve months after delivery is but little altered from what it was at the end of the first or second month. His directions for preparing a food are as follows: Seventeen and three-quarter drachms of milk-sugar are to be dissolved in a pint of hot water and the solution kept in a cool place, care being taken that at no time is it to be used if there be the slightest trace of souring in it. When the child is to be fed the nurse should mix together two tablespoonfuls of cream, one of milk, two of lime-water, and three of the sugar solution. When the mixture has been warmed sufficiently it is ready to be fed to the infant.

If the infant be healthy, this amount will not satisfy it after the first few weeks, and then these quantities will require to be doubled. The food should not, however, be given any stronger until the child is eight or nine months of age at least; but, if it be a healthy infant, it may take as much as it wants of it at each time of feeding. A robust infant will often take three pints, or even more, in the twenty four hours. In correcting the deficiency of the *carbohydrates* it is still a somewhat debated point whether milk- or cane-sugar should be employed. Dr. Jacobi strongly advocates the use of cane-sugar. Milk-sugar, he says, quickly ferments and is changed into lactic acid, any excess of which is peculiarly detrimental to infantile digestion, while cane-sugar is not so readily transformed. Professor Vaughan, on the contrary, thinks milk-sugar to be the more easily digested of the two. Malt-sugar, as found in foods prepared by Liebig's process, is, according to him, especially liable to undergo fermentation and produce irritation. In summer weather any excess of cane- or malt-sugar may prove decidedly laxative, and during that season special caution should be exercised in their use. Should either milk- or cane-sugar appear to disagree, it is advisable to have recourse at once to the other. I have frequently found a change in this way of service.

In reference to the amount of the *fats* Dr. Jacobi puts in a strong plea against allowing any excess of them to be present in our mixtures. He says that the infant intestine does not digest all the fat contained even in its mother's milk, and we ought not to increase the amount of the indigestible, appear to belong to them. In opposition to this, Dr. Rotch very pertinently remarks: "We have no right to conclude, from the fact that a certain amount of surplus fat is found in the napkins, that a small per cent. is sufficient for nutrition, or that a large per cent. will be thrown away by the infant." It is far more probable that nature introduces a certain per cent. of fat in human milk, with a purpose which can only be accomplished by that per cent.; and it will be an error on our part not to conform to her standard. My own experience coincides with that of many others, that young infants may often be fed, and will thrive, upon cream mixtures containing a fair percentage of fat, where other preparations have failed. Biedert says that while relatively small amounts of nourishment are sufficient for the good development of infants during the first few weeks of life, an increase in the amount of fat considerably above what is contained in dilute cow's milk mixtures, renders digestion easier, and increases the growth of the child. He has recommended the following schedule for the preparation of a food which varies according to the age and strength of the child:

	Cream.	Milk.	Water.	Milk-sugar.	Casein.	Fat.	Sugar.
					Per cent.	Per cent.	Per cent.
First month	125		375	15	1.0	2.5	3.8
Second month	125	60	375	15	1.4	2.6	3.8
Third month	125	125	375	15	1.8	2.7	3.9
Fourth month	125	250	375	15	2.3	2.9	4.2
Fifth month	125	375	375	15	2.6	3.0	4.3
Sixth month		500	250	15	2.9	2.3	4.1

A serious drawback in the employment of cream to any extent is the variability in its composition, and the difficulty of obtaining it fresh and good in a large city. For this reason Biedert has had compounded a cream preserve, which he has placed on the market, and which is much used in Germany. Monti and [illegible] speak very favorably of it.

Sterilization.—We have hitherto made but slight reference to the qualifications of freshness and absolute purity in cow's milk, but the great advantage of obtaining it in the country, night and morning, just fresh from the cow, free from the jolting incident to all means of transit, and from the impurities so apt to be associated with the different methods of storing it, has long been recognized by those who have had experience in infant feeding. That milk possesses to a high degree the property of absorbing gases and odors to which it may be exposed, is a matter of common observation, and recent medical literature abounds with instances where milk has acquired the infection of disease germs, and has thus become the means of communicating such disease to those who used it. Very recently, careful investigations have been made as to the presence of micro-organisms in milk, and their influence in producing the several changes which it undergoes. Dr. J. A. Jeffries, of Boston, one of the earlier workers in this field, writes: "It is a curious fact that, while adults are chiefly fed on sterilized food—that is, cooked food—infants are fed on a food peculiarly adapted by its composition and fluid state to offer a home to bacteria." On investigating the milk-supply of a city, it will be found to have an acid reaction, and to contain many growing bacteria. When kept for a day it becomes decidedly acid, has a sour taste, and is found to swarm with bacteria. Upon the character of the bacteria present will depend the character of the change that occurs—the milk-sugar may be turned to acid, the fats may be broken up, or tyrotoxicon or some other ptomaine formed. If fresh milk, however, be sterilized, and protected from germs, it undergoes no alteration, even after the lapse of long periods. These studies have advanced very greatly our knowledge of the causes underlying many of our failures in infant feeding. "Even when," says Dr. Jeffries, "we start with a food thoroughly the analogue of mother's milk, great care must be taken, or our enemy, the bacteria, will quickly invade the food, and, as if by the wave of a wicked fairy's wand, change the whole into a poison." Dr. Soxhlet, of Munich, starting with the principle advanced by Lister and Escherich, that milk in the glands in which it is secreted is aseptic, referred the introduction of the germs to the process of milking when the udders are imperfectly cleansed, or where the milking is performed in an atmosphere containing either putrefactive or pathogenic bacteria, as well as to absorption of impurities during storage or transportation. It is possible, also, that poisonous alkaloidal substances may be excreted in the milk when insufficient care is given to the feeding of the animal. The development and multiplication of these germs are much favored when the milk, after it is withdrawn from the udder, is allowed to remain at a somewhat elevated temperature. These fermentative changes are to be prevented by a sterilization of the milk, and the following method is proposed by him. Fresh milk is to be put into thoroughly cleansed flasks holding five or more ounces, which are closed with a rubber stopper, leaving beneath the stopper an empty space of the volume of several centimetres. Every rubber stopper has a central perforation into which a slender glass stopper may afterward be introduced. The flasks are then plunged up to the neck in a vessel of water under which an alcohol lamp is kept burning. When the water has reached the boiling point and the milk has risen sufficiently in the flask, the rubber stopper is secured by means of the small glass one. The water is then allowed to boil thirty minutes longer, and the milk is for that time under steam pressure at a temperature of 212° F., which will destroy all germs liable to produce fermentation. Milk so prepared will keep sweet for two or three weeks, and if the process be repeated a day or two after the first boiling, the length of time that it will keep is doubled. When the milk is to be used the bottle is put into hot water for a few minutes, the stopper is then removed and an ordinary nipple attached. It is then ready to be given to the child. Any milk remaining over after the child has fed should be thrown away. Dr. Caillé, experimenting with this method, obtained the following results: Milk heated in this apparatus for thirty minutes remained good for eighteen days. Milk boiled in small bottles for fifteen minutes, the bottles being closed before removal from the water either with rubber or with a plunger of cotton wool, remained good for five days. Milk boiled in a pot and after cooling put into small bottles which were then stoppered, became sour in four days. Milk boiled in a pot in the usual way and left standing in an open dish in an ice box: (A) ordinary store milk, turned after eighteen hours; (B) good bottle milk, turned after twenty-six hours. Dr. Jeffries prefers to steam rather than boil the milk. His apparatus is much simpler than that required by Soxhlet's method. The thoroughly cleansed flasks, from which the child is to be fed, may be first sterilized by heating them in an oven at a mild baking heat for thirty minutes, but this is not absolutely necessary. They are then filled with the food, stoppered with a plug of cotton wool, and steamed for fifteen or twenty minutes. Cotton wool, he says, forms the best stopper, as it cannot be blown out and is germ-tight. The steaming must be thorough, but any simple steamer, such as is used in ordinary cooking, will answer, provided it be filled with live steam. The vessel should be of good size, at least eight, or better twelve, inches across the bottom, and about sixteen inches high. A perforated false bottom should rest about four inches from the true bottom. The cover should be tight. When using it, two or three inches of water should be placed in the bottom and brought to a fast boil, when the flasks may be set as near the centre of the diaphragm as possible, the cover replaced, and the whole allowed to steam over a brisk flame for the requisite time. The flasks should then be taken out and placed on ice till required. When they are again to be gently warmed, the cotton plug taken out, and a clean nipple applied to the bottle. The milk should be as fresh as possible, and should be steamed as soon as received, else it may already be charged with the germs of decomposition.

The Milk-supply.—From these considerations there can be little doubt but that, when an infant is to be fed, the question of the milk-supply requires the careful investiga-

Artificial Feeding.

tion of the physician in charge. The milk should be procured with the utmost care and cleanliness, from properly fed and properly housed animals. The best animals to supply milk for children's use are not the high-bred Alderney or Jersey cows—which are very nervous animals, prone to tuberculosis—but the common red cow, which is quiet and gentle in disposition, a good feeder, and not excitable even in heat. It would be better that she should be stall-fed, but under all circumstances she should have access to abundance of clean water. The stall should be kept absolutely clean; the cow should never be milked when overheated; and the milker's hands and the cow's udders should be thoroughly cleansed before milking. No milk should be allowed from an animal not thoroughly healthy; from a cow shortly before, or shortly after, calving; or from one fed on distillery slops or brewery grains. Great care should also be taken to keep the milk in absolutely clean vessels, and to avoid jolting in its transportation. It should be at once strained and cooled to a temperature below 55° F.; should be kept in a room where the air is cool, pure, and free; and should never be delivered to consumers at a temperature higher than 60° to 65° F. No adulteration should ever be allowed, either by dilution, by antiseptics—principal among which are salicylic and boracic acids—by alkalies, or by the removal of fat. After standing it should show a minimum of twelve per cent. of cream. Professor Vaughan has recently shown that milk, under certain circumstances, may develop poisonous properties, due to the presence of a ptomaïne, which he has isolated and named tyrotoxicon. The conditions favoring its production are a comparatively warm temperature with the exclusion, or only limited supply, of air, and the presence of any condition of uncleanliness or impurity in the milk. It is apparently one of the diazo-benzol salts. In small doses it induces severe vomiting and purging, and in larger, great prostration, choleraic discharges, and death. Although this is the only ptomaïne so far isolated, yet it is probable that it is only one of a large class, owing their origin to fermentation and decomposition, and liable to be formed in infant foods. Hence the great necessity of careful sterilization by boiling or steaming. One of the most important advantages secured to breast-fed children, says Dr. Vaughan, arises from the lessened danger of their milk being infected with germs. These considerations have especial force during the more heated portion of the year, but at no time are they wanting in importance. And in the case of infants with weak digestion, it would appear very desirable that all milk used in their food should be sterilized as soon as received from the dairy; that no water, except such as has been previously boiled, should be employed, and that all prepared food should be boiled for a few minutes before it is given to the infant.

Milk from one Cow.—The propriety of obtaining milk from one cow is frequently urged by the laity. If the physician can be satisfied of the health of the cow yielding the milk, and of the way it is kept and fed, and if such milk be found to agree with the child, I think the method may have some advantages. In such cases the portion for the infant must either be taken always at the same period of milking, or from the contents of the pail after the milking is completed; otherwise it is liable to variation. It is very seldom that physicians can be sure of all these points, and therefore the ordinary mixed milk from a well-kept dairy is generally recommended as less liable to sudden change. In some instances it would appear that milk sufficiently pure and reliable for the use of infants cannot be obtained. Recourse must then be had either to one of the condensed milks, or perhaps to one of the patented infants' foods, of which we shall speak later.

Condensed Milks.—Condensed milk as a food for infants has both advocates and detractors. In the form of *fresh evaporated milk* (milk condensed without the use of cane-sugar), we think it may be of great utility, especially during the hot season. The heat employed during the earlier stages of its preparation has, by destroying any germs, removed the tendency to fermentation. The process of manufacture is said also to alter the casein, so that it coagulates in flakes not unlike those of woman's milk, and it is thus rendered easier of digestion. It keeps well for from two to six days. One part of it may be added to from seven to ten parts of water (Dessau recommends one to sixteen). To this it is advisable to add, especially when the dilution is with the larger amount of water, some fresh cream when obtainable, and some sugar of milk. Keating prescribes the following formula as making a preparation very nearly the equivalent of mother's milk:

Preserved milk	℥ j.
Water, previously boiled or filtered	℥ vij.
Fresh cream	℥ j.
Sugar of milk	℥ ss.

Dissolve.

The absence of cane-sugar in this preparation renders it valuable in summer in our large cities, when diarrhœa is prevalent. Under such circumstances it may sometimes agree better without the additional cream and sugar. Lime-water, or a decoction of barley or of flour, prepared by Dr. Smith's receipt, may take the place of pure water when deemed expedient. The ordinary canned condensed milk has the disadvantage of containing a large amount of cane-sugar, which is liable to disagree with the infant. When diluted with ten parts of water or more, as some recommend, it becomes deficient in the albuminoids and fat, and requires the addition of cream. It possesses the same advantages that the fresh preserved milk does, in being sterilized by the process it undergoes, and in the casein being rendered less coagulable, and, therefore, easier of digestion. The dilution may frequently with advantage be made with barley-water, or with the prepared flour; cream and a little salt should be afterward added. Owing to the large amount of sugar contained in it, there is said to be a tendency in babies fed upon it alone to develop fat quickly. Such infants are apt to be pale, flabby, and lethargic, and, although large, are generally far from strong, and frequently become rachitic. It may be of service, however, when not used for too long a time. Keating recommends its use in the case of young infants, and for such as are suddenly deprived of the breast, to tide over a short period till more perfect arrangements can be made. For older children, when combined with barley-water or dextrine, its use may occasionally be recommended. Should any symptoms of over-acidity of the stomach show themselves, it will be advisable to immediately make a change for another food.

Patented Foods.—When, for any reason, failure has attended attempts to feed the infant on a modified cow's milk, numerous patented artificial foods are placed at our disposal by interested agents, who loudly vaunt their special preparation as being the exact analogue of mother's milk, and the only food calculated to help the little one in its dire distress. We cannot deny that some of these are occasionally of service. It is desirable, therefore, that the physician should have some knowledge of their several properties and composition, further than the meagre and often incorrect statements contained in their advertisements. In all of these foods dependence is put, for the greater portion of the nourishment supplied, on the milk, which is either added by the user or previously introduced by the manufacturer. They are all, therefore, to be regarded as modifications of cow's milk; a fact which may explain the frequent successful results attending their use. With the exception of those which contain the milk in a condensed form, all, if administered alone, show a great deficiency in many of the most important ingredients of an infant food. The facts that they are secret preparations, over which, as physicians, we can exercise no supervision or control as to the amount of care, or to the quality of the material used in their manufacture; that analyses made by many able chemists have given very variable results, often differing widely from the manufacturers' published formulæ; that they are liable to be old and musty; and that for the poorer classes they are an expensive food without any corresponding advantages should, I think, make us resort to them with much caution. To the analyses of Dr. Leeds we are principally indebted for a knowledge of their more exact composition. He has grouped them all into three classes. The first class contains the farinaceous foods prepared from the flour of one or more of the cereals, with the starch generally slightly modified by baking. All of them yield a large proportion of starch to the acid solution, and for this reason are not suitable for infants under six months. None of them appears to possess any advantage over wheat flour, prepared according to Dr. Smith's formula, while in most of them the changes are much less complete. They are all liable to deterioration through long keeping. Among the best known of this class are the following: Imperial Granum, Blair's Wheat, Hubbell's Wheat, Hard's Food, Ridge's Food, Robinson's Patent Barley, Popeena and Bethlehem Oatmeal.

Leeds gives the following results of his analysis of these compounds:

Class I.—Farinaceous Foods.

	Blair's Wheat Food.	Hubbell's Wheat Food.	Imperial Granum.	Ridge's Food.	Robinson's Patent Barley.
Water	[illegible]	[illegible]	[illegible]	9.23	[illegible]
Fat	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Grape-sugar	[illegible]	[illegible]	none	[illegible]	[illegible]
Cane-sugar	[illegible]	[illegible]	none	[illegible]	[illegible]
Starch	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Soluble carbo-hydrates	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Albuminoids	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Gum, cellulose, etc.	[illegible]	[illegible]	[illegible]		[illegible]
Ash	[illegible]	[illegible]	1.16	[illegible]	[illegible]

In the second class are placed all those in which the starch is to a great extent converted into sugar by malting, according to Liebig's formula. This method is thus described by Dr. Leeds: "Equal parts of wheat flour and barley malt, with a certain amount of wheat bran—added, it is said, for the sake of the inherent phosphates and nitrogenous matter—together with one per cent. of bicarbonate of potash, are mixed with sufficient water to make a thin paste. The mixture is allowed to stand at an ordinary temperature for several hours, and then heated to 150° F., until the conversion of the starch is completed. It is then strained, and the residue pressed and exhausted with water. The extract is evaporated in vacuo, at as low a temperature as is consistent with rapidity of working, dried at a higher temperature, and finally, by very skilful manipulation, brought to a finely pulverulent mass which does not contain sufficient moisture to cake. . . . The starch has thus undergone conversion into dextrine and grape-sugar, which, being soluble, pass into the liquid extract; but only that portion of the albuminous matter contained in particles so fine as to pass through the strainers, together with any soluble albumen (and this is specially valuable in the nutrition of infants), are found in the final product. If the virtue of Liebig's foods resides only in their not containing starch, but the products of it, together with sufficient bicarbonate of potash to make the reaction of the infant food like milk always alkaline, then so tedious and expensive a process should not have to be resorted to in order to obtain a mixture which can be made directly very cheaply. If, on the other hand, the other substances extracted from the grain have an important dietetic value of their own, analysis should be directed to ascertain their nature and amount." The principal foods of this class are Mellin's, Horlick's, Hawley's, Keasbey & Mattison's, and Savory & Moore's, for which I quote Dr. Leeds' analyses, and the Lactated Food, for the analysis of which I quote the results obtained by Dr. B. F. Davenport, of Boston.

Class II.—Liebig's Foods.

	Mellin's [illegible]	Horlick's Food.	Hawley's Food.	Keasbey & Mattison's.	Savory & Moore's.	Lactated Food.
Water	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Fat	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Grape-sugar	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	
Cane-sugar	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	
Starch	none	[illegible]	none	none	[illegible]	[illegible]
Soluble carbo-hydrates	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Albuminoids	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Cellulose, gum, etc.					[illegible]	
Ash	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Milk-sugar						[illegible]

It will be noticed that the percentage of fat in all is extremely low, and that of grape-sugar very high. In Horlick's and Mellin's there is said to be no unconverted starch. Hawley's contains eleven per cent., while Savory & Moore's contains a large amount, as does also the Lactated Food. These foods, from the large amount of glucose they contain, are sometimes of service when the infant is of a constipated habit and suffers much from indigestion. If there be any tendency to diarrhœa they are liable to increase it. When a decided laxative effect is required it may be advisable to use them, without milk, for one or two meals in the day.

The *third* class comprises those foods to which the milk has already been added during the process of manufacture. Such foods are supposed, on the addition of water, to supply an infant food corresponding in nutritive value to human milk. All of them contain starch more or less converted into dextrine, together with condensed milk. Their mode of preparation insures more or less complete sterilization of the milk, and converts its casein into a very digestible form—important advantages during the summer season. Nestlé's is one of the oldest of these preparations, and is at present esteemed highly by many physicians. Very recently a New York firm has placed on the market a preparation which it terms Soluble Food. Dr. Earle mentions this food very favorably, and says that it is composed of forty-five per cent. powdered milk, forty-five per cent. dextrine, and ten per cent. milk-sugar. It is partly predigested, so that it should be easy of digestion. It is claimed that it approaches nearer to human milk in composition and digestibility than any other food in the market. My own experience with it has certainly in many instances been favorable. As in all of these foods the amount of fat is defective, it is better, when possible, to supplement it by the addition of a little cream. Of other preparations, Gerber's, Anglo-Swiss, and American Swiss are the best known. Dr. Leeds gives the following formula:

Class III.—Milk Foods.

	Nestlé's Food.	Anglo-Swiss.	Gerber's Food.	American Swiss.
Water	4.72	[illegible]	[illegible]	[illegible]
Fat	[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Cane-sugar	[illegible]	[illegible]	[illegible]	[illegible]
Starch	[illegible]	[illegible]	[illegible]	[illegible]

Dr. Rotch has prepared a table showing the ingredients of the several foods as usually given to the infant. A reference to the analyses of human milk, as given on the upper line, will show the errors in nutritive value and perhaps enable us to make any one of them correspond more closely to the standard. "All of these foods," he says, "are at times useful, provided we use them intelligently for the especial case; but for general use the patented foods should be avoided on account of the objections regarding their manufacture as a class. They are also the most difficult class of foods to make correspond with human milk. There is no reason why clinical results should not be much improved if physicians will only take time and trouble to approximate their artificial food to the natural aliment, and follow more uniformly nature's teaching.

* The figures are approximate and represent general averages.

Amount to be Given.—Not only is the character and composition of the food itself of importance, but the amount to be given, and the times of giving it, demand the physician's careful attention. As Biedert remarks, the infant has no instinct which guards against overfeeding. Even breast-fed children are apt to drink too much, but those artificially fed have a much greater tendency to excess, since in general they obtain their food more quickly, and with less exertion on their part. The truth should be carefully impressed upon mother and nurse, that a bottle-fed infant thrives best upon the minimum amount of food necessary for development, whereas any excess tends to induce flatulence, to interfere with digestion, and, if continued, to unfavorably affect nutrition.

We have previously referred to the very rapid increase in the capacity of the infant stomach during the first two months of life, while in the third, fourth, and fifth months the increase is but slight. Corresponding with this fact, it would appear that while the amount of nourishment required during the first few days of life is but small, the quantity should be rapidly increased up till the end of the second month, when the increase may become more gradual. A considerable increase in the quantity needed usually takes place between the sixth and tenth months. Dr. Rotch quotes the results of Smitkin's investigations at the Children's Hospital in St. Petersburg, to determine the amount that should be given during the first few weeks of life. He finds that the greater the weight, the greater is the gastric capacity, and says that one one-hundredth of the initial weight of the infant should be taken as the starting figure for each meal, and to this should be added one gramme for each day of life. Thus considering 3,000 grammes as the initial weight, 30 grammes (about ℥ j.) will be required during the first few days, while by the end of the first month the amount required will be doubled. The following tables have been prepared by him to indicate the amount and frequency of feeding required. They should be regarded, however, as merely approximate, for infants, like adults, vary much both in their appetite and power of digestion.

Average Rules for Feeding.

The average initial weight of infants is 3,000 to 3,500 grammes (about 7 to 7½ pounds).

The average weight gain per day in the first 5 months is 25 to 30 grammes (about 1 ounce).

Age.	Intervals of feeding.	Number of feedings in 24 hours.	Average amount at each feeding.	Average amount in 24 hours.
1st week	2 hours	10	1 oz.	10 oz.
2nd–6th weeks	2½ hours	8	1½ to 2 oz.	12 to 16 oz.
6th to 12th weeks, and [illegible]				
[illegible]	3 hours	6	3 to 4 oz.	18 to 24 oz.
[illegible]	3 hours	6	5 oz.	30 oz.
[illegible]	3 hours	6	7 oz.	42 oz.

The weight, including the use of balances to determine the amount of each feeding at the beginning, [illegible]

[illegible]

	Each feeding.		
Initial weight.	[illegible]	1st 15 days.	15–30 days.
2,000 grms.	30 grms. = 1 ounce	[illegible] (about 1 oz.)	[illegible] (about 1¼ oz.)
3,000 grms.	[illegible]	[illegible] (about 1½ oz.)	[illegible] (about 1¾ oz.)
4,000 grms.	[illegible]	[illegible] (about 1¾ oz.)	[illegible] (about 2 oz.)

Directions for Feeding.—In bottle-fed infants regularity in the hours of feeding should be insisted on from the very beginning. The food should be given at about blood-heat (98°–100° F.) from a smooth glass bottle which has no corners that cannot be thoroughly cleansed. It is a wise precaution for the mother to taste each bottle to see that there is nothing amiss, and that the nipple is sufficiently pervious. Dr. Parker recommends a pure gum nipple with two holes as far apart as possible. Milk coming through one hole is not as comfortable to the infant as when it comes through two, and is more apt to induce attacks of choking. The infant should be fed lying in the nurse's arms with its head slightly raised, and its body in somewhat the same position as if it were being nursed at the breast. When it has finished nursing it should, if it be drowsy, be laid gently on its right side and allowed to sleep. Under no circumstances should it be tossed about or romped with shortly after it has had its food. The bottle, after the infant has finished nursing, should be at once removed, emptied, and cleansed; no playing with it by the child should be permitted. If any food remain in it unfinished, it must always be thrown away, for as the child draws milk from the bottle, the air which replaces the milk is that exhaled by the child, and would act quickly as a putrefacient. In selecting and ordering the food for an infant, it must always be borne in mind that no hard and fast rules are applicable to all infants. Careful watching is necessary to find out that the child thrives, that its flesh grows firm, and that it makes a reasonable gain in weight from week to week. Regurgitation, flatulence, hiccough, acidity of the stomach, constipation, or diarrhœa, with pains and the passage of curds or foul-smelling or clayey motions are all evidences of indigestion, and demand careful consideration and rectifying. The fæces should be carefully examined for abnormality and undigested materials. Occasionally superfluous fats resemble curds, and may be mistaken for them, but are at once detected by their solubility in alcohol.

Very early, in the case of immature and very sickly babies, and of infants with cleft palate, the ordinary feeding-bottle is inefficient owing to the infants not having power to suck. Feeding by spoon is slow and wearisome to the infant. In these cases Dr. Jarvis recommends the use of [illegible]. In this feeding-bottle simple pressure on the rubber piece, either by the lips or gums of the infant or on the exposed portion of the tube outside the bottle by the fingers of the nurse, will cause the food to escape from the bottle. Dr. Jarvis says that in many cases it has done good service. It can be obtained of surgical instrument dealers in New York.

Gavage.—Very recently Dr. Tarnier of Paris has advocated the method of gavage in infants prematurely born, or in such as are congenitally weak. The apparatus necessary for the purpose is very simple: a soft rubber catheter, No. 14 or 16 French, or a piece of gutta-percha tubing with a small glass receptacle of sufficient size to hold the amount of milk to be administered, attached to the distal end. The child is placed on the knee of the nurse with its head slightly raised. The tube is moistened with milk and introduced at the base of the tongue, and then very gently forced down the œsophagus to a distance of 15 ctm. The tube is then pinched between the two fingers, and the food is introduced into the receptacle. On relaxing the fingers and raising the receptacle the food flows gently into the stomach. Care must be taken to remove the tube gently and quickly; the infant must then be replaced in its warm cradle or couveuse. To the weakest infants eight grammes of food are given every hour. In spite of this feeding, the infant frequently loses weight for the first few days, but soon begins to gain steadily. Dr. Tarnier is said to have achieved marvellous results by this method.

AUDITORY CANAL, ECZEMA AND DERMATITIS OF THE. Following an example set by the Editor of the REFERENCE HANDBOOK in his very practical treatise entitled "A Manual of Diseases of the Ear," I shall, in this article, make no attempt to draw a fine and accurate line of distinction between those acute and chronic inflammations of the skin lining the auditory canal which are clearly and unmistakably eczematous in their nature, and those others which, in greater or less degree departing from this standard, present rather the clinical features of a simple dermatitis accompanied by, or not accompanied by, consecutive inflammation of the underlying perichondrium and periosteum. Many of my readers have found, and others of my readers will surely find, that in practice the line of distinction between these two varieties of inflammation is often entirely undiscoverable, and that any attempt to lay down an infallible rule for its detection, based upon the varying classifications of writers on dermatology, will surely be misleading and in practice quite profitless, at least when they come to consider the subject of dermatology as applied to the external auditory canal.

A study of the subject of eczema as the disease affects any portion of the skin demonstrates the fact that under this title have been grouped together a great number of varying lesions, so that it is common to speak of the "protean aspects" of eczema. In the auditory canal so-called characteristic lesions of the disease are more commonly wanting than is the case in eczema of other regions; thus, for example, the vesicles of an acute eczema, a very helpful sign in diagnosticating the disease elsewhere, are almost never discoverable; and the subjective symptom of itching—considered so characteristic of eczema, although, of course, not pathognomonic of eczematous inflammation—while generally present, is, nevertheless, occasionally absent in what, but for this single exception, would be most manifestly an eczematous dermatitis of the canal. It becomes us to be careful how we give names to diseased conditions before we clearly understand what they are, lest we be misled by the very system of classification which is supposedly intended for our guidance. "Lucus a non lucendo:" let us beware lest we fail to see the wood, not indeed for the trees, but for the labels that a multiplicity of guides has tacked upon the trees.

There is, of course, such a thing as a well-marked eczematous inflammation of the auditory canal; as, for example, in the case of a suddenly occurring invasion of this region by a typical eczema which has spread from the auricle; or, again, in a case marked by the sudden onset of such a symptom as erythema, accompanied by slight burning pain and itching, and occurring in the auditory canal of a person in whom careful examination has demonstrated the absence of any form of otitis media on the one side, or of any affection of the skin covering the auricle or other parts of the body on the other, and where, moreover, the absence of any chemical or mechanical irritation of the skin surface of the canal can be positively proved. Undoubtedly, also, there is such a thing as a simple dermatitis of the canal, caused by chemical or mechanical irritation, and occurring in a person who has never given evidence of any tendency to eczematous or eczematoid inflammation of the skin. But between these two extremes lies an almost infinite series of gradations, and these middle-ground cases are the ones most commonly seen in practice. In a goodly proportion of such cases positive diagnosis between eczematous and non-eczematous dermatitis of the canal can only be made after a patient has been for some time under observation, long enough for his physician to have observed the tendencies of the disease rather than its precise local lesions; while in some instances, the physician never can say positively whether or not there be an eczematous element in the case.

When we come to consider what is, at least in our patients' estimation, the most practical aspect of the question under such circumstances, viz., the treatment of the disease, it is an undoubted fact that, so far as *local* measures are concerned, it makes no difference whether eczema be or be not the chief causative element in the case, provided that the idiosyncrasies of a typical eczema, during its earlier stages, in regard to the use of certain external applications (as notably water, strong preparations of tar, and strong irritants generally), be borne in mind, and that these idiosyncrasies be carefully respected in any doubtful case, the physician acting upon the assumption that such case is one of pure eczema.

Acute Eczema.—Acute eczema of the auditory canal may occur either as the extension of an acute or chronic eczema of the auricle, or as a purely local lesion. When occurring primarily and wholly within the auditory meatus, it is a rare affection, and the writer cannot remember at this moment having seen a single case of primary acute eczema thus limited in its area. As the extension of an eczematous inflammation previously existing upon the auricle, an acute eczema of the canal is by no means uncommon: as the exacerbation of a chronic eczematous dermatitis limited to the canal, it is of quite frequent occurrence: while a purely traumatic dermatitis of the canal, in a patient predisposed to eczema, is quite apt to present well-marked features of the eczematous process at some period of its course; possibly at the very beginning, in a striking disparity shown between the violence of the exciting cause and the resulting symptoms; possibly later on, by the manifestation of a special tendency to chronicity, by the production of an unusual degree of itching and a surprisingly protracted and abundant desquamation; or, it may be, finally, by yielding to treatment only after a course of internal medication, directed toward improvement of the gastro-intestinal and hepatic digestion, and, in this way, toward an elimination of imperfectly oxidized matters from the blood, has indirectly proved the existence of a so-called "gouty dyscrasia" to be a part cause, or a chief cause of the skin lesion.

The subjective symptoms of an acute eczema are pain in the ear, shortly followed by a diminution in the hearing power, and commonly followed by tinnitus, and by a feeling of fulness in the head. All of these, it will be noticed by the reader, are equally symptoms of an acute otitis media. How, then, may these two affections, in their incipient stage, be diagnosticated the one from the other? Such diagnosis based upon symptoms alone would be difficult in any case, impossible in many cases. Provided it was known that the patient had not previously been troubled by, or affected by, chronic eczematous dermatitis of the canal, the association of a sensation of itching with the four other symptoms just mentioned would justify the physician in suspecting eczema of the canal as the cause of all five symptoms; and if, in addition, he learned that the pain was of a burning or pricking character rather than lancinating, that it seemed to the patient to be very strictly limited to the ear, and not felt deeply within the head, or radiating widely from the ear, and that the hearing power was but slightly diminished, and the tinnitus not very annoying, he would have additional grounds for so suspecting.

The objective symptoms presented would be an erythema of the wall of the auditory canal, probably, but not invariably, involving its entire surface, and usually implicating the dermoid surface of the drum-membrane. But the examiner would be very apt to discover a degree of stenosis of the canal so great as to preclude a thorough inspection of its wall, and, in many instances, advanced to such a point as completely to prevent a view of its fundus, that is, of the membrane. At a very early stage of the process it might be possible to detect a vesicular lifting of the epidermal layer over some part of its extent (an appearance which the writer himself has never detected in eczema of this region, although he believes himself to have seen it in a case of impetigo contagiosa involving the canal lining). At a little later, although still a very early stage of the process, and perhaps within a few hours of its beginning, the walls of the canal might be seen to present a moist appearance, being already coated with the discharge,—at first serous, afterward sero-purulent, and perhaps profuse in amount,—which is exuded from the surface of the inflamed skin.

Such an examination as has been just indicated, if conducted by speculum, would be painful to the patient, perhaps intolerably so, and, therefore, not permitted; so that, for inspection of the canal, its partial straightening and dilatation by gentle traction on the auricle, would have to suffice the examiner, and by such examination he would, in most instances, be able to see but a short distance beyond the meatus. Nay, more, this very traction in itself would be apt to cause the patient pain; but, as a compensation to the examiner thus hampered in his investigation, it should be stated that *decided* pain resulting from gentle traction on the auricle is in itself an indication of inflammation seated in the auditory canal, although, of course, no proof of its being limited thereto; and that *extreme* pain on traction of the auricle is an indication rather of phlegmonous inflammation located *near the meatus*, and notably of furuncle, than a sign of an inflamed condition of the *inner* portion of the canal wall, whether existing independently of, or as secondary to, intra-tympanic inflammation. Such extreme pain attending traction on the auricle, added to the subjective symptoms of pain in the ear (especially if notably increased from the start by movements of the jaw in chewing), of slight deafness and tinnitus, and slight fulness in the head, and very often slight itching, should lead the examiner to search for prominent and tender spots near the meatus, and, at least for the moment, to suspect the existence of one or more furuncles as the sole cause of his patient's discomfort; and it would be only after excluding these that he could assume the existence of a more diffused and probably eczematous inflammation of the canal as its more probable cause.

Tenderness to pressure, made either in front of the tragus or close to the insertion of the auricle over the mastoid pressure exists in the former than in the latter affection, but possibly in both—is an objective symptom present in acute eczema when severe in its degree; present also in furuncle and other severe inflammations of the canal walls; and, as is well known, in severe intra-tympanic inflammations. The existence of swelling in front of, immediately below, or behind the auricle, common to all forms of severe inflammation within the ear, is yet oftener a symptom in extra- than it is in intra-tympanic inflammation; and, while in disease of the tympanum it is chiefly over the mastoid process that we expect to find the swelling, in inflammation of the canal walls we look rather to the skin area in front of the tragus, and to that lying immediately below the pinna, as likely to be the chosen seats of such swelling; and this is no wonder, as in inflammation of the canal walls it is rather an implication of the lymphatic vessels than of the periosteal covering of the temporal bone that is concerned as chief producing factor of the swelling. For the same reason it is found that the lymphatic glands lying over the mastoid, below the auricle, and over the parotid gland, are more apt to be involved in extra- than in intra-tympanic inflammation—a point that the physician will not infrequently find helpful in diagnosticating diseases of the ear, although it is one, among many clinical indications, the value of which he should aim rather to underestimate than to overestimate.

Probably enough has already been said regarding the early symptoms, both subjective and objective, accompanying an idiopathic acute eczema limited to the auditory canal, to show that the positive diagnosis of this affection, when seen for the first time within a day or two of its inception, is fraught with difficulty, and may be not only well-nigh, but quite impossible, and that in such cases it is only from the subsequent course of the disease that it can be positively identified. One means of diagnosis between the formative dermatitis of the canal and the acute otitis media for which it might be mistaken, would be the inflation of the tympanum by Politzer's method, or by catheter; and in very mild cases, accompanied by a slight degree of pain, or where an ocular examination of the membrana tympani being practicable, it is seen to occupy the normal plane and to be almost free from congestion, this procedure would be entirely justifiable. In such cases, however, it would almost never be necessary; as the examination by other means and notably by speculum, would have shown the disease to be clearly limited to the outer portion of the auditory canal. On the other hand, where stenosis of the canal rendered a good view of the membrane impossible of attainment, this very stenosis, coupled with the marked pain and unusually pronounced deafness and tinnitus, which together had led the physician to suspect the tympanic cavity as either the primary seat of the whole trouble, or at least as secondarily involved through congestion of its vessels, and that, too, in a marked degree, would, or should, forbid the inflation of the drum by any method as a means of establishing a more accurate diagnosis. The interests of the patient in such a case would not so emphatically demand an accurate diagnosis as to justify the risk of exacerbating a suspected otitis media by inflating the tympanum during its early and acutely painful stage; while the line of treatment to be adopted under such circumstances should be one equally suitable for an acute inflammation of the external, or for one of the middle ear, and harmful to neither. It may sound strange to some of my readers, but I make bold to say that, in a doubtful case of this kind, a paracentesis of the drum membrane, made despite the existing stenosis of the canal and without a view of the membrane previously obtained, and executed, as by skilled hands it could be even under such adverse conditions, in the hope of promptly relieving a severe otitis media whose existence was strongly suspected, would be far more justifiable than would be the tentative use of inflation as a means of diagnosis alone; while as a method of treatment simply, inflation, under such conditions, would be absurdly out of place, and would be dangerous to the patient. As the writer has already stated in his article on the examination of the ear (Vol. II. of REFERENCE HANDBOOK, p. 677), it is not admissible to inflate the tympanum by any method for diagnostic purposes when decided pain in the ear is present. It is true that very rarely, and under special conditions, the otological specialist may see fit to assume the responsibility, and the concomitantly involved risk, of violating a rule thus boldly expressed; but to all comers it may be added that the general practitioner will err on the safe side, and will thereby consult his own interests, if he keep the rule inviolate.

Treatment in this early stage of an acute eczema, as in the early stage of an acute otitis media, should be directed toward a relief of the congestion underlying the inflammation. Rest in bed, a mild cathartic, and the abstraction of blood by leeches or by the artificial leech, applied in front of the tragus, are the chief means to be used for this purpose. Pain, if severe, may be relieved by the application of dry heat to the affected side of the head, supplemented, if need be, by the internal or hypodermic administration of morphine, or of some other narcotic. Cocaine solutions, laudanum, almond oil, etc., should not be dropped into the ear.

This line of treatment is, of course, equally applicable to a primary and to a secondary acute eczema in its early stage. As soon as a discharge from the ear makes its appearance, it becomes necessary to resort to gentle syringing of the canal, more or less frequently repeated, in order to remove as quickly as possible the exuded secretion, which experience has proved to be more irritating to the inflamed skin than is the warm water employed for its removal.

Acute Eczema occurring in the course of Chronic Suppuration of the Tympanum, and the same occurring as the Exacerbation of a Chronic Dermatitis.—Acute inflammation of the auditory canal walls is, as is well known, no uncommon occurrence during the course of a chronic suppurative otitis media. Occasionally an unusual suddenness in onset and an unusual violence in the attack, and a disproportion between its violence and the degree of intra-tympanic inflammation, together with the appearance of a very profuse and greatly augmented discharge, the rapid involvement of the skin over the auricle and adjoining the same, and possibly the presence, synchronously, on some distant part of the body of a distinctively eczematous eruption, may combine to show the new symptoms to be due to eczema of the canal, rather than to any of the more serious conditions lying deeper within the ear, which are, indeed, in most cases and of [illegible], the underlying cause of such secondary trouble in the outer ear. An improper local treatment of the pre-existing chronic otitis media is often the exciter of this condition, and the writer recalls one instance, recently observed, where the insufflation of iodoform powder in a case of scantily discharging otitis media pretty evidently served, on two separate occasions, to excite a violent eczema of the canal and auricle in a little patient in whom other indications of a predisposition to eczema had been present. On both occasions the use of a mild mercurial cathartic, followed by a pretty free dosing with bicarbonate of soda for several days, and combined with the use of starch dustings of the acutely inflamed auricle, sufficed to check the severe symptoms and to cause a rapid disappearance of the complicating eczema. The extreme stenosis of the canal, and the great tenderness of its inflamed and swollen walls, almost entirely precluded the use of the syringe during these attacks, although both before and after their occurrence its employment had been found an indispensable element in the treatment of the discharging otitis media.

As already remarked, this occurrence of an acute eczema of the canal during the course of a chronic suppurative otitis media is a rare phenomenon in aural surgery. A far more common, and indeed the most common, method of occurrence is that in which an acute eczema suddenly supervenes upon, and appears as the exacerbation of, a chronic dermatitis of the canal. Under these circumstances, a valuable aid to diagnosis generally exists in the history of the pre-existing chronic affection. But this is not invariably the case, forasmuch as chronic dermatitis of the canal may exist for years without making its presence evident by symptoms which are annoying to the person affected; and this, of course, is particularly liable to be true in the case of a patient who is of a low order of intelligence, and of a disposition not easily affected by trifling symptoms.

In its method of manifestation such an acute eczema would differ little, if at all, from the primary form, or from that secondary to, and dependent upon, the chemical irritation produced by the discharge from an otitis media, or by the medicaments used in combating this latter; and the treatment of the condition would be the same in all three cases.

Chronic Eczematous Dermatitis.—And now, finally, we come to a consideration of that chronic inflammation of the skin of the external auditory canal, which is one of the commonest of those conditions which the aural surgeon is called upon to treat; a condition that, whatever be its exciting cause of origin, or whatever its method of manifestation, probably owes its existence, in the first instance, in a vast majority of cases, to a perversion in the constitution of the patient's blood, brought about by faulty elaboration of its constituents, and existing in what is known as the "gouty" or "lithæmic dyscrasia." The ill-understood condition of the nervous system known as "neurasthenia," may in some instances play the part of causative agent in initiating or maintaining this chronic dermatitis; but "neurasthenia," and that other and far commoner condition clinically recognized by all physicians, though accurately understood by none, and known as "struma," or the "strumous diathesis," are probably rather causative agents in the production of *acute* eczema of the canal, or of the acute *exacerbations* of a chronic eczema, than they are of a chronic dermatitis in this region which only occasionally, or it may be never, presents well-marked features of the typically eczematous process.

The rather common coincidence of a more or less distinctly eczematous dermatitis of the auditory canal, acute or chronic, with a catarrhal condition of the naso-pharyngeal mucous lining, has led some observers to suspect the existence of a "reflex" connection of cause and effect between the throat lesions and those in the ear; and such a relation between the two sets of lesions and symptoms cannot be positively denied; yet to the writer it appears equally reasonable to assume that in such a case the pharyngeal and aural troubles are simply coincident, and that both are equally the secondary manifestations of an underlying dyspeptic or "gouty" poisoning of the patient's blood.

A like relation, and one seemingly of a more indisputably "reflex" nature, subsists between dermatitis of the auditory canal and functional or pathological disturbances in the uterus and ovaries; for it is a matter of common observation among aural surgeons that this form of aural disease is of frequent occurrence in women affected with disturbance in these distant organs, and particularly in those reaching the menopause; and that in such cases the aid not only of the family physician, but occasionally also of the gynecologist, is demanded for the radical and permanent cure of the obstinately recurring aural affection.

In chronic eczematous dermatitis there is seldom or never a profuse fluid excretion, the presence of an abundant discharge generally signifying an exacerbation of the disease. The discharge, when present, may be serous, sero-sanguineous, or sero-purulent in character; is intermingled with a greater or less quantity of desquamated epithelial scales, and is apt to have a bad odor of a peculiarly pungent character, and different from the equally disagreeable smell of a discharge originating in, and proceeding wholly from, the tympanum. The desquamative process is always present in greater or less degree; sometimes evidenced only by a furfuraceous coating of the canal wall, which in such cases may be slightly congested, or may appear of the normal color; sometimes shown in a shedding of veritable sheets of skin which may be superimposed and packed together so as to form a dry occluding plug; sometimes shown in the presence of a blotting-paper-like mass of mingled epidermis and foul pus or sero-pus, so as to form a moist occluding plug. The walls, more or less congested, are often considerably thickened as the result of the chronic dermatitis itself, or of the latter combined with the thickening left by intercurrent attacks of periostitis and perichondritis; and of course, from such thickening there results a stenosis in the calibre of the canal. This thickening of its dermal wall, involving the outer surface of the drum-membrane, leads to decided impairment of the hearing-power, an impairment increased of course by obstruction of the canal calibre from an epidermal plug when such is present, further increased by the stenosis of the canal where this exists, and, as in the case of a transient acute inflammation of the canal lining, dependent also in part upon a secondary congestion and thickening of the tympanic mucous membrane, or upon the presence within the tympanum of an effusion from its walls thus secondarily involved in the inflammatory process.

From what has just been said, the reader will naturally and properly infer that a *marked degree* of deafness is characteristic rather of a chronic dermatitis than of an acute eczema of the auditory canal. From what was said shortly before concerning the common coincidence of naso-pharyngeal catarrh with external otitis, he will with equal propriety infer that the intra-tympanic factors of such deafness may, in the case of both acute and chronic otitis externa, be equally or more dependent in origin upon the pharyngeal lesions than they are upon those co-incidentally existing in the external auditory canal.

Among the rarer phenomena attendant upon a chronic dermatitis of the canal is the appearance of polypoidal growths springing from some point of the canal wall, and owing their origin to the supervention of actual ulceration of the wall or of localized necrosis of the underlying bone. It is probable that the presence of fungous growths in the ear is as frequently due to a chronic dermatitis as it is to any other cause; the sporules of these fungi lodging and finding a soil suited to their growth in the scantily secreting lining of the canal, just as they do occasionally in the similarly secreting lining of the tympanic cavity during the late stage of a diminishing purulent inflammation of this cavity. This condition, which is to be regarded as rather an accidental complicating symptom than as a self-existing disease, will be found fully discussed under the heading of "Parasitic Inflammation of the External Auditory Canal," in Dr. Frank Buller's article describing the congenital defects, diseases, and injuries of that canal (Vol. I. of this REFERENCE HANDBOOK, pp. 420 and 421). No better means exists for the destruction of these growths,—at least where they are confined wholly to the canal, and probably also in most other cases,—than the nitrate of silver treatment, presently to be mentioned as a leading remedy in combating the external otitis they so commonly accompany. In certain rare instances the long persistence of a chronic suppurative otitis media, resulting in extensive destruction of the membrana tympani, and a subsequent covering of the exposed tympanic wall by cicatricial membrane, appears, as it were, to convert the exposed portion of the tympanic cavity thus lined with epithelium into the inner extremity or fundus of the auditory canal, and to give rise therein to a very persistent form of desquamative dermatitis of its wall. This condition may be regarded either as a desquamative inflammation of the tympanum, or as a deep-seated inflammation of the wall of the external auditory canal, to which this cicatrized portion of the tympanum has been added as a sort of pathological annex. The freeing of such a deeply lying and irregularly shaped cavity from the dense plug of epithelium, more or less mixed with pus, that in certain cases tightly occludes it, is a task of no little difficulty. One case of this kind, in which it seemed that a distinctively eczematous element entered into the nature of the pathological process, and where several fragments of wood were discovered beneath the occluding plug, has been briefly described by the writer in his article on "Foreign thelium in the Tympanum" (HANDBOOK, Vol. VII., p. 480).

A somewhat similar case, but one in which the intra-tympanic space is almost exclusively involved, is at present under the writer's observation at the Vanderbilt Clinic. The analogy existing between the condition in which, from chronic desquamative inflammation, the auditory canal becomes occluded with a laminated plug of epithelium more or less mingled with [illegible] ("keratosis obturans"), and the so-called "cholesteatoma" of the tympanum of [illegible] intra-tympanic origin, has been pointed out by Dr. Burnett in the article already cited (Vol. I., p. 426). The process is the same in both instances, and some of these cases appear to lie in the borderland between a pure and it may be a primary external otitis and that form of otitis media characterized by the accumulation of a considerable mass of inspissated pus and caseous matter in the tympanic vault and antrum, which leads ultimately to mastoid sclerosis.

The treatment of chronic dermatitis of the auditory canal may be divided into two heads, comprising, respectively, the constitutional treatment of the dyscratic condition, or of the "lithæmic dyscrasia," the "strumous dyscrasia," or state of malnutrition,—one or the other of which will almost always be found to underlie the local pathological processes in the ear,—and the purely local treatment of these local lesions. Of these two lines of treatment, the former demands no special discussion in this place; concerning the latter, it will be proper to say a few words before bringing our article to a close.

Except during the acute exacerbations of the disease, whose treatment has already been sufficiently indicated under the heading of "Acute Eczema," no better local application for controlling the inflammation can be found than is the filling of the canal, from time to time, with solutions of nitrate of silver, varying in strength from 30 to 180 grains to the ounce. The method of employing such a solution is as follows: The canal should first be, so far as possible, cleansed of pus and epithelium by syringing with warm water. It should then be dried with absorbent cotton. Next, the patient being directed to lay his head on a table, so as to bring the axis of the canal to a vertical position, the physician should fill the canal with the solution by means of a dropper. The patient is then told to report to the operator as soon as he experiences a sensation of heat in the filled ear, and directly he so reports, the solution is to be immediately syringed out again with warm water. The canal is then dried once more, and then thoroughly smeared with vaseline, or borated vaseline, or weakly carbolized vaseline, and the operation is done. Such an application may be made once a week, or once in every ten days in the less severe cases; twice a week in those of greater severity. The strength of the solution selected should be in inverse ratio to the amount of congestion and the amount of fluid discharge present, and of course especial care is to be taken, in regard to the use of the stronger solutions, where a perforation of the membrana tympani is seen, or where its existence is suspected. The benefit derivable from applications of this sort is often simply surprising, even in the most inveterate cases the annoying itching being sometimes greatly allayed and the hearing power greatly increased by a single application. During the intervals between the applications the patient should be directed to syringe the ear as little as may be consistent with a proper freeing of the canal from a still persisting discharge, and should be directed to instil into the ear from time to time some five or six drops of vaseline oil, to which may be added (in cases where the itching is very annoying, or the desquamative tendency of the process especially marked) either oil of cade in the strength of one drop to the drachm, or carbolic acid in the strength of from one to three drops to the ounce.

For the removal of occluding plugs, simple syringing with warm water will frequently be found insufficient, and the physician may find it necessary to resort to the use of the blunt curette, probe, hook, and angular forceps, alternating such use with repeated syringings. And not infrequently, it is only after a succession of attempts thus made on different occasions, that the canal will be sufficiently cleared to permit a reaching of its entire wall with the silver fluids and emollient applications just described. The addition of bicarbonate of soda to the water employed in syringing will occasionally prove serviceable as tending to soften the hard epithelial mass.

Huntington Richards.

AUSTRALIA. Forasmuch as the only portions of the Australian Continent hitherto considered, or ever likely to be considered, suited to the residence of invalids, have been already discussed in the articles entitled Melbourne, New South Wales, and Victoria, and inasmuch as any account of the purely intra-tropical climate of Northern Australia, or of the peculiarly dry and "extreme" climate of the great inland basin (beyond such data as have been already elsewhere presented), would be out of place, no attempt to present additional information respecting the meteorology of Australia, taken as a whole, will be made; and the writer, having departed from his original intention of presenting such information in a general article on Australia, and having devoted up so much of this general information as properly belongs within the pages of a purely medical work between the three articles already cited, now begs to refer readers of the HANDBOOK to those articles.

H. R.

BADEN is a small town of about 4,000 inhabitants, in the Canton of Aargau, or Argovie, Switzerland, in which are numerous thermal springs. The town lies at an elevation of 1,250 feet above sea-level. There are twenty or more springs, having a temperature of from 116° to 120° F., of which the best known are the Limmat, the Heisserstein, and the Sainte Vérène. The composition of the last-named spring, computed in grams per litre, is as follows (Müller):

Sodium chloride	[illegible]
Calcium chloride	[illegible]
Magnesium chloride	[illegible]
Calcium sulphate	[illegible]
Strontium sulphate	[illegible]
Sodium sulphate	[illegible]
Potassium sulphate	0.127
Magnesium carbonate	[illegible]
Silicic acid	[illegible]
Manganese, bromide and iodide, [illegible]	[illegible]
Total	[illegible]

The waters are employed chiefly in the form of douches and baths, and are taken internally only in certain cases. The principal indications for these waters are gout and rheumatism, lead poisoning, chronic catarrhal inflammation of the respiratory passages, certain forms of neuralgia, and skin diseases in rheumatic and gouty subjects.

The bathing season proper extends from May to October, but the resort is visited more or less during the entire year. The number of guests at Baden is estimated at from 15,000 to 20,000 in the course of the year.

T. L. S.

BADEN-BADEN, so called to distinguish it from the other Badens, is one of the oldest and most celebrated of the German spas. It is a city of some 15,000 inhabitants, in the Grand Duchy of Baden, situated at the northern extremity of the Black Forest, at an elevation of 660 feet above the level of the sea. The climate is mild, rather moist, and free, as a rule, from sudden changes of temperature. The average temperature for the spring months is 47.4° F.; for the summer, 62.9°; for the autumn, 48.6°; and for the winter, 34°. On account of its equable climate the resort is frequented throughout the year by many sufferers from rheumatism, and serves as a resting place in the spring and fall for patients with pulmonary disorders travelling from and to Meran and other winter resorts.

There are very many thermal springs at Baden-Baden, which, however, differ but little among themselves in the relative proportions of mineral constituents. The most important springs are the Hollenquelle, Judenquelle, Ungemachquelle, Brühbrunnen, and Kühlerbrunnen. The waters from these springs are brought to a common reservoir and thence distributed through pipes to different establishments in the city. There is a separate reservoir for the water of the Ursprung, but it is generally mixed with the rest in its distribution throughout the city. The principal constituents of the water of the Ursprung, and their amount in parts per thousand, are, according to the most recent analysis by Bunsen, as follows:

Sodium chloride	2.151
Potassium chloride	0.163
Calcium carbonate	0.165
Calcium sulphate	0.202

In some of the springs Bunsen has recently found lithium chloride in the proportion of 0.0295 to 0.0306 Gm. per litre. The temperature of the different springs varies between 149° and 155.5° F.

All of the alleged therapeutic methods commonly used at the German spas, mud-baths, douches, herb-juice baths, milk-cure, whey-cure, grape-cure, etc., are carried out at Baden-Baden. The summer season extends from the beginning of May to the end of October, but, as mentioned above, the resort is frequented more or less during the entire year.

The principal diseases for the relief of which a course of the waters at Baden-Baden is recommended are gout, rheumatism, paralyses, and various affections of the nervous system. Recently it has become fashionable to send here patients with skin diseases or disorders of the digestive system, and women with affections of the reproductive organs. On account of the mild and equable climate many sufferers from pulmonary affections, and convalescents from acute disease, often derive considerable benefit from a residence of longer or shorter duration at this resort. Many others visit Baden-Baden merely for pleasure. *T. L. S.*

BADEN-BEI-WIEN, so called to distinguish it from other places on the continent of Europe having the same name, is a watering-place in Austria, and a popular summer resort for the Viennese. There are upward of thirteen thermal springs here, with a temperature ranging from 77° to 97° F. The water is clear as it emerges from the ground, but becomes turbid on exposure to the air, and possesses a strong odor and taste of sulphuretted hydrogen. The waters are used, as a rule, only for bathing purposes, that of the Ursprungsquelle, or Römerquelle, however, being also employed internally in certain cases, usually mixed with milk, or whey, or with other mineral waters. The principal constituents of this spring, according to an analysis by Keller, are as follows: One litre contains of

	Grams.
Calcium sulphate	0.3458
Calcium carbonate	0.3387
Sodium chloride	0.0670
Sodium carbonate	0.0064
Sodium sulphate	0.1882
Potassium sulphate	0.0640
Magnesium chloride	0.0500
Magnesium sulphide	0.0016
Silicic acid	0.0020
Organic matters	0.0013
Total	1.0650

The gases are carbonic acid, nitrogen, oxygen, and sulphuretted hydrogen.

The baths of Austrian Baden are recommended for those suffering from the so-called scrofulous troubles, chronic respiratory catarrhs, chronic rheumatism and gout, and some forms of sluggish skin diseases.

Baden-bei-Wien lies on the eastern slope of the Alps, at an elevation of a little over 700 feet above sea-level. The climate is fresh and invigorating, but sudden changes of temperature are not uncommon, necessitating caution on the part of those suffering from affections of the respiratory organs. The resort is visited the year through, but is naturally more frequented during the summer season, which extends from the first of May to the middle of October. *T. L. S.*

BAGNÈRES-DE-BIGORRE, or Bagnères-sur-l'Adour, is a thermal station in the department of the Hautes-Pyrénées, France. It is a little town of some 10,000 inhabitants, situated in the valley of the Adour, on a sheltered slope of the mountain, at an elevation of 1,900 feet above sea-level. The climate is mild and not subject to very great or sudden variations of temperature. There are some forty chalybeate springs here, having a temperature ranging in the different springs from 68° to 149° F. The following is the composition of two of these springs, according to analyses by Ganderax, computed in grams per litre:

	Source de la Reine.	Source du Dauphin.
Sodium chloride	0.062	0.040
Magnesium chloride	0.130	0.104
Sodium sulphate	0.396	0.400
Calcium sulphate	1.680	1.900
Magnesium carbonate	0.044	0.119
Calcium carbonate	0.206	0.142
Ferrous carbonate	0.080	0.114
Silicic acid	0.036	0.044
Organic matters	0.006	0.017
Loss	0.054	0.020
Totals	2.751	2.900

These waters are used internally and in baths in the treatment of anæmia and chlorosis, intestinal sluggishness occurring as a result of a sedentary life, hepatic congestion, etc. Bigorre is a favorite summer resort for Parisians, and the accommodations for guests are excellent. *T. L. S.*

BAGNÈRES-DE-LUCHON is a small town in the department of the Haute-Garonne, France, not far from the Spanish border. It lies in a valley of the Pyrenees, at an elevation of about 2,000 feet above sea-level, and the climate, though rather mild, is subject to sudden and wide variations of temperature. There are forty-nine thermal sulphur springs in the place, the temperature of which ranges from 61° to 154.5° F. The following is the composition of the Source de la Reine, according to an analysis by Filhol. One litre contains of

	Grams
Sodium sulphide	0.0508
Iron sulphide	0.0022
Manganese sulphide	0.0028
Copper sulphide	trace
Sodium chloride	0.0624
Sodium sulphate	0.0212
Potassium sulphate	0.0092
Calcium sulphate	0.0312
Sodium silicate	trace
Calcium silicate	0.0102
Magnesium silicate	0.0048
Aluminum silicate	0.0255
Silicic acid	0.0299
Total	0.2512

The gases are oxygen, nitrogen, and sulphuretted hydrogen. The temperature of the water is 132.4° F.

The waters of the Luchon springs are employed internally and externally in the treatment of rheumatic and gouty affections, caries and necrosis, various skin diseases, chronic mercurial poisoning, syphilis, etc.

Luchon is the most celebrated of the many springs in the Pyrenees, and is visited by upward of 20,000 persons during the season, which extends from the middle of June to the middle of October. *T. L. S.*

BRAIN. GROSS OR MACROSCOPIC ANATOMY.—§ 1. *Scope of this article.*—The histological, physiological and surgical aspects of the brain are discussed elsewhere in this and in preceding volumes; here, therefore, the organ will be considered mainly from the morphological stand-point.

§ 2. The liberal provision of the publishers for illustrations has rendered it possible to compose the text largely of commentaries upon the points illustrated by the figures. Of the 105 figures, 80 represent preparations made by the writer for the museum of Cornell University;* these preparations are designated by their analogous members; the drawings have been executed, from the specimens and from photographs, by Professor R. C. Carpenter (C.), Mrs. S. H. Gage (G. or S. P. G.), and Mrs. Wilder (W.). The 13 borrowed figures are credited to their sources. The remaining illustrations are original diagrams.

---

* The writer desires to acknowledge his indebtedness for material and assistance to many students, past and present, and especially to his colleague Professor S. H. Gage, whose suggestions also have been of great value.

§ 2. Points relating to the brain illustrated upon Figure 1.—A. The relative location and extent of the cranial and hemal regions of the head so far as they appear at the meson.

B. The continuity of the two portions of the neuraxis, the myel ("spinal cord"), and the brain (encephal), or at least the junction of the cranium with the spine.

C. The impossibility of determining the exact limits of these two neuraxial regions, since they pass insensibly the one into the other.

D. The obvious subdivision of the brain into several regions represented, for example, by the cerebellum, the cerebrum, and the intervening narrower part, which is sometimes called *isthmus encephali*.

E. The impossibility of determining the precise limits of these regions since they are continuous, and do not present either articulations or joints as with the skeletal segments.

F. The possibility of recognizing in the adult brain five divisions or segments of encephalic cavities corresponding with the five embryonic encephalic vesicles and with the divisions of more nearly equal size in certain other vertebrates.

G. The convenience of indicating the approximate boundaries of these segments by lines.

H. The representation of each segment at the meson by some well-known part; the metencephal by the postoblongata; the epencephal by the cerebellum and pons; the mesencephal by the crura and geminal lobes; the diencephal by the thalami, conarium, and hypophysis; and the prosencephal by the cerebrum.

I. The existence in each of these segments of a cavity which communicates with the adjoining cavities, the whole series being apparently an enlarged continuation of the myelic canal.

J. The insignificance of the mesal cavity of the prosencephal as compared with not only the other cavities but the cerebrum itself.

K. The presence of an orifice, the porta ("foramen of Monro"), evidently leading lateral from the mesal aula into a cavity within the right hemicerebrum.

L. The relations of the masses to the cavities, as are related the floors, roofs, and side-walls of an edifice to the apartments.

M. The great difference in the thickness of the roofs and floors at different points.

N. The continuity of the side-walls, floors, and (except at one point) of the roofs.

O. The existence of certain fibrous masses, commissures, extending across the meson, and therefore divided in this preparation.

P. The existence of a subspherical appendage of the base of the brain, the hypophysis, in a deep pit in the floor of the cranium (the "pituitary" or hypophyseal fossa).

Q. The change in direction of the cranial floor at about this point, the remnant of the embryonic cranial flexure.

R. The similar angle formed by the base of the brain.

S. The still more decided angle formed by the general outlines of the floors of the encephalic cavities at a point nearly corresponding with the cephalic end of the mesencephalic cavity.

T. The liability of misapprehension from the employment of the ordinary descriptive terms, *anterior*, *posterior*, *superior*, *inferior*, upper, and lower; since each of these terms would have one meaning for the myel and postoblongata, and another for the diencephal. It is as if two adjoining houses faced, one to the east and the other to the south; the employment of *front* and *back* as designating structural features of the two would necessarily lead to misapprehension.

U. The convenience of regarding the entire floor as ventral, the entire roof as dorsal, any region of the brain nearer the myel as relatively caudal, and any region farther therefrom as relatively cephalic.

V. The dorsal expansion of most of the segments. The wedge-like shape of the mesencephal is easily recognized; the thalami are not wholly exposed, but the region is more extended dorsally than ventrally; the cerebellum is much larger than the pons; while the disproportion of the cerebral hemispheres to their strictly basal, mesal part, the aula, is one of the many remarkable features of the adult human brain.

W. The tendency of certain segments to overlap adjoining parts, especially in the caudal direction; see §§ 29 and 41.

X. The lack of exact collocation between the encephalic regions and the cranial bones; the cerebellum corresponds to less than half of the supraoccipital bone, and extends a little beyond its margin at the *foramen magnum*.

Y. The connection of the lambdoidal suture with the dorsal end of the occipital fissure, and the location of the dorsal end of the central fissure nearly dorsad of the splenium, the caudal margin of the callosum.

Z. The location of the mesal craniometric points, nasion, bregma, lambda, and inion.

§ 4. Order of Treatment.—I. Introduction, §§ 1-5.

II. General constitution of the brain, segments, etc., §§ 6-61.

III. The metencephal (postoblongata), §§ 62-74.

IV. The epencephal (preoblongata, cerebellum and pons), §§ 75-93.

V. The mesencephal (gemina and crura), §§ 94-104.

VI. The diencephal (thalami), §§ 105-117.

VII. The prosencephal: *a*, the cavities; *b*, the parietes; *c*, the commissures; *d*, the fissures; *e*, the gyres; *f*, brain weights, etc., §§ 118-289.

VIII. Bibliography.

§ 5. *Method.*—What seem to the writer the more important facts and fundamental ideas respecting human encephalic morphology are stated in a series of propositions, brief and direct, and numbered for ready reference. Unless otherwise stated, these propositions apply to the human brain, and may not always hold good for those of other vertebrates, or even other members of the mammalian class. Few now question the advantages of dissecting more available animal brains as a preparation for work upon the human organ; the use of animal brains will be considered in the article **Removal of the Brain**. From their simplicity, also, or their smaller size, or because they emphasize some particular feature, the brains of certain animals may profitably be studied before or in connection with that of man; but the writer deprecates the extent to which merely curious or startling details of comparative anatomy are sometimes introduced into medical publications, and has here confined himself as closely as possible to the human structure; see his previously expressed opinion on this point (*New York Medical Journal*, October, 1877). Most of the statements are parts of common anatomical knowledge, and special references are seldom given. In this connection, therefore, the following extract from the preface to Huxley's "Anatomy of Vertebrated Animals" may be appropriately added:

"The reader, while he is justly entitled to hold me responsible for any errors he may detect, will do well to give me no credit for what may seem original, unless his knowledge is sufficient to render him a competent judge on that head."

§ 6. Prop. I. *Definition.*—The *brain* (Gr., ἐγκέφαλος; Lat., *cerebrum*; late Lat., *encephalon*; It., *cervello*, *cerebro*; Sp., *cérebro*; Fr., *cerveau*; Ger., *Gehirn*; Eng., *encephalon*, *encephal*) is the enlarged, segmented, cephalic ("anterior") portion of the neuraxis (nervous axis, cerebro-spinal axis, central nervous system, myelencephalon, neuron, etc.).

For common equivalents of vernacular terms see the Index. For considerations in favor of the terms herein employed, see the article **Terminology, Anatomical**, in this volume.

§ 7. Prop. II. The brain is but one of the three great mesal (median) organs which is nearest the dorsal surface of the body, and farthest from the heart; Fig. 4685. The other two are the *enteron* (alimentary canal; Fig. 4685, *œsophagus*, and the *axon* (skeletal or body axis; notochord in early embryos, but in later stages and adults the series of centrums or bodies of the vertebræ), Fig. 4684, *odontoid process*, etc. The enteron is in the ventral (hæmal) cavity; the neuraxis occupies the dorsal (neural or cerebro-spinal) cavity; the axon forms a partition between the two.

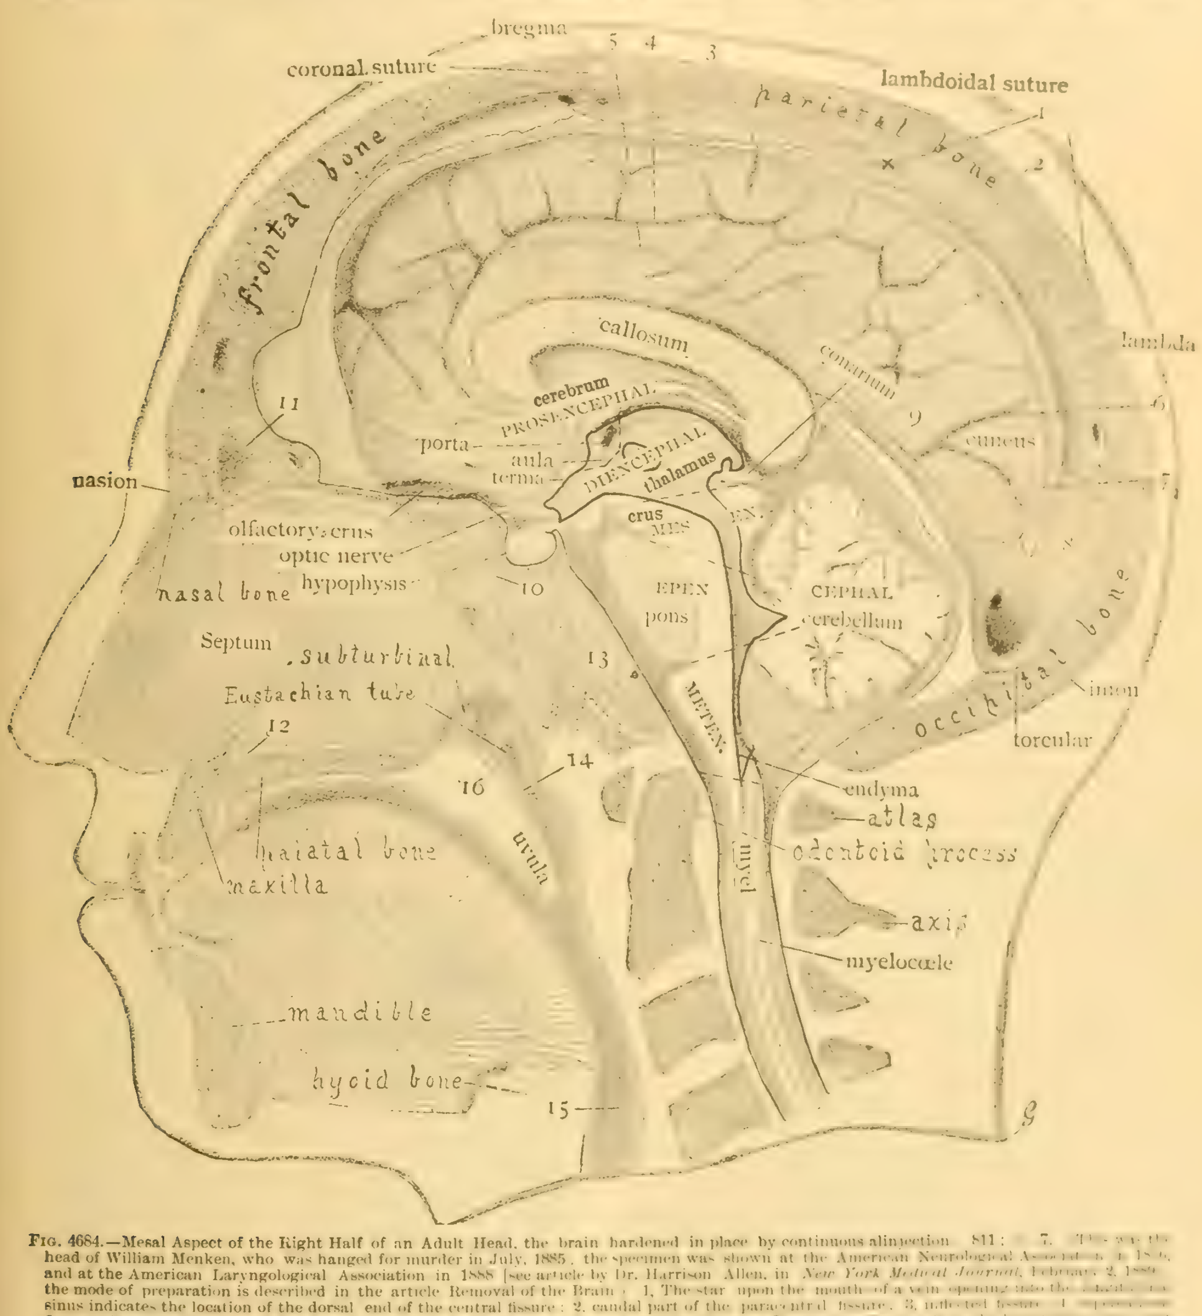

FIG. 4684.—Mesal Aspect of the Right Half of an Adult Head, the brain hardened in place by continuous alinjection (§11 ; [illegible] 7). This was the head of William Menken, who was hanged for murder in July, 1885; the specimen was shown at the American Neurological Association in 1886, and at the American Laryngological Association in 1888 [see article by Dr. Harrison Allen, in *New York Medical Journal*, February 2, 1889; the mode of preparation is described in the article Removal of the Brain]. 1, The star upon the mouth of a vein opening into the [illegible] sinus indicates the location of the dorsal end of the central fissure; 2, caudal part of the paracentral fissure; 3, [illegible] fissure; 4, [illegible] fissure; 5, callosal margin of the falx, indicated by the interrupted line; 6, occipital fissure; 7, calcarine fissure; 8, in the [illegible] dorsad of the torcular; 9, tentorial sinus; 10, a sphenoidal sinus (not vascular, but a cavity in the sphenoid bone); 11, a frontal sinus; 12, [illegible] palatine canal; 13, basioccipital bone; the basisphenoid has 10 upon it, but the two bones are continuous; 14, naso-pharynx; 15, [illegible]; 16, soft palate.

Defects.—The planes of section of the brain and of the other parts are not absolutely identical, although perhaps nearly enough so for most purposes. The section-plane, as made by the saw, passed just sinistral of the meson so as to leave attached to the right half the [illegible] septum, the latter scored slightly in its cephalic part; the preparation was photographed in this condition, but later the [illegible] excepting along the longitudinal sinus, so as to expose the fissures; then the various parts that cross the meson (callosum, fornix, [illegible]) were gradually pared down until the exposed surfaces were very nearly mesal; the changes in these parts were so slight that the [illegible] photograph served to locate all the parts; the fissures, however, were drawn from measurements of their relative distances. [illegible] and all the soft, vascular parts are swollen by the alinjection; the margins of the tongue are moulded upon the teeth; [illegible] wall of the pharynx are obviously thickened, and the subturbinal projects beyond the true margin of the septum; [illegible] perhaps the case temporarily during the congestion attending a severe "cold in the head." No attempt has been made to [illegible] the structure of the skin, the exact direction of the lingual muscles, or the details of the nuchal region. As a whole, the present figure is intended to serve mainly as a diagram, and the specimen will be more completely described and figured hereafter. See § [illegible].

§ 8. Points Illustrated by Fig. 4685.—A. The existence, in most of the entire length of two parallel body cavities, a dorsal or neural, and a ventral or hæmal, separated by the bone, the vertebral axis.

B. The presence, in the ventral cavity, of the heart, a

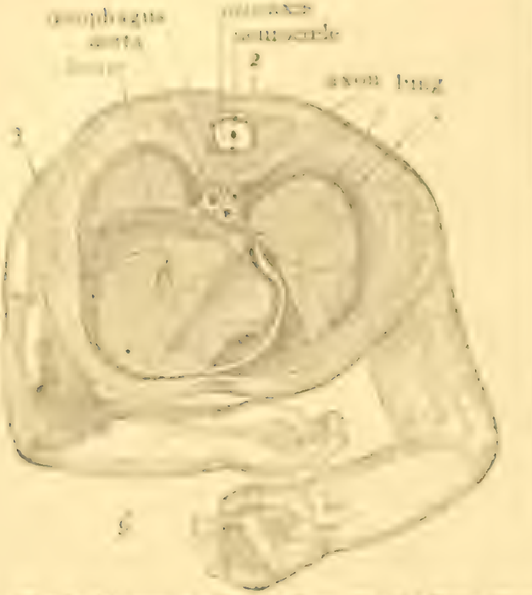

Fig. 4685.—Caudal Aspect of a Thoracic Transection of a Fetus about [illegible]

[illegible].—[illegible]

hollow muscular organ, rhythmically contractile during life.

C. The presence, in the ventral cavity, of a muscular tube, the enteron (alimentary canal).

D. The presence, in the dorsal cavity, of a subcylindrical rod, the neuraxis (cerebro-spinal axis), itself con-

Fig. 4686.—[illegible]

[illegible]

taining a cavity, the neurocoele (central canal and ventricles).

E. The greater distance of the neuraxis than of the enteron from the heart.

§ 9. Prop. III. Excepting at its first formation (when it is a groove with a dorsal furrow) the entire neuraxis is a tube, a subcylindrical mass inclosing a cavity. This cavity is the neurocoele, and the inclosing material constitutes the cœlian parietes. The existence of the neurocoele may be demonstrated by the transection of any part of

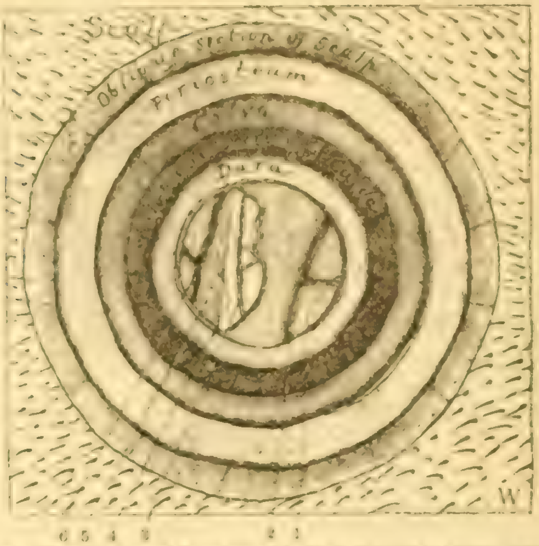

Fig. 4687.—The several Coverings of the Brain Exposed as a Series of [illegible]

[illegible].—[illegible]

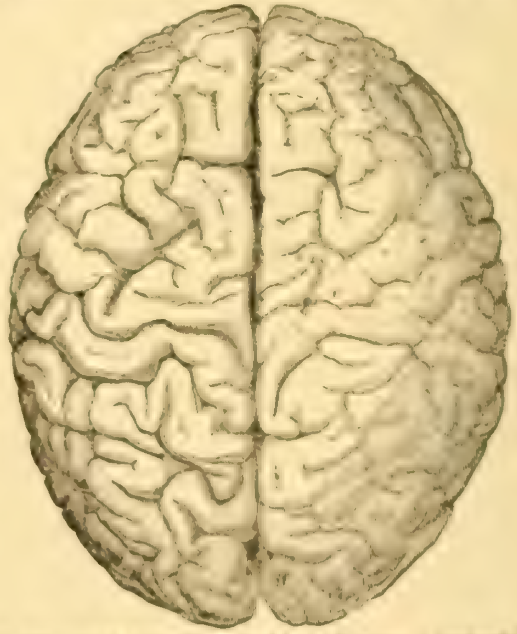

Fig. 4688.—Dorsal Aspect of the Brain of C. F. Gauss, a Distinguished Mathematician, who died at 78 years. (From R. Wagner, after Quain; [illegible])

the neuraxis in any other vertebrate, and in an immature human being; but with the adult, in certain regions, the olfactory bulbs (Fig. 4689) and most of the myel (spinal cord, Fig. 4684), the cavity is more or less completely obliterated.

§ 10. Prop. IV. *Location.*—The brain is contained mainly within the cranium, although part of the post-oblongata or even, as appears in Fig. 4684, a little of the cerebellum, may extend beyond the limits of the *Foramen magnum.* It is remarkably sheltered and clothed by the cranial bones and by the soft parts ectad and entad of them, Figs. 4686 and 4687.

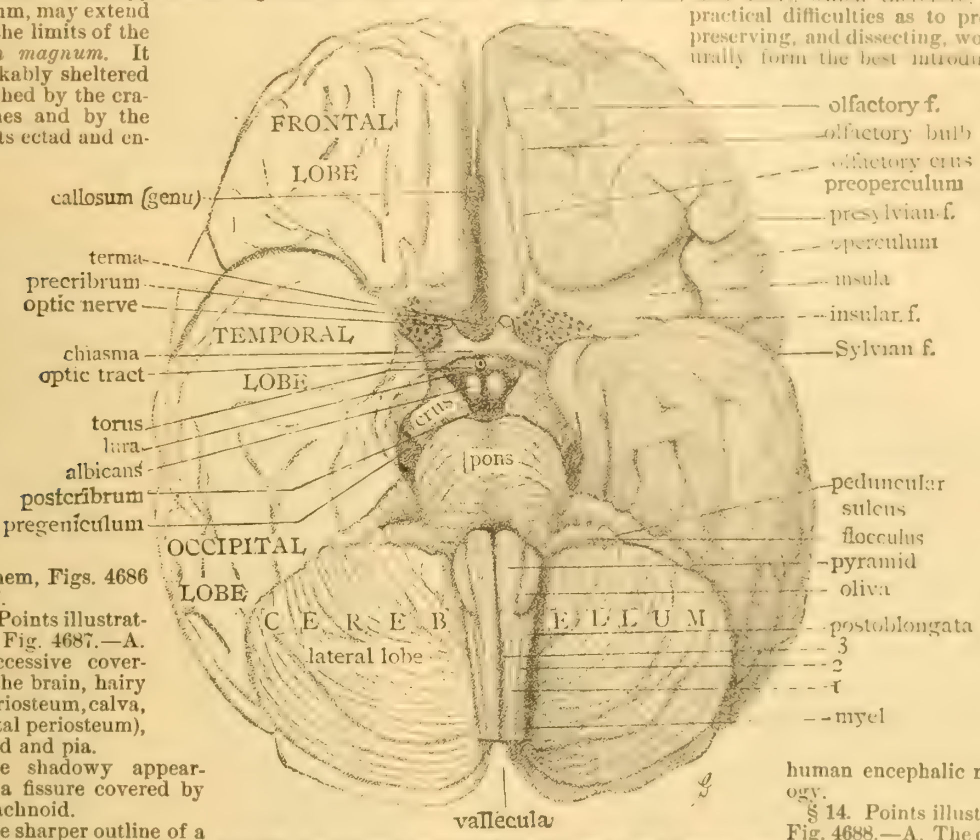

FIG. 4689. Base (Ventral Aspect) of the Brain. From Henle, Edinger, and nature; × .7. 1, Ventral ("anterior") column; 2, line between the ventral and lateral column; 3, ventrimesal fissure.

Preparation.—The cerebellum has been allowed to fall dorsad by its own weight; thereby the occipital lobes are divaricated somewhat, the encephalic curvature is reduced, and the crura are more fully exposed. The hypophysis and infundibulum have been severed from the torus, and the pia removed, together with the cranial nerve roots, excepting the optic. The right olfactory crus has been divided near its attachment. On the left the operculums are divaricated somewhat, so as to expose the ventro-lateral aspect of the insula.

Defects.—As may be seen from profile views of the brain (Figs. 4684 and 4711), in the natural condition of the organ the pons and the chiasma are nearly in contact, and the intervening region, crura, etc., is practically invisible; the ventral surface of the metepencephal also forms little more than a right angle with that of the prosodiencephal; consequently in a direct view of either region the other is greatly foreshortened, and even the equal division of the obliquity between them shows neither to advantage. The fresh or imperfectly preserved brain, when resting upon the dorsal aspect, will, however, straighten itself, as it is commonly represented. To include so large a surface within a figure of moderate size certain details must be inadequately presented or omitted altogether. For enlarged views and descriptions of special regions see the following figures: Postoblongata and pons, 4712 and 4720; crura and hypophysis, 4712 and 4728; cerebellum, 4717 and 4720; frontal lobe, 4752; entire hemicerebrum, 4770; cranial nerves, 4712. The fissures in the present figure, substantially as given by Henle, need not be regarded as signifying anything more than the general aspect of the cerebrum.

§ 11. Points illustrated upon Fig. 4687.—A. The successive coverings of the brain, hairy scalp, periosteum, calva, dura (ental periosteum), arachnoid and pia.

B. The shadowy appearance of a fissure covered by the piarachnoid.

C. The sharper outline of a fissure when the piarachnoid is removed.

D. The difficulty of separating the arachnoid from the pia; in a transection of a fissure, however, the former will be seen to pass across the fissure from gyre to gyre, while the latter, with blood-vessels, dips into the fissure as a fold.

E. The presence on the ental surface of the piarachnoid of a pial fold, the *ruga.*

F. The minutely punctate aspect of the depiated cortex by reason of the extraction of minute vessels entering from the pia. The ental surface of the pia, here represented smooth, should have a flocculent appearance, called *tomentum,* from the attachment of these vessels.

§ 12. Prop. V. The fundamental morphological idea of the brain is that it consists of a *series of segments,* comparable, although not, probably, strictly equivalent. The development (Vol. I., p. 636) and comparative anatomy of the organ can hardly be treated upon any other basis; it is recognized in the discussion of encephalic physiology and of psychology, and the descriptive anatomy of the organ is most conveniently based thereon.

§ 13. Prop. VI. The *segmental constitution* of the brain is invisible from the dorsal aspect (Fig. 4688), hardly suggested when the cerebellum as well as the cerebrum is in view; more obvious from the lateral aspect (Fig. 4715); still more so from the ventral side (Fig. 4689), clearer still from the mesal aspect (Figs. 4684, 4711, and 4718), and unmistakable with early embryos (Figs. 4690, 4693, and 4697), which therefore, but for practical difficulties as to procuring, preserving, and dissecting, would naturally form the best introduction to human encephalic morphology.

§ 14. Points illustrated by Fig. 4688.—A. The complete absence of any appearance of segmentation, all other regions being concealed from view by the preponderating cerebrum.

B. The division of the cerebrum into two approximately symmetrical halves, the hemicerebrums ("cerebral hemispheres") by a deep fissure, the intercerebral or "great longitudinal."

C. The general form of the cerebrum, and the extent of its fissuration in a highly educated man.

D. The lack of exact symmetry even with such principal fissures as the central (just cephalad of which on the right side is an *r*), and the occipital (deep indentations near the caudal end

§ 15. Points illustrated upon Fig 4689. A. The enormous preponderance of the visible parts of the prosencephal and epencephal over the other segments, thereby occasioning the not unnatural though very unphilosophical division of the entire brain into cerebrum (cerebrum proper, olfactory bulbs, and thalami) and cerebellum (with pons and postoblongata), the intervening narrow mesencephal being regarded as an isthmus merely.

From the morphological standpoint, however, the statement would be nearly reversed. The mesencephal is at one period the most prominent and distinct region; the cerebellum may be characterized as an hypertrophied bridge over the "fourth ventricle," and there are some grounds for regarding the olfactory bulbs as primary, and the cerebral hemispheres as their secondary appendages. See the writer's paper, "The Dipnoan Brain," *American Naturalist*, June, 1887.

B. The expansion of the cerebrum beyond all other parts of the brain, the occipital lobes overlapping the cerebellum even when the latter is allowed to displace the former. For the relations of these parts to the anthropoid apes, see the writer's paper in the *American Association, Proceedings*, 1884, p. 424.

C. The absence of visible indication of the pyramid decussation; although this feature is commonly included, as in Fig. 4715, it is the exception rather than the rule in the writer's preparations, and is therefore omitted in this general view.

D. The overlap of the temporal lobe over the optic tract, as shown by the two interrupted curved lines on the right.

§ 16. Prop. VII. *The encephalic flexures.*—These are described in the article Development of the Brain (Vol. I., p. 668) as three, the cranial, the pons, and the neck. The second and third are temporary in man, respectively indicating the junction of the "myel" with the postoblongata and of the latter with the preoblongata. The cranial or mesencephalic flexure is a permanent feature of the human brain, as shown in Figs. 4684 and 4711. There is, in addition, a flexure, likewise permanent, at the diencephal, so that the prosencephal is dorsal instead of cephalad of it; this occurs in man and other Mammals and in Birds and Reptiles, but with Amphibia and "fishes" the prosocele and diacele are on approximately the same level; see the writer's paper, *American Association, Proceedings*, 1887, pp. 250, 251, and *American Naturalist*, October, 1887, pp. 914–917.

The relative positions of the several encephalic flexures although not their relative sharpness or the length of the intervening parts of the brain may be indicated to the eye approximately by a capital **W**, with an oblique line (half of a **V**) for the myel. In the accompanying diagram the three flexures commonly named are indicated by the words Cranial, Pons and Neck. Pr. stands for the prosencephalic region, and D for the diencephalic flexure.

§ 17. Points illustrated upon Fig. 4690.—A. The great relative bulk of the head, constituting about one-half of the entire body.

B. The indication of encephalic segmentation by slight furrows, represented by the converging lines upon the side of the head.

C. The prominence of the prosencephal at this period, forming the "top" of the head.

D. The sharpness of the cranial flexure, whereby two of the segments appear as a dorsal series, and two as a ventral, while the fifth appears partly in both series, as shown by Figs. 4690 and 4692.

E. The conditions of the eye and ear; the greater differentiation of the manus than of the pes; the presence of a short but distinct tail.

§ 18. Points illustrated upon Fig. 4691.—A. The continuation of the myelocele ("central canal") even to the root of the tail.

B. The sudden and great expansion to constitute the metacele ("fourth ventricle").

C. The marked constriction between the mesocele and the epicele.

D. The existence, on the contrary, of the greatest width of the metepicele opposite the ventral transverse furrow which is regarded by the writer as demarcating the cephalic portion (epicele) from the caudal (metacele).

E. The distinctness of that transverse depression of the floor. With some human embryos of this and later stages there is a marked flexion (the pons flexure) of this entire region, at about the middle of its length, so that the two segments are easily distinguished.

§ 19. Points illustrated upon Fig. 4692.—A. The greater width of the mesocele than of the diacele, so that the latter might be described as merely a passage between the former and the prosocele.

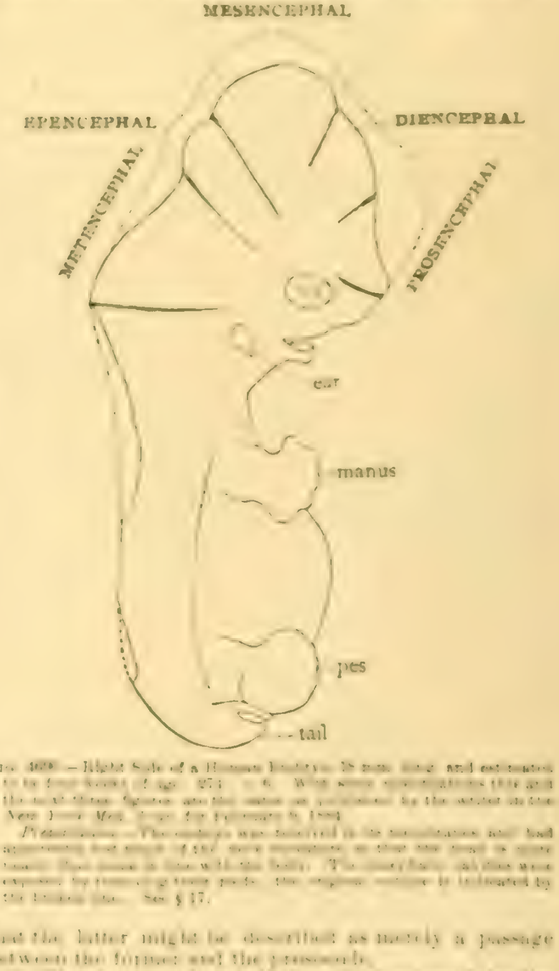

Fig. 4690.—Right Side of a Human Embryo 28 mm. long, and estimated to be four weeks of age. (27.) × 6. With some modifications this and the next three figures are the same as published by the writer in the New York Med. Jour. for February 9, 1884.

Preparation.—The embryo was hardened in [illegible] and had apparently lost [illegible] so that the head is more nearly than usual in line with the body. The encephalic cavities were exposed by removing these parts; the original outline is indicated by the broken line. See § 17.

B. The absence of any distinct thickening of the diacelian walls to indicate the formation of the thalami.

C. The mesal depression in the diacelian floor, probably representing the infundibulum.

D. The lateral extension of the paraceles, the cavities of the future hemicerebrums.

E. The presence of an elevation of the paracelian floor, probably representing the caudatum.

F. The continuity of the cavities at the junction of the prosencephal with the diencephal, and the absence of any indication of plexal intrusion at this period.

§ 20. Prop. VIII. *Normalization.*—This term is used to include all processes by which modified or morphologically abnormal forms and relations may be restored, either actually or ideally, to their known primitive and presumed normal conditions. *Rectification* would have nearly the same significance; it denotes the reduction of complex structures to simple, of irregular to regular, of crooked to straight, and of rough to plain. Examples of this process are the representation of the segments as subequal in size and on the same plane (Figs. 4693, 4695, and 4696); the lateral extension of the various outgrowths of the mesal parts (Figs. 4699, 4704, and 4705); the straightening of the medicornu (Fig. 4754); the schematic representation of the fissures (Figs. 4768 and 4769), and the designation of the human geniculums as pre and post rather than external and internal (§ 22, H).

§ 21. Prop. IX. The adult human brain presents great and perhaps peculiar departures from the general type as based upon embryology and comparative anatomy, and while anatomically admirable and physiologically nearly perfect, it may fairly be characterized as a morphological monstrosity. Among other general features, the segmentation of the brain is more easily recognized in many lower or more generalized vertebrates, and even in mammals where the cerebrum is less preponderant than in man; Figs. 4694 and 4698.

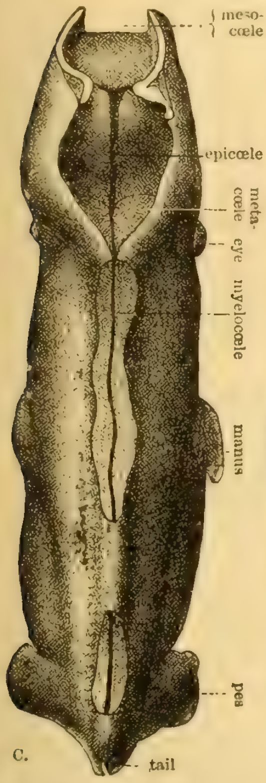

Fig. 4691.—Dorsal Aspect of the Embryo shown in Fig. 4690. 274; × 6. This and the three following figures are too deeply shaded. See § 18.

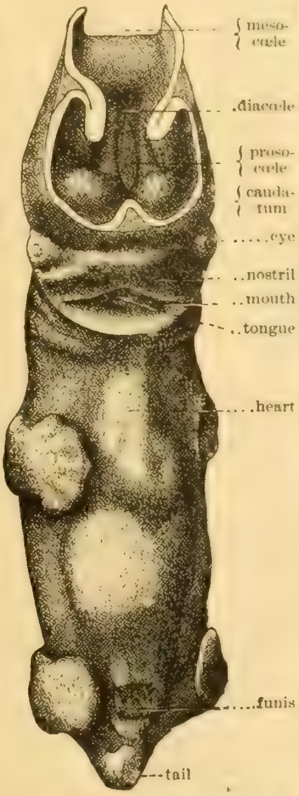

Fig. 4692.—Ventral Aspect of the Embryo shown in Figs. 4690, 4691, and 4693. 274; × 6. The left arm has been removed. See § 19.

§ 22. Points illustrated upon Fig. 4694.—A. The greater obviousness of the segmental constitution than with the adult human brain from any point of view.

B. The smaller relative size of the cerebrum than in man or the cat (Fig. 4698).

C. The much less extent of the callosum than in man or the cat, making it possible to uncover the diencephal without the medisection required in the cat (Fig. 4698).

D. The presence of a distinct roof of the diacœle, the interthalamic space, notwithstanding the cerebrum has been removed.

E. The relation of this roof, the diatela, to the habenas, the ridges demarcating the dorsal and ectocœlian from the mesal or entocœlian surfaces of the thalami.

F. The non-adhesion of the thalamus to the hemicerebrum in any way such as to indicate that the former enters into the composition of the paracœlian floor.

G. The less extension of the caudatum at the side of the thalamus, which so gravely modifies and complicates the segmental relations in man.

H. The less projection of the pregeniculum laterad of the postgeniculum, so that they present much more nearly than in man their proper relations of cephalic and caudal elevations of the diencephal.

I. The slightness of the transverse furrow between the pregeminum and postgeminum.

J. The more nearly equal size of the lateral and mesal (vermis) lobes of the cerebellum, and the concomitant absence of the vallecula, which is so obvious on the caudal aspect of the adult human cerebellum (Figs. 4689 and 4717).

§ 23. Prop. X. The recognition of the brain as a segmented organ is not dependent upon the determination of the exact number of segments, their equivalency, or their boundaries. It is quite probable, for example, that the postoblongata represents two or more *potential* segments or neuromeres, but practically it may be regarded as single.

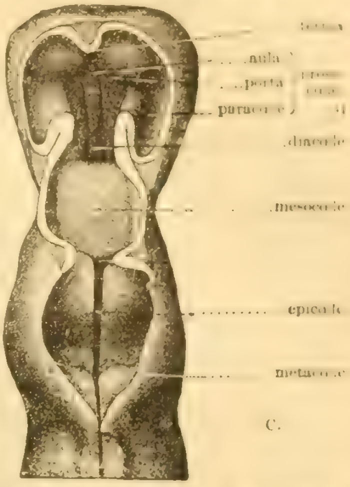

Fig. 4693.—The Entire Series of Encephalic Cavities of the Embryo shown in Figs. 4690–4692 Represented upon One Plane. This figure is a combination of parts of Figs. 4691 and 4692, as if the encephalic curvature were obliterated. This ideal straightening, a form of normalization (§ 20), may be illustrated as follows: Flex the index finger upon itself as far as possible; let the nail represent the prosocœle, the knuckle the metepicœle, and the prominent middle joint the mesocœle; from either the dorsal or palmar aspect only part of the convex surfaces are visible; but if the finger be extended all fall into one view. The object of this figure is to enable a comparison to be made between the encephalic cavities of this early embryo and those of the adult cat as shown in Fig. 4710. The differences are much greater in appearance than in reality, consisting mainly in the reduction of most of the cavities; the thickening of most of the parietes; the great and irregular extension of the lateral masses, hemicerebrums, containing the paracœles ("lateral ventricles").

§ 24. Prop. XI. Among living anatomists there is a very general, though not universal, admission of *five, definitive, encephalic segments*, represented respectively

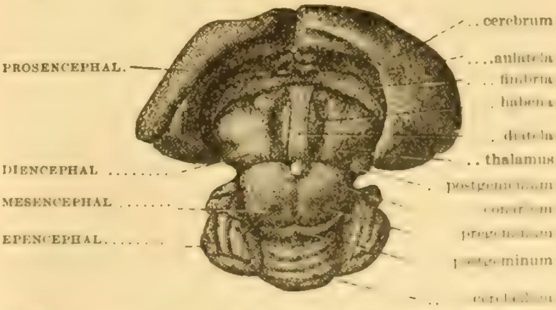

Fig. 4694. Dorsal Aspect of the Brain of a Young Rabbit, the Cerebrum and Cerebellum Pushed in Opposite Directions.

Preparation.—While fresh, the cerebellum was [illegible] caudad and the hemispheres cephalad, and the velum removed; the brain was then placed in strong alcohol so as to retain the [illegible] shape. The segmental names are at the left, the names of particular parts at the right. The specimen has been lost or destroyed.

[illegible]*

§ 25. Prop. XII. The chief differences of opinion respecting the number of these segments and their designations are indicated in the following Table:

Table of the Names of the Encephalic Segments, with their Principal Synonyms.

I. [illegible]	II. [illegible]	III. [illegible]	IV. [illegible]	V. [illegible]	VI. [illegible]	VII. [illegible]	VIII. [illegible]	IX. Fol (1884).	X. Rabl-Rückhard (1884).	XI. Haeckel [illegible]
Prosencephal	[illegible]	[illegible]	Forebrain	[illegible]	Prosen.	Prosen.	Prosen. (in part)	Prosen.	[illegible]	Proto-psyche
Diencephal	[illegible]	Thalamencephalon	[illegible]	[illegible]	Mesen. (in part)	[illegible]	Prosen. (in part)	[illegible]	[illegible]	Deuto-psyche
Mesencephal	[illegible]	[illegible]	Midbrain	[illegible]	Mesen. (in part)	Mesen.	Mesen.	Mesen.	Mesen.	Meso-psyche
Epencephal	[illegible]	[illegible]	Hindbrain	[illegible]	[illegible] (in part)	[illegible]	[illegible] (in part)	Epen.	[illegible]	Meta-psyche
Metencephal	[illegible]	[illegible]	Afterbrain	[illegible]	[illegible] (in part)	[illegible]	[illegible] (in part)	[illegible]	[illegible]	Epi-psyche

§ 26. *Commentary on the tabular arrangement of the names of the encephalic segments.*—The order of the columns is not chronological, and is determined by various considerations. In VI.–X. the components of encephalon, where they occur, are abridged by the dropping of the last three syllables.

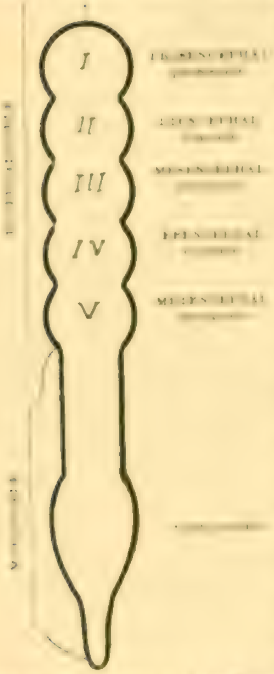

Fig. 4695.—[illegible]

With unimportant differences this table was published in the *New York Medical Journal*, March 28, 1885, and in "Anatomical Technology," 1886.

I. No originality is claimed for these terms. Aside from their terminations (which are English instead of Latin, after the analogy of many terms, *e.g.*) they are identical with those of Quain, excepting that *diencephalon* is preferred to *thalamencephalon*, both because it is shorter and because the prefix is readily compounded with words giving *diacœle*, *diaplexus*, *diatela*, *diaterma*, etc. *Diencephalon* is given (Quain, ii., 828) as a synonym of *thalamencephalon*, and it is adopted in the recent paper of H. F. Osborn (*Journal of Morphology*, II, No. 1).

VI. Owen seems to be alone in regarding the mesencephal as including the thalami (I., 277 [illegible] 97, 102).

IX. Fol's [illegible] and [illegible] present no advantages over the terms here employed.

X. Rabl-Rückhard does not actually use the term [illegible], but it seems to be the logical alternative of his [illegible].

XI. Aside from the unsuitable substitution of a metaphysical term for the anatomical ones, Haeckel has caused needless confusion by transposing the commonly accepted Greek equivalents for *Vorder* and *Nach*.

§ 27. Commentary on Fig. 4695.—A. The myel is made to be longer than the brain; the expansion near its caudal end is well marked in birds and some other vertebrates.

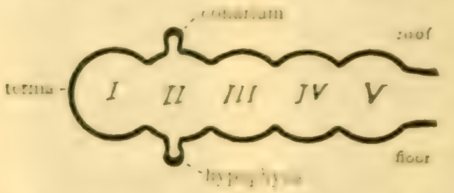

Fig. 4696.—Diagram of the [illegible] Brain, as it were the Mesal [illegible] of the Right Half of Fig. 4695. [illegible] See § 14.

B. The five divisions of the encephalocœle are made of equal size, not because they actually are so at any particular period of development, but because, as the writer understands it, each vesicle is at some period as large as any other vesicle has been at some (not usually the same) period.

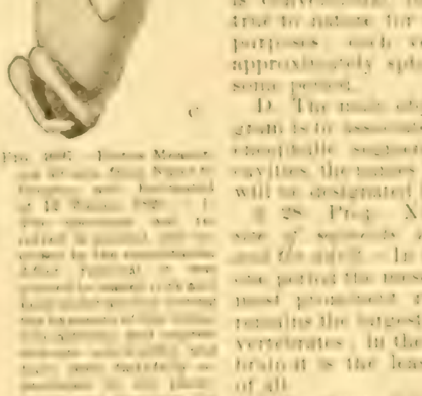

Fig. 4697.—[illegible]

C. The form adopted is conventional, but sufficiently true to nature for diagrammatic purposes; each vesicle has an approximately spherical form at some period.

D. The main object of the diagram is to associate with the five encephalic segments and their cavities the names by which they will be designated in this article.

§ 28. Prop. XIII. *Relative size of segments in the embryo and the adult.*—In the embryo at one period the mesencephal is the most prominent region, and it remains the largest in some lower vertebrates; in the adult human brain it is the least conspicuous of all.

§ 29. Prop. XIV. *Segmental inequality.*—Although originally subequal in size, certain segments early manifest a tendency to extend beyond their neighbors in one or more directions. In man and the mammals generally this overlapping is in inverse ratio to the original size of the parts. The mesencephal, at one period most prominent, is encroached upon by the diencephal at the sides, by the pons ventrad, the cerebellum dorsad, and all are eventually covered by the cerebrum, primarily a comparatively insignificant portion of the brain.

---

* [illegible]

§ 30. Points illustrated upon Fig. 4697.—A. The general form of the body and limbs at this period.

B. The visibility of all the encephalic segments, excepting the diencephal; even this may be regarded as represented by the optic nerve, dimly seen through the indentation at the ventral margin of the cerebrum.

C. The marked preponderance of the cerebrum.

D. The absence of any lateral fissures excepting the Sylvian fossa; compare, however, the right hemicerebrum, as shown in Fig. 4756.

E. The simplicity of the other regions, better shown in Fig. 4756; the cerebellum is a narrow and undivided mass, as in Fig. 4714; the mesencephal presents a slight transverse depression between the pregeminum and postgeminum.

§ 31. Prop. XV. This segmental overlapping is, upon the whole, greater caudad than cephalad, most of the segments presenting something like the "rake" of the mast of a ship. The cerebellum, for example, not only extends both cephalad and caudad from its connections with the epencephalic floor, but is tilted distinctly caudad (Figs. 4684, 4711, 4719, and 4721).

§ 32. Points illustrated upon Fig. 4698.—A. The possibility, even with so high a mammal as the cat, of making a preparation that, without disturbing the essential, morphological features of the organ, may exhibit all of the encephalic segments, in part at least, excepting the last, the metencephal.

B. The tendency of three of the encephalic segments to overlap those caudad of them. The cerebellum, the epencephalic roof, partly conceals the postoblongata, metencephal, in its natural attitude; in the present figure it is tilted caudad. The mesencephal (geminal or optic lobes) is covered partly by the cerebellum and partly by the cerebrum, and also at the sides overlapped somewhat by the postgeniculums, elements of the diencephal; in the figure these bodies are in deep shadow, crossed by the line 3 on the right, and on the left by the line leading to the postgeminum. Finally, the cerebrum conceals the diencephal and mesencephal, and even the cephalic slope of the cerebellum in the cat, while in man it alone is visible when the brain is viewed from the dorsal aspect.

C. The relations of the callosum and fornicommissure to the two hemicerebrums, as lines of secondary adhesion between the two, the one dorsal and the other ventral.

D. That the triangular area, hemiseptum, is really only a portion of the mesal wall of either hemicerebrum, which has been intercepted between the two lines of junction above named.

E. That the interval, pseudocœle ("fifth ventricle") between the two hemiseptums, has no connection with the true encephalic cavities.

F. That the callosum and fornix are in no sense parts of the roof of the diacœle (third ventricle): this is constituted by (1) its proper endyma, (2) the pia covering this, as all other parts of the brain, (3) the pia pertaining to the fornix, which, with the layer (2) and the intervening vessels, constitutes the velum.

G. Incidentally it may be remarked that the cruciate fissure in cats and dogs constitutes, as it were, a gash across the mesal margin near the cephalic end of the hemicerebrum; it appears, therefore, upon both the mesal and the dorso-lateral aspects; the well-known and easily-experimented upon motor areas of the limbs occupy the U-shaped gyre between the cruciate and coronal fissures. It does not follow, however, that the cruciate fissure and the human central fissure are homologous.

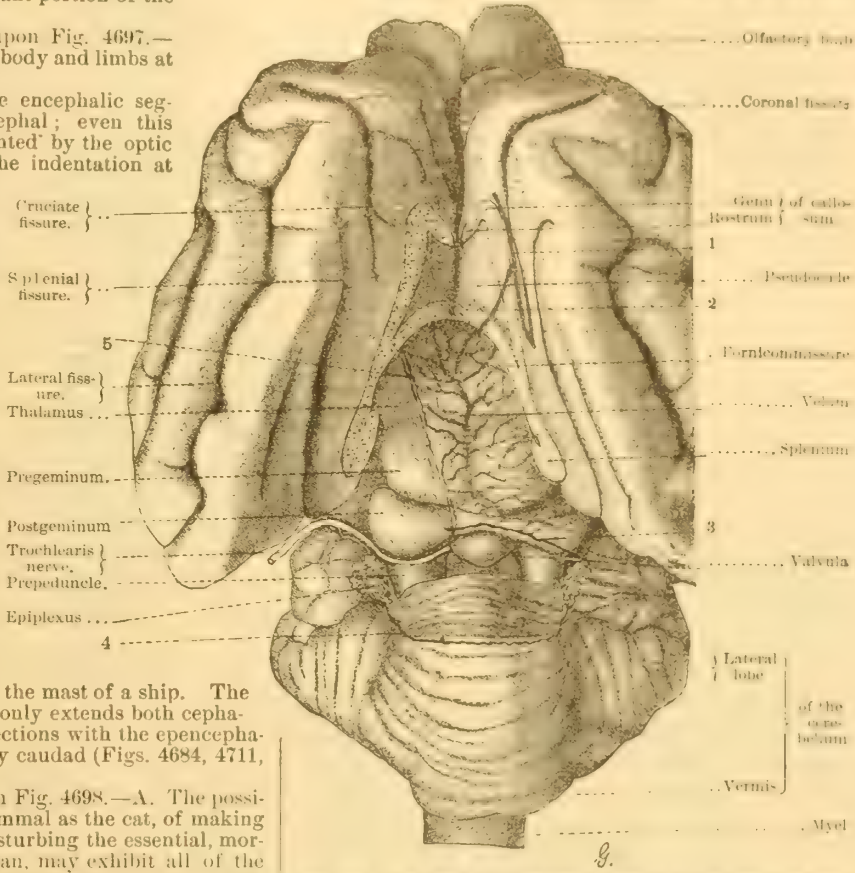

FIG. 4698.—The Brain of a Cat from the Dorsal Aspect, after the Callosum and Fornix had been Divided and the Hemicerebrums Divaricated. 4/4 : 2. 1, Artery (precerebral ?); 2, artery joining 1, perforating the callosum from the velum; 3, 4, lines of division of the arachnoid, between the cerebrum and cerebellum; 5, line of division of the velum, which is partly removed on the left side so as to expose the thalamus and gemina of that side. See § 32.

Preparation.—While fresh and supported by the *basis cranii*, the hemicerebrums were carefully separated so as to expose the callosum; this was divided, beginning with the splenium, then the fornicommissure until the incision reached the point of attachment of the velum. The cerebellum was tilted caudad and the arachnoid between it and the postgeminum divided; the cerebellar edge of the arachnoid is represented by the line 5. The cephalic part of the valvula is shown as if inflated with air. On the left side, along a line (5) extending obliquely caudo-mesad from under the margin of the fornicommissure, the two layers of pia constituting the velum were divided, and the part at the left removed so as to expose more distinctly the postgeminum, pregeminum, and thalamus. The cerebral pia was removed.

Defects.—The arteries should have been injected with a red mass, for the better exposition of the pia, the plexuses, and especially the mesal artery (2) which penetrates the callosum. No attempt has been made to show the lines of reflection of the arachnoid between the two hemicerebrums, along a line corresponding with the ventral margin of the falx and indicated approximately in the [illegible]. The fornicommissure is represented too thick at a [illegible]. The trochlearis nerve (N. iv.) stops too sharply at the margin of the valvula, from which it arises. The convexity of the [illegible] is too sharply defined. A similar preparation of the human brain would be desirable, but extremely difficult to make, on account of the weight of the hemicerebrums.

§ 33. Prop. XVI. The relations of the prosencephal in the diencephal are further complicated by the intimate fusion of the crura of the latter (thalami) with the fibers of the former (consulstriata). Although, therefore, in the early embryonic stages (Fig. 4692), it is very easy to distinguish between the two segments, there is some difficulty in the adult. For convenience, in the present article, the capsula ("internal capsule") is adopted provisionally as the boundary so far as regards the thalamus and the lenticula (part of the striatum); but the same [illegible] relation [illegible] between the [illegible] and the caudatum, [illegible] prosencephalic parts, and the whole subject requires further elucidation.

§ 34. Prop. XVII. Transections at any level crosswise of the brain usually affect two or more segments. This is illustrated in the following diagrams (Fig. 4699).

FIG. 4699.—Diagrams Illustrating the Lateral Overlapping of the Mesencephal [illegible]

§ 35. Prop. XVIII. Potential triplicity of the encephalic segments.—Although primarily mesal and simple, each segment excepting the last* (metencephal) presents at some period and in some vertebrates a distinctly threefold condition with one mesal and two lateral portions. The prosencephalic triplicity is exhibited in all air-breathing vertebrates and some aquatic forms (Dipnoans, etc.); with birds and frogs the mesencephal is markedly tripartite (Fig. 4700); with man and other mammals, and likewise with some other vertebrates, the epicoele presents more or less extensive "lateral recesses" parepicoelia (Figs. 4702, 4704, and 4720); finally, with most vertebrates whose development has been studied the embryonic diencephal protrudes at either side as optic vesicle that becomes the retina and optic nerve (Figs. 4704 and 4703).

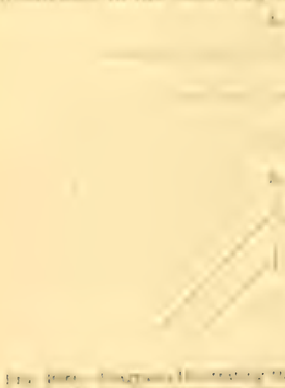

FIG. 4700.—Brain of Frog [illegible]

§ 36. Points illustrated upon Fig. 4702.—A. The effect of the cranial flexure, the two segments, prosencephal and [illegible], with their cavities, appearing upon the same section surface.

B. The triplicity of the epicoele, consisting as it does of a mesal portion and two lateral extensions, the lateral recesses (parepicoelia).

C. The embryonic continuity of the endyma and more substantial elements of the parietes around the lateral recesses which are almost invariably torn open in the removal or manipulation of the brain (see Fig. 4720).

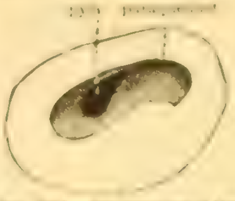

FIG. 4701.—[illegible]

D. The corrugation of the thin portion of the parepicoelian parietes preparatory to the formation of the epiplexus.

§ 37. Points illustrated upon Fig. 4703.—A. The continuity, general form, and relative size of the several divisions of the adult human encephalocoele, as viewed obliquely from the ventro-dextral aspect.

B. The obvious triplicity of the prosocoele and the existence of lateral extensions of the epicoele.

C. The slenderness of the mesocoele as compared with its relative size in the embryo (Fig. 4690) and in the adults of some other vertebrates (Fig. 4701).

D. The general modifications of the primitive and typical condition of the encephalic cavity which led the older anatomists, and still lead some of their modern successors, to regard the whole as comprising four "ventricles," a first and second (lateral), a "third," and a "fourth," the aula being ignored and the mesocoele considered merely as a "passage from the third ventricle to the fourth."

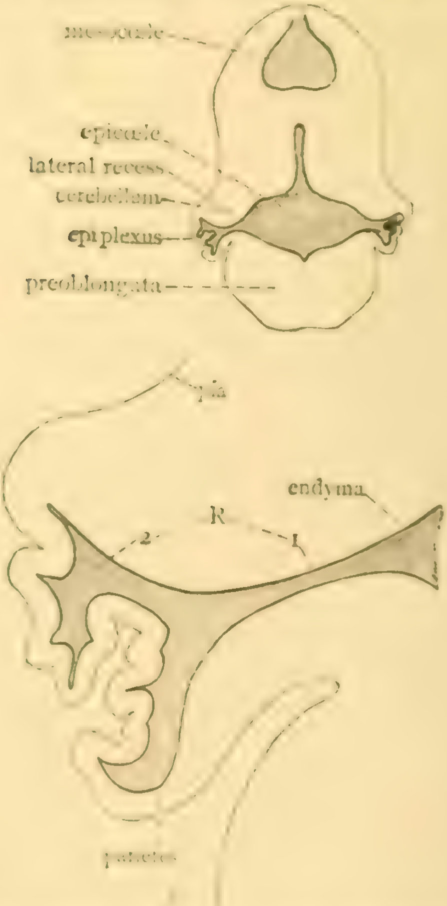

FIG. 4702.—Transection of the Head of an Embryo Rabbit, Sixteen Days [illegible]. Upper figure × [illegible]; lower, × [illegible], enlargement of part of the upper.

---

* [illegible]

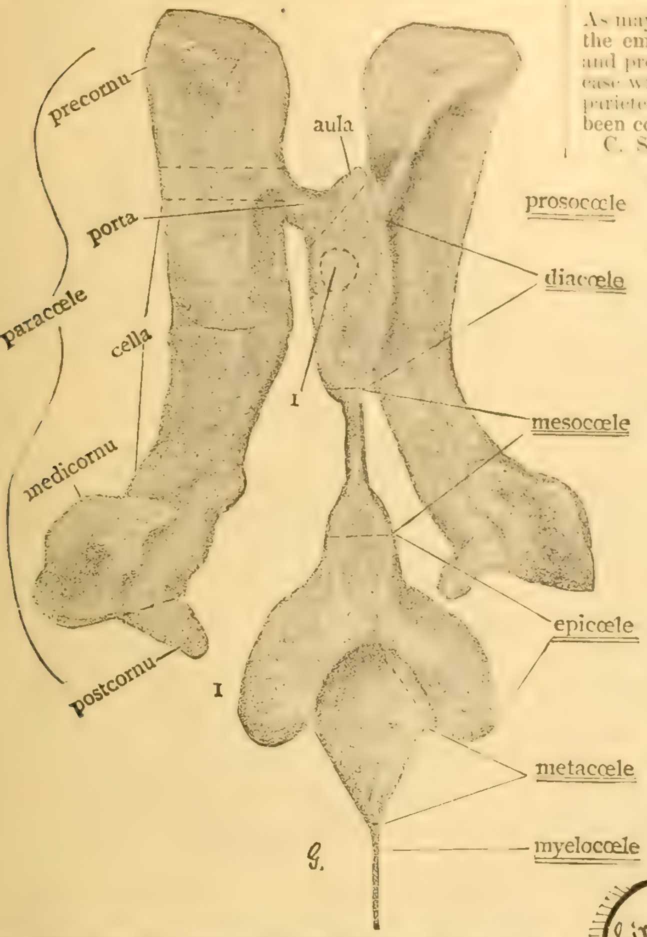

FIG. 4703.—Cast of the Encephalic Cavities, Ventral Aspect : approximately correct. · 1 (?). From Weisker, modified. The names at the right, doubly underlined, designate the five divisions of the encephalocœle, together with the slender myelocœle (central canal of the spinal cord). The metacœle and epicœle together constitute the "fourth ventricle" of the text-books; the mesocœle corresponds to the aqueduct or iter ; the diacœle equals the "third ventricle" less the aula, which is the mesal part of the prosocœle ; prosocœle includes all not already specified, viz., the mesal aula, the lateral paracœles ("lateral ventricles") and the two portas through which they are continuous. The names at the left designate the parts of the paracœle, viz., the cella, extending caudad from the porta ; the precornu, extending cephalad ; the medicornu, extending in a spiral direction laterad, ventrad, cephalad, and mesad, successively ; and the postcornu projecting caudad from the cella. I is placed near the top of the right lateral recess of the epicœle. The larger part of the figure is modified from a photograph of the wax model made by Weisker, of Freiburg ; the metacœle, myelocœle, and part of the epicœle are from a cast of the cavities in a child. The ventral aspect was chosen in order to display to better advantage the uninterrupted series of mesal cavities, and the portas.

Defects.—The writer doubts whether any part represents the corresponding cavity accurately. The portas are too long ; compare Fig. 4741. The diacœle presents neither the orifice for the medicommissure (the presumed location of which is indicated by the dotted circle (2) just caudad of the portas) nor the marked ventral extension toward the hypophysis. The medicornua are not sufficiently curved ; in reality the extremity of each approaches the diacœle within about 2.5 ctm.; the postcornua are too short ; the boundaries of the epicœle are vaguely and perhaps incorrectly indicated.

§ 38. Prop. XIX. Commentary on Fig. 4704.—A. As stated above, this diagram must be regarded as the expression of the writer's present morphological ideas respecting the brain as a series of mesal segments, with or without lateral extensions. These ideas may or may not be sound, but the facts upon which they are based belong to the common stock of knowledge, and need be but briefly stated here.

B. In all mammals where they have been looked for, and in some other vertebrates (probably in most) there extends latero-ventrad from the "fourth ventricle" a recess which is commonly described as open at the end. As may be seen from Fig. 4702, it is certainly closed in the embryo ; it is closed in an alinjected shark's brain, and probably the common idea respecting it is due to the ease with which, in the adult mammal, its membranous parietes are torn in the removal of the brain. They have been compared by Burdach to the "lateral ventricles."

C. Some adult human brains present a slight groove at each side of the aqueduct, the contracted mesocœle ; with frogs, some Reptiles, and all Birds, the mesencephalic cavity is distinctly tripartite, with distinct and considerable cavities (paraqueducts) in the lateral lobes (Fig. 4700).

§ 39. Points illustrated by Fig. 4706.—A. The communication of the paracœle (lateral ventricle) with the mesal series of encephalic cavities solely through the porta ("Foramen of Monro").

B. The reduction in size of the aula, the mesal division of the prosocœle, relatively to the diacœle, and to the prosocœlian lateral extensions, the paracœles.

C. The location, in man and other mammals, of the aula at the dorso-cephalic side of the diacœle, instead of directly cephalad as in Amphibia ; see § 16.

D. The concomitant change in the direction of the diacœlian and prosocœlian floors ; instead of cephalo-caudal, their direction is more or less nearly dorso-ventral.

E. The crowding of the conarium caudad by the overlying cerebrum ; the conarium and hypophysis are retained in the figure, however, mainly as landmarks.

F. The relation of the rima (essential part of the "great transverse fissure") to the porta. The line along the meso-ventral aspect of the hemicerebrum represents a narrow tract where the paracœlian parietes are reduced to the lining endyma and the covering pia, and where the latter,

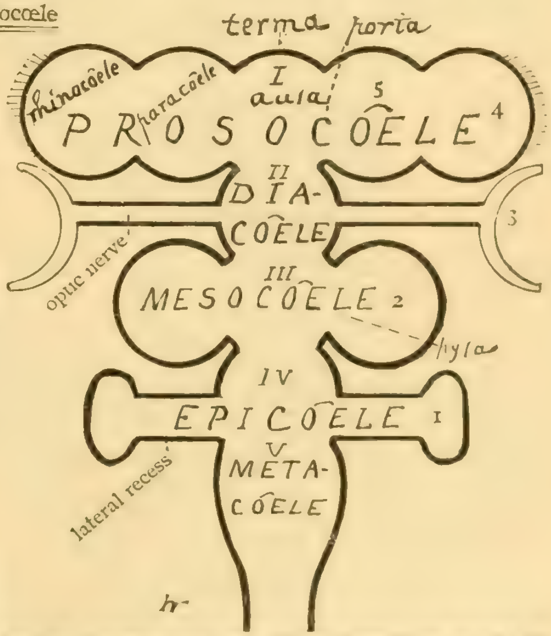

FIG. 4704.—Diagram Exhibiting the Writer's Present Ideas respecting the Relations of the Lateral Extensions of the Encephalocœle. The Roman numerals, as in Fig. 4695, designate the five encephalic vesicles, and *not the "ventricles."* 1, "Lateral recess" parepicœle; 2, "optic ventricle" (paraqueduct), optocœle of "Anatomical Technology"; 3, the optic nerve and retina, formed originally (see Vol. I., Fig. 509) as the "optic vesicle," an outgrowth of the diencephalic vesicle prior to the formation of the "cerebral vesicle"; 4, the rhinocœle or cavity of the olfactory bulb; 5, the paracœle or "lateral ventricle" proper, the cavity of either hemicerebrum, communicating through the porta ("Foramen of Monro") with the aula or mesal division of the prosocœle, and thus only through it with the caudal portions of the encephalocœle.

or its vessels) intrudes into the paracœle, still covered, however, by the endyma. The rima always begins at the margin of the porta, and extends in man to near the tip of the medicornu; see § 113 and Figs. 4748 and 4757.

(f) The secondary and morphologically unessential nature of the [illegible] thalami, the enormous thickening of the thalamus, the lateral wall of the diacœle and of the [illegible], the floor and [illegible] of the paracœle. This feature of the mammalian brain, which is very confusing and not altogether easy to describe, may be learned by a diagram like the above, where the parietes are represented of nearly uniform thickness, as in the embryo and in adult [illegible].

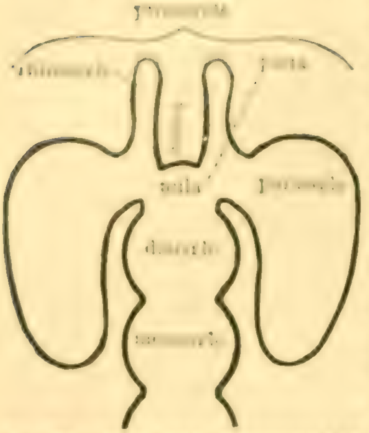

FIG. 4705.—Diagram of the Prosocœle and [illegible] Adjoining Cavities, from the Dorsal (or Ventral) Aspect.

§ 40. Prop. XX. The cavity commonly called "third ventricle" really represents the mesal portions of the cavities of two segments. The larger is the interval between the thalami, surrounding the medicommissure and extending ventrad to the tuber; this is the diacœle. The smaller is the mesal portion of the prosocœle, and connects at either side through the porta with the lateral division of the prosocœle, the paracœle; this mesal part, bounded laterally by the portas, cephalad by the fornicolumns and præcommissure, and limited caudad by the cephalic margins of the thalami and ventrad by the ventral ends of the portas, has been called aula by the writer since 1878 for the sake of indicating his estimate of its morphological significance; in some lower vertebrates it is much larger than in man.

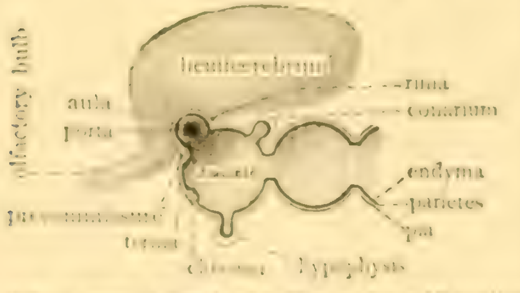

FIG. 4706.—Diagrammatic Vertical Section of the Prosencephal and Thalamencephal [illegible] the Hemicerebrum; corresponding to the right half of Fig. 4705, seen from the mesal aspect. (See § 40.)

§ 41. Prop. XXI. The porta ("Foramen of Monro") is an orifice at either side of the aula connecting it with the paracœle ("lateral ventricle"). It is a constant and essential feature of every brain since the distinctly tripartite condition of the prosencephal segment. It has only a secondary relation with the rima and should not be confounded with it. The porta is completely circumscribed, its dorsal limit being as definite and its dorsal wall as [illegible], though less substantial than the ventral (see Figs. 4741, 4742, and 4744).

§ 42. Prop. XXII. The rima (part of the "great transverse fissure") is secondary in development and not constant even where there is a distinct [illegible]. It is a line along the side of the [illegible], beginning at the dorsal end of the porta, where the proper parietes are thinned or wholly obliterated for the intrusion of a pial prolongation (paraplexus). But (1) this plexus fills the space, and (2) the endyma is carried before it, so that there is no true solution of continuity. The only way in which the porta and the rima can become continuous is by the artificial rupture of the membranous attachments.

§ 43. Prop. XXIII. The simplest expression of an encephalic segment is by a short tube comprising (1) a cavity (cœle or "ventricle"); surrounded by its parietes, a [illegible] mass covered by a vascular membrane (pia) and lined by a ciliated epithelium (endyma).

§ 44. Prop. XXIV. In what may be regarded as an approximately typical condition, the parietes consist of three layers or strata, viz., an ental, mainly cellular, adjoining the endyma, the entocinerea ("central tubular gray"); an ectal, mainly cellular, adjoining the pia, the ectocinerea (cortex); and intermediate, fibrous, between the other two, the alba or medulla (see Fig. 4707).

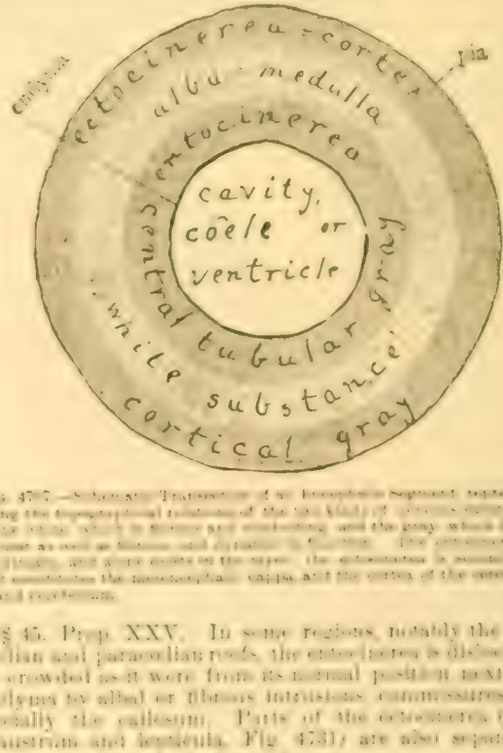

FIG. 4707.—Schematic Transection of an Encephalic Segment, representing the hypothetical relations of the [illegible] kinds of nervous substance, the white, which is fibrous and conducting, and the gray, which is [illegible] as well as fibrous and [illegible] in function. The entocinerea is primary, and [illegible]; the ectocinerea is secondary, [illegible] and the cortex of the cerebrum and [illegible].

§ 45. Prop. XXV. In some regions, notably the epicœlian and paracœlian roofs, the entocinerea is dislocated or crowded as it were from its normal position next the endyma by allied or fibrous intrusions, commissures, especially the callosum. Parts of the ectocinerea (e.g., claustrum and lenticula, Fig. 4731) are also separated more or less completely from the rest.

§ 46. Prop. XXVI. Unequal thickness of the parietes.—In the earliest stages the cœlian parietes are of approximately equal thickness throughout, although it may be, as held by Spitzka, that the roof is never so thick as the floor. With some low or generalized vertebrates—e.g., *Squatina*, a shark (Parker, *Nature*, December 30, 1886); *Menopoma*, a salamander (the writer, *New York Medical Journal*, February 9, 1884, Fig. 16); *Ceratodus*, a Dipnoan (the writer, *American Naturalist*, June, 1887)—this condition prevails throughout life, at least with certain regions; with man, until the fœtus attains a length of at least 6 ctm. and an estimated age of 12 weeks (see Fig. 4708), the hemicerebral parietes are almost uniformly thin; when 24 ctm. long and about 20 weeks old, certain regions are considerably thicker than others, as seen in Fig. 4709; in the adult brain of man, and indeed of mammals generally (Figs. 4710 and 4746), the difference between even closely adjacent portions of the parietes is simply enormous; compare, e.g., the mesencephalic floor (crura) with the caudal part of its roof, valvula (Figs. 4684 and 4711); the two divisions of the epicœlian roof, cerebellum and lingula (Figs. 4684, 4711, and 4719); the diacœlian sides, thalami, with the floor, tuber or terma (Figs. 4684 or 4711); the thin or membranous parts (lamina, terma, pala, etc.) adjoining the rima with the adjoining hippocamp and caudatum (Figs. 4709 and 4751); or the translucent hemiseptum with the mass just cephalad of the precornu (Figs. 4710 and 4746).

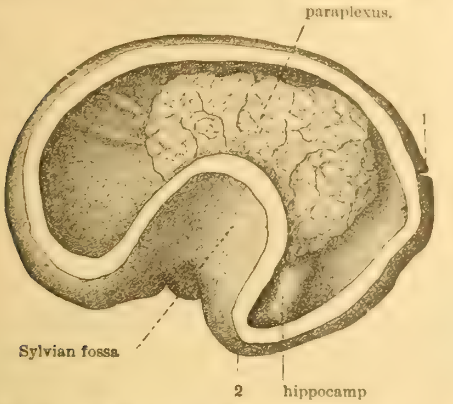

FIG. 4708.—The Hemicerebrum of a Fœtus (Measuring 6 ctm. from Bregma to Heel and Estimated at 12 Weeks) Opened from the Lateral Aspect. 340; × 3. This preparation (really the right hemicerebrum, but reversed in drawing) is figured in the *New York Medical Journal* for February 16, 1884, but unreversed and of half the present size; the length of the fœtus is there given incorrectly as 4 ctm. 1, A fissure, occipital, calcarine or lambdoidal; 2, tip of temporal lobe.

§ 47. Points illustrated by Fig. 4708.—A. The large size of the paracœle and the thinness of the parietes.

B. The nearly uniform thickness of the parietes so far as exposed.

C. The extent of the paraplexus, and its fulness as compared with that in the adult; possibly when fresh it entirely filled the paracœle, but was contracted by the alcohol.

D. The similarity of the precornu and medicornu.

E. The absence of distinct indication of the postcornu, indicating that this may be formed eventually not by a special protrusion caudad but by the thickening of the parietes in such a way as to leave an occipital space of variable size.

F. The commencing formation of the hippocamp as a corrugation of the mesal wall of the medicornu.

G. The non-extension of the paraplexus and thus of the rima to the extremity of the medicornu.

H. The presence of at least one distinct fissure (1), the calcarine, occipital, or lambdoidal.

I. The evidences of some mesal fissures, perhaps transitory, as slight corrugations just cephalad of the plexus.

J. The formation of the Sylvian fossa, with as yet no trace of the insula.

§ 48. Points illustrated by Fig. 4709.—A. The great extent of the paracœles at this period, relatively to the entire cerebrum, and to the mesal part of the prosocœle, the aula.

B. The less difference in the thickness of the parietes than in the adult.

C. The distinct collocation of the hippocamp with the hippocampal fissure.

D. The topographical relation of the Sylvian fossa, the first stage of the Sylvian fissure, to the caudatum.

E. The extension of the postcornu farther caudad of the aula than the precornu extends cephalad.

F. The absence of the insula at this period.

G. The outgrowing margin of the operculum.

H. The depth and peculiar shape of the lambdoidal fissure; See Fig. 4758.

§ 49. Prop. XXVII. *The brain as a house.*—Within certain limits the brain may be likened to an edifice, and the comparison has been carried out in some detail by the writer in "Anatomical Technology" (p. 413). with Schwalbe and others he believes that architectural terms, *floor*, *roof*, *sides*, may be employed appropriately in indicating the general locations of the segmental parts relatively to each other and to the common cavity, and he has proposed two specific terms, *aula* (a hall), and *porta* (a doorway), for the designation of certain portions of the cavity.

§ 50. Prop. XXVIII. *Irregularities of contour.*—In the brain straight lines and plane surfaces are infrequent, and the spiral form is not uncommon; hence dissections are often more instructive than mechanical sections, and normalization, actual or ideal (§ 20), is sometimes desirable.

§ 51. Prop. XXIX. *Commissures, etc.*—Of the parts connecting lateral masses across the meson, whether cellular or fibrous, whether direct (true commissures) or oblique (decussations), some are merely specializations of pre-existing floors or roofs; *e.g.*, precommissure, postcommissure, supracommissure, pons; others, the callosum and fornicommissure, are either new formations or marked extensions of pre-existing lines or areas of conjunction (Fig. 4757); the medicommissure, finally, as well remarked by Spitzka, is rather a fusion of contiguous surfaces than a commissure in the usual sense of the word.

§ 52. Prop. XXX. *Atrophic parts.*—Certain parts, (terma, hemiseptum, valvula, torus) which are very thin and apparently functionless, nevertheless serve to contain the cœliolymph (cerebro-spinal liquid), and may have a morphological significance as representing parts more

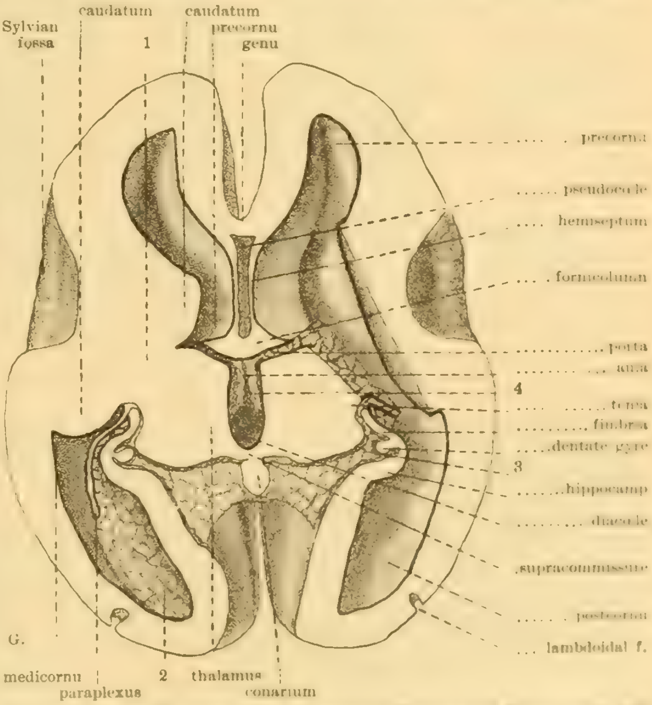

FIG. 4709.—Ventral Exposure of the Prosocœle of a Fœtus about 24 ctm. Long, and Estimated to be 20 Weeks Old. 499; × 1.5. 1, Line of junction between the thalamus and the caudatum; 2, thin extension of the paraplexus into the postcornu; soon after the preparation was made this became detached and was lost; another specimen must be depended upon to show whether or not such extension exists, and in what way it is disposed of in case it be deciduous; 3, hippocampal fissure; 4, diaplexus.

Preparation. The brain was hardened in place by arterial injection; the scalp and calva were removed piecemeal, and the dorsal part of the cerebrum removed by one sweep of the knife under alcohol. The [illegible] at each side as indicated by the heavy line [illegible]. The left caudatum was removed so as to expose the paracœle more completely on that side and make the figure comparable with that of the cat [illegible].

developed in other forms. Two other parts, the conarium (pineal body) and the hypophysis (pituitary body) [illegible], but are not known to have definite functions. Their peculiarities will be considered in connection with the diencephal (§ 114), of which they are appendages.

§ 54. Prop. XXXI. *Riparian parts.*—Along the ripas, or lines of reflection of the endyma upon itself or plexus, the contiguous nervous portions are commonly reduced in thickness, so as to resemble the terma, valvula, and velum in some degree. Such are the ligula and obex at the caudal end of the metacœle; the fimbria along the hippocampal margin of the rima, the tænia along its caudal margin, and the pedicle at its extremity (Figs. 4751, 4756, and 4757); a similar part may probably be recognized with careful inspection along the line of reflection of the endyma from the velum and adjacent lobes of the cerebellum (Figs. 4711, 4717, and 4719).

§ 55. Prop. XXXII. The riparian condition may not be incompatible with distinct and even important functions. The supracommissure (Fig. 4730) and the fornix (Fig. 4726), for example, may be in one sense parts of transition from nonnervous to nervous portions, but they probably, like the fimbria, have some distinct use.

§ 55. Prop. XXXIII. *Marginal tissues.*—The riparian parts mentioned under Prop. XXXI. consist of alba; but with the cerebrum and cerebellum the cortical margins have a special morphological interest, and are but little known. In the depths of the callosal fissure, for example, the cinerea has a rostral margin (Fig. 4736); this is probably continuous caudad over the splenium (Fig. 4764) with the dentate gyre (*fascia dentata* and *fasciola cinerea*) and cephalad over the genu with the prelaminal cortex. Even less known are the ental margins of the cerebellum; the lingula comprises one portion, and of course there is a continuity of cortical edge on either side over the peduncles to the medulla.

§ 56. Prop. XXXIV. Physiologically the intermediate portions of organs are commonly most important, as well as most easily recognized and examined; but morphologically the extremes have great significance, and present as yet unsolved problems for future investigation.

§ 57. Points illustrated by Fig. 4710.—A. An arrangement and circumscription of the encephalic cavities in the adult cat not essentially (naturally) essentially identical with that in the human adult (Fig. 4746) and fœtus (Fig. 4709) and in vertebrates generally.

B. The great differences in size and shape between the various divisions of the encephalocœle; the præcœle is little larger than the myelocœle and is tubular; the mesocœle is narrow but high; the metacœle wide but shallow; the diacœle is very irregular; the myelocœle is patent throughout, while in man it is nearly obliterated. The [illegible] lateral recesses are not exposed, so the triple constitution of a typical segmental cavity is exhibited only by the prosocœle with its mesal aula and lateral paracœles.

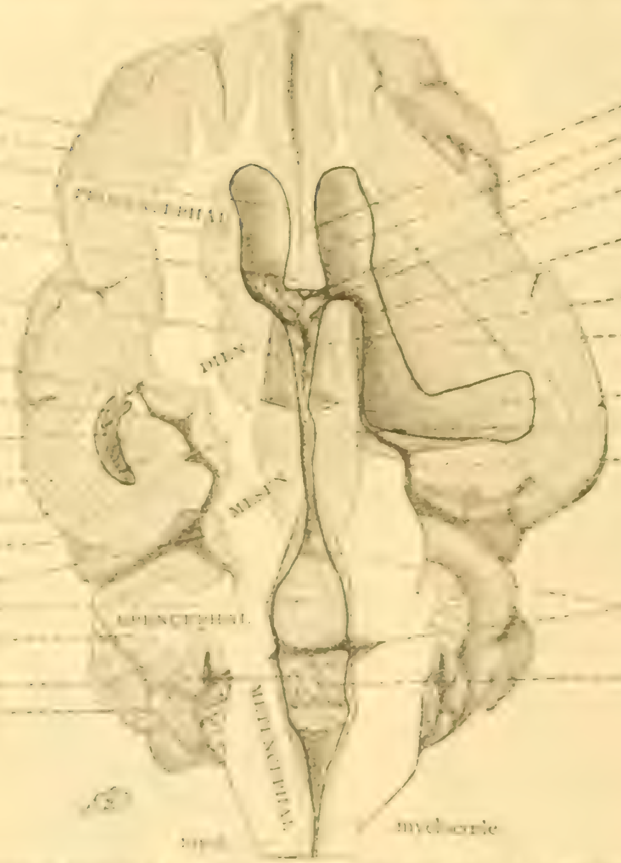

FIG. 4710.—The Encephalic Cavities of a Cat. Exposed from the Ventral Side. [illegible]

[illegible]

C. The different constitution of the various parietes. The roofs of the aula, diacœle, and metacœle are membranous, with plexuses on the ental surface.

D. The reduced thickness of the parietes near the rima, constituting the fimbria, one of the riparian or marginal parts.

E. The apparent interruption of the wall of the mesocœle at the rima (great transverse fissure); on close examination, however, although the proper nervous parietes are absent, the intruded plexus fold (paraplexus) is seen to be covered by the endyma reflected from the adjoining parts, so that the injected alcohol was completely confined.

F. The not very obvious relation of the ectal furrow, hippocampal fissure, to the ental elevation or colliculus, hippocamp; on the right the line from *postgeniculum* crosses the end of the fissure, which is not otherwise indicated.

G. The relations of the alba (medulla) to the ectocinerea (cortex) and the entocinerea ("central tubular gray"); the metepencephalic entocinerea has been removed in exposing the cavities, but it is distinct and abundant at the sides of the mesocœle (aqueduct), of the diacœle, constituting the thalamus, and of the prosencephalic precornu, constituting the caudatum and—unexpectedly—the hemiseptum and fornicolumn, all which were distinctly gray in the fresh preparation.

H. The caudal extension of the cerebrum so as to reach the cerebellum, and thus conceal the lateral aspect of the intervening segments, diencephal and mesencephal.

I. The fusion of the thalamus with the caudatum, of the diacœlian side-wall with the paracœlian floor; the line of junction of the two segments may be regarded as indicated approximately by the word *dien*.

J. The absence or inconspicuousness of the lenticula, claustrum and insula (compare Fig. 4731).

K. The less width of the diencephal than in man, so that the geniculums maintain their proper morphological relation of cephalic (pre) and caudal (post), rather than of lateral, or "external," and mesal, or "internal," as in man.

L. The extension of the paracœles, the proper cavities of the hemicerebrums caudad from the aula even farther than cephalad, thereby warranting the diagrammatic representation of the paracœles as lateral extensions, not cephalic only.

M. The absence of a postcornu in the cat, as in most other mammals, the exceptions being man, monkeys, seals, porpoises, and some, if not all, dogs.

N. The distinctness of the fornicrista in the cat; it is not named on the figure, but may be seen as a conical elevation at the cephalic side of the aula.

§ 58. Prop. XXXV. A convenient classification of the encephalic parts, as in the following Table, assigns them first to the segments in which, at least provisionally, they may be held to belong; second, to the floor, sides, and roof of the segments; third, to categories according to their thickness or other feature; from the nature of the case, several parts may be named more than once; on the other hand, some are omitted altogether.

Provisional Classification of Encephalic Parts according to Segments, Relations to Cavities, and Other Characteristics.

Segments and chief parts.	PROSENCEPHAL: Cerebrum.	DIENCEPHAL: Thalami.	MESENCEPHAL: Gemina.	EPENCEPHAL: Cerebellum.	METENCEPHAL: Postoblongata.
General cavities	Prosocœle	Diacœle	Mesocœle	Epicœle	Metacœle.
Cavitary divisions	Paracœle, porta, aula, cornu.	Aulix, infundibulum		Lateral recess.	
Floors	Fornix, caudatum	Torus, etc.	Crura	Preoblongata and pons.	Postoblongata.
Sides	Hemiseptum, etc.	Thalami	Gemina	Peduncles	Restis, clava.
Roofs	Aulatela and callosum	Diatela	Gemina and valvula.	Cerebellum and lingula.	Metatela, obex.
Commissures and decussations.	Callosum, precommissure, fornix.	Medicommissure, supracommissure, chiasma.	Postcommissure	Pons	Decussation of pyramids; dorsal and ventral commissures.
Marginal parts	Tenia, fimbria, pala	Habena			Obex and ligula.
Telas	Aulatela	Diatela			Metatela.
Plexuses	Prosoplexus	Diaplexus		Epiplexus.	Metaplexus.
Atrophied parts	Prosoterma	Torus	Valvula	Lingula	
Appendages	Olfactory bulb (?)	Conarium, hypophysis		Flocculus and paraflocculus.	
Ental elevations	Caudatum, hippocamp, calcar, collateral, occipital and callosal eminences.	Habena			
Ectal elevations	Gyres, insula	Pulvinar, pregeniculum, postgeniculum, albicans.	Postgeminum, pregeminum, postbrachium, prebrachium, cimbia.	Folia	Oliva, clava, tubercle of Rolando.
Ectal depressions	Fissures	Trigonum, habenal, fimbrial, and tenial sulci.	Lateral sulcus	Peduncular sulcus, rimulæ, prepeduncular fossa.	Postfovea.
Ectocinerea	Cortex		Cappa	Cortex.	
Parts of ectocinerea	Claustrum, amygdala, lenticula.				
Entocinerea	Caudatum		Aqueduct cinerea.		
Parts of entocinerea		Habenar ganglion, etc.		Fastigatum, embolus, globulus, dentatum.	
Other parts		Precribrum, postcribrum.	Intercalatum	Arbor.	

§ 59. Points illustrated by Fig. 4711.—A. The bloodvessels are fully discussed elsewhere in this volume and only three matters connected therewith are referred to here: 1, The presence of a subfalcial sinus marked (2) on the figure; according to Browning ("Veins of the Brain," p. 21), this is often absent, but here, as in some other preparations examined by the writer, it reaches a point a little cephalad of the middle of the length of the callosum where it receives several considerable veins, not shown in this figure; 2, the absence of a distinct precommunicant ("anterior communicating") artery, as in most of the brains examined by the writer with reference to that point; the two precerebral arteries simply converge, join, and again diverge just dorsad of the chiasma; in this preparation the caudal of the two orifices, crossed by the line from the precommissure, represents the place of junction of the two precerebral arteries; the cephalic orifice, just cephalad of the line from *aula*, was caused by the partial slicing off of the right precerebral, part of its wall appearing between the two orifices; 3, the termatic artery springs from the place of junction of the two precerebrals, or from the middle of the precommunicant, when this distinctly exists; its course has not been fully followed out; in this specimen it is soon concealed by the precerebral.

B. This figure also illustrates many of the strictly encephalic points presented in connection with Fig. 4684, which should be compared with this and with the excellent though incomplete representation of the mesal encephalic cavities in Quain's "Anatomy," ii., Fig. 290; frequent reference should be made to the representations of the base and transections of the brain (Figs. 4689 and 4751).

C. It is to be noted that the segmental names are omitted and that the names introduced apply to the parts as such. Most of the cavities are designated by their general titles, metacœle, etc., but the diacœle is not named at all, and the mesocœle is called aqueduct.

§ 60. Prop. XXXVI. *Cœlian circumscription.*—The facts of development and comparative anatomy, and analogy with other hollow organs warrant the presumption that the encephalic cavities communicate only with one another and with the myelocœle. Any communication with the ectal surface is presumably artificial, ex-

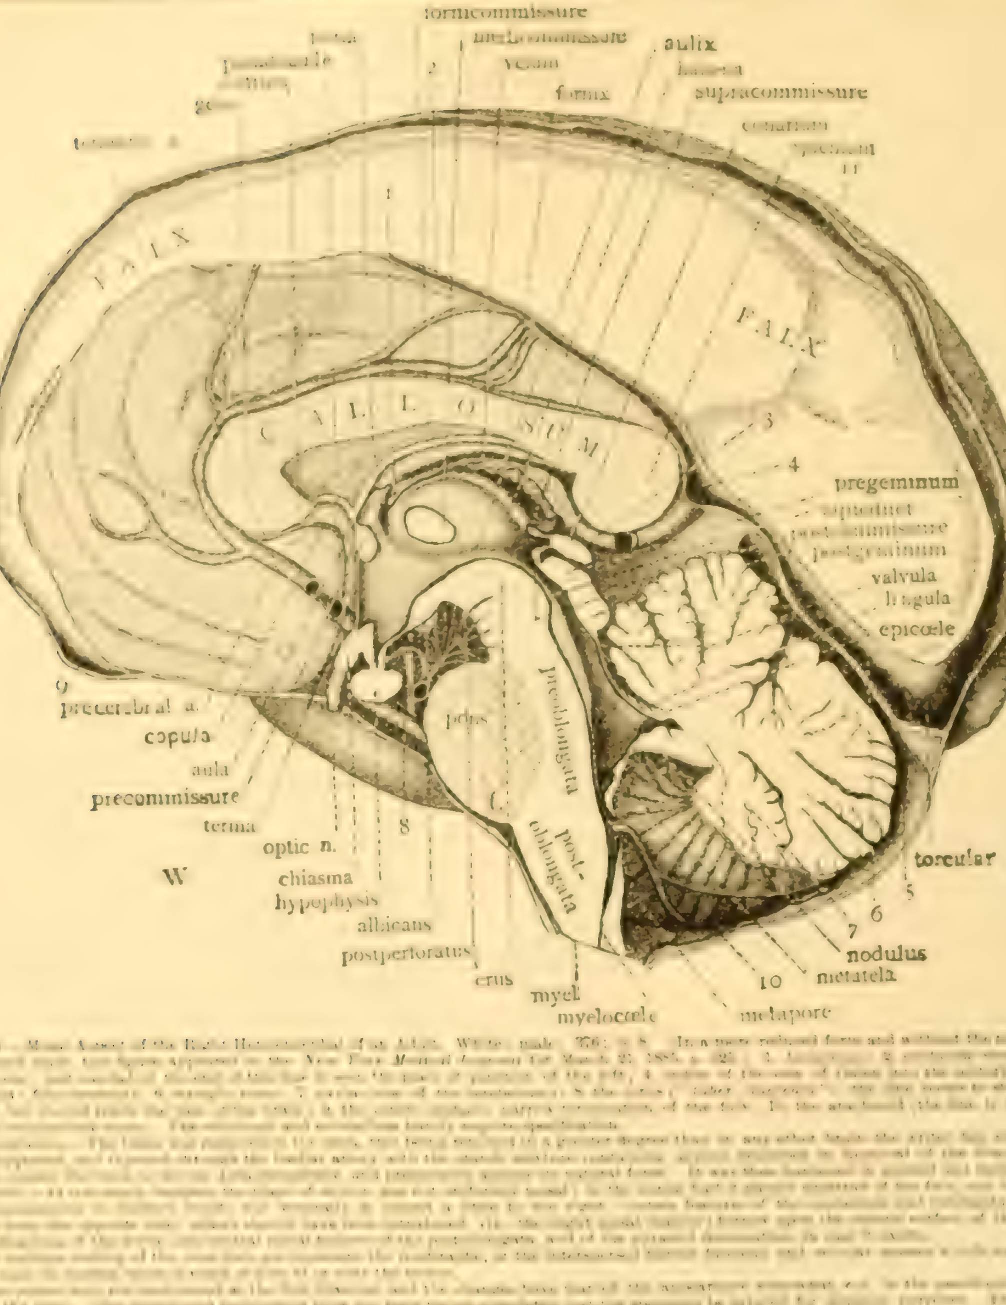

FIG. [illegible].—Mesal Aspect of the Right Hemicerebrum of an Adult White, male. [illegible]

cepting only the metapore ("Foramen of Magendie") which undoubtedly exists in man, though not perhaps in other vertebrates.

§ 61. Prop. XXXVII. *Endymal continuity.*—The endyma is the essential and absolutely constant constituent of the cœlian parietes; hence, in all figures purporting to illustrate cœlian circumscription the line representing the endyma should be distinct and uninterrupted, excepting of course at the metapore.

§ 62. Prop. XXXVIII. In tracing the continuity of the endyma upon the meson, it is best to begin with a region where a rupture could hardly occur in either fresh, [illegible], or older, and where also a transection is most readily effected when the entire brain is to be studied in two parts, a cerebral and a cerebellar portion. This "place of election" is the aqueduct (*iter a tertio ad quartum ventriculum*), the slender adult human remnant of what was in the embryo and remains in some other vertebrates a "vast and spacious cavity" of the most conspicuous portion of the brain.

A. The endyma covering the floor of the aqueduct may be traced caudad (actually almost directly ventrad) with slight depressions and elevations through the oblongata to the myel where it lines the slender myelocœle, the "canal of the cord."

B. Recommencing at the same point in the aqueduct, the floor endyma turns quite sharply ventrad over the cephalic curvature of the crus, passes the albicans and reaches a region where the floor is thin and frequently torn in removing the brain; this is the torus, commonly called "*tuber cinereum*," which is continuous with the tube, infundibulum, and thus with the hypophysis. The cephalic part of the torus joins the chiasma, the ental margin of which presents a marked transverse ridge, sloping caudad into the torus and cephalad into the optic recess. In Figs. 4712 and 4728, the chiasma and torus are shown with the hypophysis attached, but in Fig. 4689 it is detached, leaving an orifice, the lura.

C. Directly dorsad from the chiasma, the cephalic wall of the diacœle is the terma (*lamina terminalis*, or *l. cinerea*) so thin and delicate as to be not infrequently ruptured during the removal or manipulation of the brain; the proper nervous material of the terma seems hardly more substantial than the lining endyma and the covering pia, here represented by the ental and ectal lines; the ectal aspect of the terma is shown in Fig. 4726.

D. Suddenly there is a marked thickening of the cephalic wall, from the reinforcement, so to speak, of the terma by a fibrous cord, oval or elliptical in section; this, the precommissure, connects portions of the cerebrum upon opposite sides, and hence belongs to the prosencephal, and the cavity just caudad and dorsad of it is the aula, the mesal portion of the prosocœle.

E. From the precommissure caudad to the roof of the aqueduct the course of the endyma is extremely irregular, and the nature and shape of the roofs very diverse; the immediate roof is largely membranous, and the condition is further complicated by blood-vessels large and small, and by plexuses; finally, the parts lying directly upon the meson differ materially from those just laterad of it, and as the chances are altogether against a medisection being exactly mesal in the whole of its course, there is nearly a certainty that upon the first inspection one will miss anticipated features and see what one does not understand.

F. The recognition and comprehension of the actual facts in a given preparation will be facilitated by recalling the diagrams (Fig. 4706), and the representations of the brains of the cat and rabbit (Figs. 4710 and 4694). The important point to bear in mind is that the complete circumscription of the mesal encephalic cavities would be unaffected were the entire cerebrum removed, including the callosum, hemiseptum (the lateral wall of the pseudocœle), and fornicommissure (the mesal continuity of the fornix), down to the point where the heavy line representing the endyma leaves the narrow, white area representing the fornicommissure to cross the convex surface of the fornicolumn and be reflected upon the auliplexus. The details of this, the aulic and portal region, are more clearly seen in an enlarged figure of the porta, in the article Malformations of the Brain.

G. From the auliplexus (at or very near the meson) or from the portiplexus (if the section-plane passes through the right or left porta instead of the mesal aula) the endyma may be traced caudad upon the ventral surface of a membranous fold, the velum. Strictly speaking, between the endyma and the velum, which is a fold of pia, intervenes the remnant of the primitive nervous roof of the diacœle; this may persist in some animals, but in the adult cat and in man, so far as the writer is aware, there is practically nothing between the pia constituting the velum and the endyma. At each side of the meson there depends a more or less distinct vascular fringe, the diaplexus, continuous with the auliplexus, the portiplexus, and thus with the paraplexus, these last three being successive members of the prosoplexus.

H. The relations of the endyma to the velum and plexuses are more clearly shown in Fig. 4751, representing a transection of the diacœle. There also are shown the relations of the habena. This is a low ridge following a curved line along the mesal aspect of the thalamus from the dorsal end of the porta to near the conarium; it is covered by endyma, but just dorsad of it, dimly seen in the figure, is a shallow furrow, the habenal sulcus, from which the endyma is reflected first dorsad, and then mesad, upon the velum and the diaplexus. The habena unites with its opposite fellow of the other side at the supracommissure. The endyma line is seen to leave the velum, and descend to the dorsal (really cephalic) surface of the conarium, whence it extends cephalad to and over the margin of the supracommissure, then into and out of the conarial recess, and over the convex cephalic surface of the postcommissure, whence it enters the aqueduct, where the tracing of its continuity was begun, only it is now the lining of the roof, the geminal bodies, instead of the floor.

I. Continuing caudad, there is but slight change in the direction of the roof of the aqueduct; a great reduction in its thickness occurs in the transition from the postgeminum to the valvula; the succeeding part, the lingula, is somewhat thicker and trends slightly dorsad, to become continuous with the cerebellum proper. The cavity here resembles a gable roof, with a sharp dorsal angle. The caudal slope is formed by the nodulus, a comparatively massive mesal lobe; but from its margin, commonly more rounded than appears in this figure, the endyma is abruptly reflected, together with the pia which had covered its caudal surface; these two membranes, closely united, and with apparently little or no trace of the primitive nervous roof, constitute the metatela. This is suddenly interrupted by the orifice here called metapore, but commonly known as "foramen of Magendie," see Hess, in *Morphologisches Jahrbuch*, vol. x.; in the present figure it is at the point where an artery appears; caudad of the metapore, the metacœlian roof is a thin lamina, the obex, which is continuous with the dorsal commissure of the oblongata and that of the myel, constituting the roof of the myelocœle.

§ 63. Prop. XXXIX. *Encephalic variations.*—Excepting as to the fissures and gyres, and the pyramidal decussation (well discussed in *Quain*, ii., 278 and 289), treatises upon anatomy seldom refer to variations or anomalies of the surfaces or ental structures of the brain, yet they are frequent, and sometimes significant, morphologically if not physiologically. So far as the present writer can determine from his own materials, and from figures and descriptions, there is hardly a feature of the human brain respecting which it can be stated confidently what is normal, or how frequently certain peculiarities occur.

The foregoing account of the brain as a whole constitutes an introduction to the description of each of the five segments, beginning with that immediately succeeding the myel.

§ 64. METENCEPHAL.—Synonyms: Metencephalon, after-brain, myelencephalon, macromyelon.

Tabular arrangement of parts.—Chief part: postoblongata (caudal portion of "medulla oblongata"). Cavity: metacœle (caudal portion of "fourth ventricle"). Floor: postoblongata. Sides: restes ("restiform bodies") and ligula. Roof: metatela and obex. Plexuses: metaplexuses. Orifice: metapore ("Foramen of Magendie"). Decussation: Dec. of the pyramids. Other ectocœlian parts and features: Ventral sulcus; ventral column; pyramid; oliva; arciform fibres; lateral column; funiculus of Rolando; tubercle of Rolando; cuneate funiculus; *funiculus gracilis;* clava; ligula; obex. Other entocœlian parts and features: Mesal sulcus; *ala cinerea;* postfovea; *eminentia cinerea.*

§ 65. Prop. XL. The postoblongata (Figs. 4684, 4689, 4712, 4713, 4719, and 4721) is so obviously a continuation of the myel that if there were no parts cephalad of it, and if it were wholly contained within the spinal canal, it would probably be regarded as merely a somewhat modified region of the myel, comparable with the lumbar enlargement near its other extremity, which also in birds contains a distinct and thin-roofed dilatation, the rhombocœle. There is, therefore, ample warrant for the name *macromyelon* (large myel region), applied by Owen, and for *myelencephalon* (myel-like brain region), employed by Huxley. On account, however, of its equally obvious continuity with the preoblongata (especially in animals lacking the pons), its location, mostly within the cranium, and the number, peculiarity and vital importance of the [illegible] connected with it, the postoblongata is [illegible] regarded as a division of the brain, [illegible] the segmental [illegible].*

§ 66. Points illustrated upon Fig. 4712.—A. The ectal origins of the cranial nerves (see Vol. V., Fig. 3024).

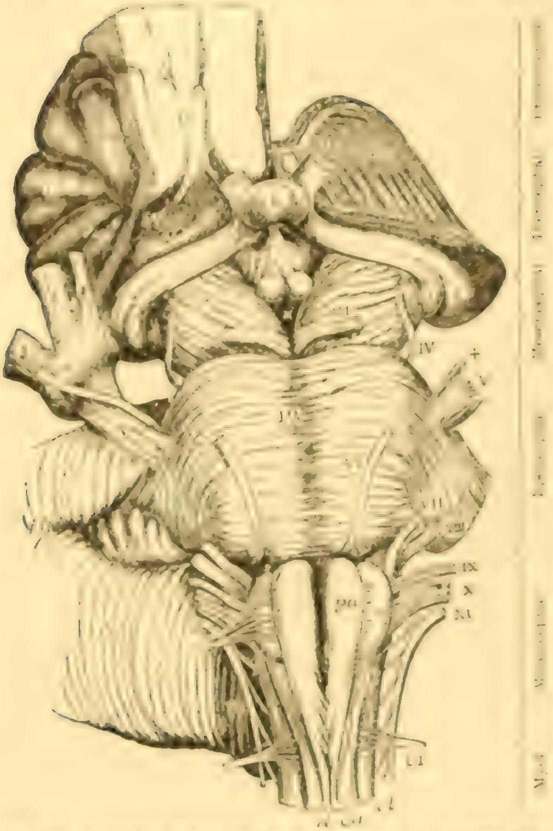

Fig. 4712.—Ventral Aspect of the Human Brain-stem. × 1. (From Quain; compare Fig. [illegible].) The Roman numerals I.–XII. designate the ectal origins of cranial nerves, described in Vol. II. [illegible] internal [illegible]

B. The ventral aspect of the adult insula (comp. Figs. 4689, 4782, and 4784).

C. The continuity of the optic tract with both geniculums.

D. The decussation of the pyramids (see under Fig. 4689).

E. The representation of all five segments upon the ventral aspect of such a preparation, including the parts of what is commonly called the "brain-stem."

F. The overlapping of the more cephalic fasciculi of the pons upon the more caudal (comp. Fig. 4713).

§ 67. Prop. XLI. The postoblongata differs from a corresponding length of the myel in size, shape, amount of alba, amount and arrangement of cinerea, extent and and form of the cavity, and the nature of its roof.

§ 68. Prop. XLII. In the myel the two halves dorsad of the commissures are in contact. This is the case also with the caudal extremity of the postoblongata; but for most of its length the originally mesal surfaces are separated by a rapidly widening interval, so that what was mesal becomes successively dorsal, and finally lateral, while what was lateral becomes approximately ventral. These changes materially increase the width of the segment.

§ 69. Prop. XLIII. The cavity, a tube in the myel and caudal part of the postoblongata, is expanded into an irregular triangular fossa, the metacoele or caudal part of the fourth ventricle. The roof of this cavity has lost its true nervous character and consists of only the lining endyma and the covering pia, constituting the metatela.

§ 70. Prop. XLIV. The increased cinerea of the postoblongata consists of (1) the continuous expanded masses of the ventral and dorsal cornua, especially the latter, which, with the modified ventral commissures, constitute the metacoelian floor; (2) special masses of cinerea, more or less completely separate, the nuclei of Spitzka, the "nuclei" of most writers, constituting the ental or deep origin of certain cranial nerves (Vol. II., Fig. 766) and presumably representing detachments of the cornua; (3) the dentoliva (*dentatum olivæ* or olivary nucleus), a capsule of cinerea within the oliva resembling the cerebellar dentatum (see in the next article on Histology of the Brain).

§ 71. Points illustrated upon Fig. 4713.—A. The insensible transition from the myel to the postoblongata, and thus from the myel as a whole to the brain as a whole.

B. The apparently sharp demarcation between the epencephal, represented here mainly by the pons, and

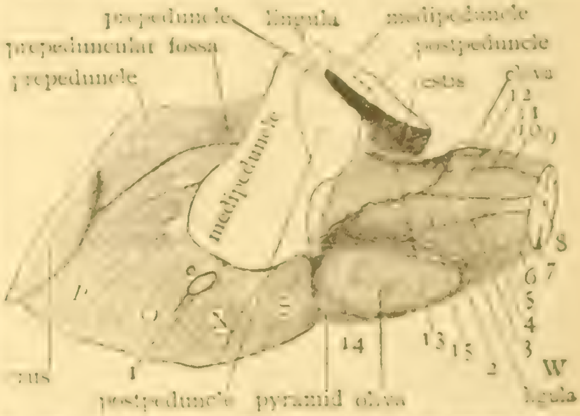

Fig. 4713.—Left Side of the Metencephal (after the Removal of the Cerebellum) [illegible]

---

* [illegible]

the adjoining segment; in reality, however, not only do the cephalic and caudal margins overhang the adjoining surfaces to a certain extent (see Fig. 4719, 1 and 2), but it is by no means certain that the pons covers no more and no less than the epencephalic portion of the oblongata; in the cat, for example, the trapezium, here invisible, is exposed, while with many lower vertebrates the pons is rudimentary or absent altogether, and the boundaries between metencephal and epencephal must be otherwise determined.

C. The lapping of the cephalic portion of the pons over the caudal, giving the appearance of a twist or rotation of the medipeduncle upon its own axis to the extent of the fourth of a circle.

D. The relation to the oliva of the arciform fibres (2), which appear to be derived from the pyramid and to pass around the caudal end of the oliva to enter into the composition of the restis and postpeduncle.

E. The projection of the right clava beyond the left, a marked lack of symmetry in this specimen.

F. The ligula, or line of demarcation between the general, pial surface of the myel and oblongata, and the endymal, metacœlian surface; the ligula consists of the pia and endyma with, in some specimens (Fig. 4719), a thin intervening lamina of nervous substance.

G. The prepeduncular fossa, a shallow depression on the dorso-lateral surface of the prepeduncle, near the medipeduncle.

§ 72. Prop. XLV. The visible longitudinal divisions of the postoblongata do not correspond altogether with the myelic columns. The following account of the principal differences is condensed and modified somewhat from *Quain*, ii., 286, 288, 298.

§ 73. Prop. XLVI. The ventral column (Fig. 4689, *i*, Fig. 4712, *ca*, Fig. 4713, 6) continues cephalad partly in the pyramid of the same side, as would naturally be expected, but mostly dips entad of the pyramid and oliva and forms longitudinal fasciculi near the meson farther dorsad.

§ 74. Prop. XLVII. Of the lateral column (Fig. 4712, *cl*, and Fig. 4713, I) a large part crosses at the decussation (shown in Fig. 4712, but not always visible) to constitute mainly the pyramid of the opposite side; some of the fibres join the restis of the same side, constituting the "direct lateral cerebellar tract;" the rest of the lateral column dips entad of the oliva and "forms the longitudinal fibres of the *substantia reticularis grisea.*"

§ 75. Prop. XLVIII. The dorsal column of the larger portion of the myel is displaced in the cervical region by the dorso-mesal ("posterior median") column (Vol. II., Fig. 760; Fig. 4713, 10); this, in the postoblongata, is called *funiculus gracilis;* near the apex of the metacœle it presents a distinct enlargement, the clava (Fig. 4713), cephalad of which the funiculus is no longer distinct. Between the *funiculus gracilis* and the lateral column (Fig. 4713, 4) there intervene, in the postoblongata, two funiculi, of which the more lateral (15) is regarded as the direct continuation of the dorsal column of the myel, but is commonly called funiculus of Rolando, sometimes "lateral cuneate"; between it and the dorso-mesal column (*funiculus gracilis*) intervenes another interpolated funiculus, the cuneate (12); this and the funiculus of Rolando appear to enter into the composition of the restis ("restiform body") which is continued as the postpeduncle into the cerebellum; but, according to *Quain*, ii., 288, this relation is rather apparent than real, the components of the restis and postpeduncle being (*a*) the arciform fibres (Fig. 4713, 2) from the ventral column, and (*b*) the "direct cerebellar tract" of the lateral column.

§ 76. Prop. XLIX. The increased bulk of the postoblongata is due also in part to the entrance (or exit) of the roots of the accessory, hypoglossal, vagus, and glossopharyngeal nerves, which are more numerous than the spinal nerve roots upon a similar length of the myel; see Figs. 4689, 4712, and Vol. II., Fig. 760.

For fuller details of the structure of the postoblongata see the next article on Histology of the Brain.

§ 77. EPENCEPHAL.—Synonyms: Epencephalon, hindbrain. Tabular arrangement of parts: Chief parts: cerebellum. Cavity: epicœle (cephalic portion of "fourth ventricle"). Floor: preoblongata and pons. Sides: peduncles. Roof: cerebellum and lingula. Lateral extensions: parepicœles. Ectocinerea: cortex. Entocinerea: dentatum, fastigatum, globulus, embolus. Main cerebellar divisions: vermis and lateral lobes. Other parts and features are named upon the figures.

§ 78. Prop. L. The *cerebellum* is essentially an arch over the epicœle (cephalic part of the "fourth ventricle"); Figs. 4697 and 4714. This condition exists in the embryo, and persists in many of the lower vertebrates. The adult human organ, however, is a foliated mass of complex fibrous and cellular structure, well meriting the adjective, *hypertrophied*, applied to it by Spitzka.

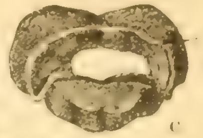

FIG. 4714. Caudal Aspect of the Epencephal (Cerebellum) and Preoblongata of a Fœtus. (Size and age and magnification uncertain, specimen and notes having been lost; it probably resembled quite nearly the specimen shown in Fig. 4697.)

§ 79. Points shown upon Fig. 4714.—A. The large size of the epicœle at this period, as compared with the thickness of the parietes.

B. The extensions latero-ventrad constituting the parepicœles or "lateral recesses" (comp. Figs. 4702 and 4703).

C. The non-appearance of the mesal lobe, vermis, at this period.

D. The continuity of the riparian part, *a*, along the line of junction of the ectal pia and ental endyma, they not being represented distinctly.

§ 80. Prop. LI. The adult cerebellum comprises a mesal lobe, the *vermis*, and two *lateral lobes*, sometimes called "hemispheres." On the cephalic aspect, the vermis (prevermis) is prominent (Fig. 4716); but on the caudal the lateral lobes project decidedly beyond the postvermis, the surface of which is thus at the bottom of a deep mesal crevice, the *vallecula* (Fig. 4717). The cephalic and caudal regions of the cerebellum, both lateral lobes and vermis, are separated, though not completely, by a deep cleft, commonly called the "great horizontal fissure," but here named *peduncular sulcus* from its obvious relation to the medipeduncle at each side (Figs. 4715, 4716, and 4717).

§ 81. Prop. LII. *Folia*, *rimulæ*, and *lobes*.—The entire surface of the adult cerebellum presents numerous lines, for the most part parallel and having a generally transverse direction. These lines represent crevices of greater or less depth, the rimulæ, and the intervening thin plates are the folia. Certain of the interfoliar crevices are so deep or so distinct as to warrant the recognition of the intervening groups of folia as lobes.

§ 82. Points illustrated upon Fig. 4715.—A. The general form and foliation of the lateral aspect of the cerebellum. The flocculus is seen in the interval between the pons and the oliva, and the peduncular sulcus, dividing the cephalic from the caudal region, is represented by the rather heavy line beginning at the flocculus and ending at the dorsal margin, where it is intersected by the line 13.

B. As upon the mesal aspect (Fig. 4718), the remarkably complete fissuration in a child at term.

C. The perfect exemplification of the typical relations of the insula, the operculums and the Sylvian fissure; compare the fœtal brains (Figs. 4759, 4760, 4762 and 4782) and the adults (Figs. 4767, 4778 and 4779) in which the presylvian and subsylvian fissures are united for a certain distance.

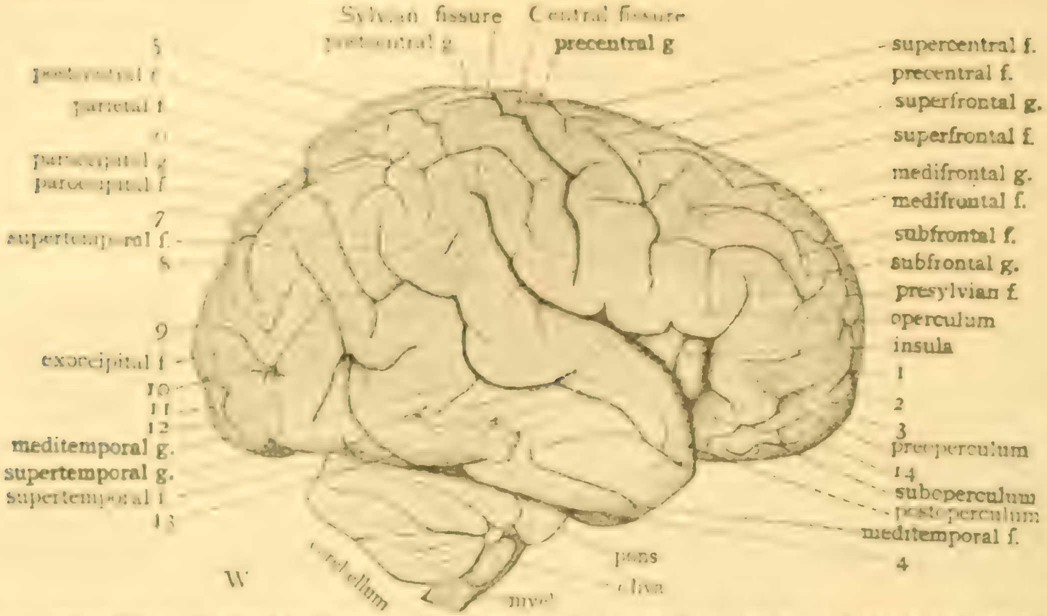
D. The presence of a distinct medifrontal fissure, subdividing the medifrontal gyre.

E. The independence of the postcentral, parietal, and paroccipital fissures (see also Fig. 4774).

F. The presence of the exoccipital (the "ape fissure" of some writers)

G. The frequency of the zygal or H shaped form of fissure; *e.g.*, paroccipital, parietal, postcentral, subfrontal, orbital, and fissure 1.

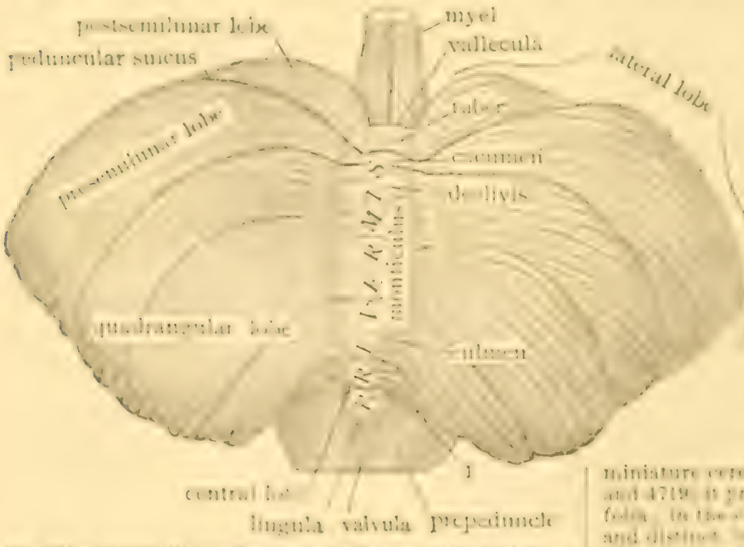
§ 83. Prop. LIII. The commonly received division of the two regions of the cerebellum into lobes is indicated



[illegible]

upon the figures. The writer is free to admit, however, that he is by no means fully satisfied therewith.

§ 84. Points illustrated by Fig. 4716.—1. The natural tilt caudad of the cerebellum so that its normally cephalic surface looks dorso-cephalad even when the oblongata is held in the cephalo-caudal plane.



[illegible]

2. The extension of the cerebellum so as to overhang the postoblongata.

3. The enormous preponderance of the lateral lobes over the mesal lobe (vermis) in the adult; compare, however, Fig. 4697, and, in Vol. I., Fig. 512.

4. The slight demarcation between the vermis and lateral lobes on this aspect.

5. The appearance of part of the postsemilunar lobes, and of the peduncular sulcus, both these appearing partly also upon the caudal surface.

6. The connection of the two presemilunar lobes by means of a single folium, the cacumen, not always present.

§ 85. Prop. LIV. *Lingula.*—Between the substantial postgeminum and the massive cerebellum the roof of the continuous mesocoele and epicoele is constituted by a relatively insignificant lamina, the valvula and the lingula. The former will be considered in connection with the rest of the mesencephal; the latter may be regarded as a miniature cerebellum. In medisection (Figs. 4711, 4718, and 4719) it presents several (3-5) elevations, cerebelliform folia. In the child at birth the lingual folia are rounded and distinct, but in the adult they are relatively smaller, often flattened as if by pressure of the overhanging cerebellum and sometimes (at least in certain insane brains) nearly or completely absent. The cephalic folium is narrowest and has a rounded outline (Fig. 4716); the pia adheres quite firmly to these folia, so that they are liable to be torn off.

§ 86. Points illustrated upon Fig. 4718.—A. In connection with Figs. 4715 and 4719, the perfection and beauty of form of the human brain at birth.

B. The relatively small size of the cerebellum at birth.

C. The distinctness and prominence of the pons.

D. The lateral extent of the pseudocœle; at the genu (cephalic curvature) of the callosum it is 1 mm. deep, representing about one-half of its entire lateral extent.

E. The continuity of the callosum and fornix.

F. The distinctness and depth of the principal fissures and the large number of minor ones.

G. The peculiar ventral curve of the caudal half of the calcarine fissure, and the concomitant expansion of the cuneus.

H. The length of the fissure in the subcalcarine gyre.

I. The appearance of the cephalic stipe of the paroccipital fissure (18) upon the mesal aspect; compare Figs. 4773, 4774, and 4776.

§ 87. Points illustrated by Fig. 4719.—A. The mesal topography of the cerebellum and adjacent parts when brought into nearly their "normal position," *i.e.*, when the metepencephalic floor is nearly horizontal (cephalocaudal) and when the longer axis of the cerebellum is nearly dorso-ventral; this is nearly their condition in a body lying prone, with the axon and longer portion of the neuraxis (myel) approximately horizontal, as with most quadrupeds and the majority of walking and swimming vertebrates (see § 3, I, and the article on Anatomical Terminology). For comparison with Figs. 4684, 4711, and 4718, this or they must be regarded as turned about one-fourth of a circle.

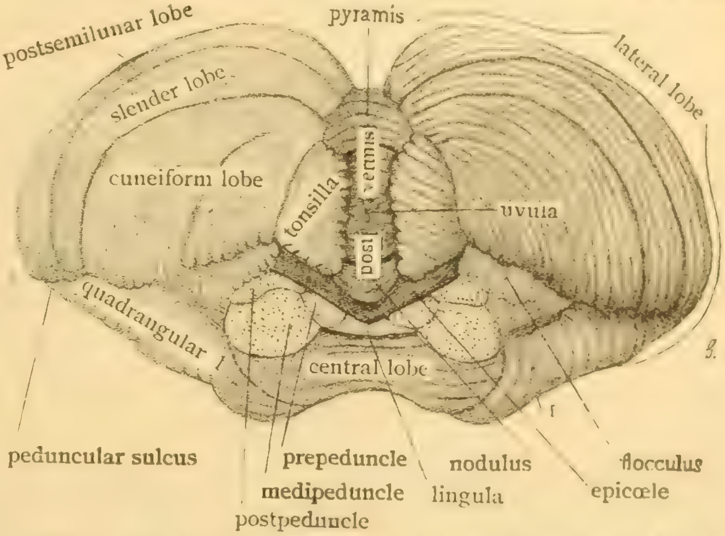


FIG. 4717.—Caudal ("lower" or "posterior") Aspect of the Adult Cerebellum. A little less than natural size; from Edinger, inverted and slightly modified. 1, Part of the right quadrangular lobe. The cut ends of the peduncles are dotted; the large medipeduncles extend latero-dorsad into the lateral lobes; the flocculi are attached to the medipeduncles. The continuity of the vermian divisions with those of the lateral lobes is not apparent upon this aspect.

Defects.—In addition to the general remark made under Fig. 4716 the following special deficiencies are to be noted: 1, There is no line to represent the divided endyma of the metatela along the caudal (here upper) side of the cavity (epicœle); all this region requires elucidation in respect to cœlian circumscription; 2, the omission of the plexuses and nerve roots; 3, the postvermis should be more deeply shaded to indicate its depth below the level of the tonsillæ, which also are really almost in contact; 4, on this, or on Fig. 4716, the vermis should present a line indicating the reflection of the arachnoid.

B. The exact number and form of the cerebellar folia and subfolia at birth, so far as they appear upon an approximate medisection.

C. The combination of the folia to form lobes, more or less well defined.

D. The arboriform arrangement, whence the name *arbor vitæ* (herein mononymized to *arbor*).

E. The topographical relations of the mesal lobe (vermis) to the lateral lobes; caudad, dorsad and at the ventro-cephalic region the lateral lobes project beyond the vermis, but the latter is the more prominent with the culmen at the cephalic side and with the nodulus at the caudo-ventral angle. The interval between the lateral lobes on the caudal aspect constitutes the vallecula.

F. The depth of the peduncular sulcus, and the coincidence of its general direction with that of the hypercœle (6), dividing the "stem" of the arbor (*corpus trapezoides*) into a preramus ("vertical" branch) and a postramus ("horizontal" branch).

G. The similar division of the folia of the mesal lobe into a prevermis ("superior" vermiform process) and a postvermis ("inferior" vermiform process).

H. The enormous size of the cerebellum as compared with its cavity, even had the dorsal part of the latter (hypercœle) been maintained at its natural size by alinjection.

I. The projection of the cerebellum beyond its attachments and proper cavity. Cephalad, it overhangs not only the valvula but the postgeminum, these being parts of the mesencephal; caudad, whatever exact limit be assigned to the epicœle, the vermis covers the entire "fourth ventricle," and the lateral lobes.

J. The distinctness of the four lingular folia, constituting the transition from the massive cerebellum to the atrophic (?) valvula.

K. The apparent absence of the cacumen, the single folium which, when present, rises from the bottom of the peduncular sulcus and connects the presemilunar lobes of the two sides. According to Henle, it is not constantly present.

L. The prominence of the cephalic and caudal margins of the pons, and the concomitant depth of the prepontile and postpontile recesses.

M. The merging of the dorsal commissure of the myel and postoblongata into the obex, and of this into the lingula; in the adult this latter seems to be hardly more than the combined pia and endyma (see Fig. 4713), but in the child's brain from which this feature was derived, although the meninges had been removed, there was, nevertheless, a distinct lamina of nervous substance.

§ 88. Prop. LV. The adult *epicœle* is extremely irregular in form; the main portion is a direct and slightly narrowing cephalic continuation of the metacœle; there is a cephalic extension covered by the lingula; a dorsal into the cerebellum, the cephalic and caudal slopes of which meet like a gable roof, whence the name *fastigium*; and a lateral at each side, curving ventrad, the "lateral recess" or parepicœle. Neither Fig. 4703 nor any representation known to the writer, fairly indicates the remarkable shape of this portion of the encephalic cavity.

§ 89. Prop. LVI. *Flocculus.*—Attached to the medipeduncle at the beginning of the peduncular sulcus, and wedged, as it were, between the rounded contiguous angles of the cephalic and the caudal regions of the cerebellum (Figs. 4689 and 4717) are three small foliated masses, the flocculus (in two lobes), and the paraflocculus (a single lobe), Fig. 4720. Their functions and their representatives in other mammals are little known. The stem or peduncle of the flocculus forms one of the sides of the lateral recess (Fig. 4720).*

§ 90. Points illustrated upon Fig. 4720.—A. The location and form of the flocculus, with its two divisions and rounded folia, and of the smaller paraflocculus, presenting but slight traces of foliation. All are attached to the medipeduncle, and the flocculus is sometimes called the peduncular lobe.

B. The general location of the lateral recess (2) or parepicœle, between the peduncles cephalad, the restis and other parts of the postoblongata mesad, and the flocculus and lateral. Its peculiar relations with the [illegible] ganglia and [illegible] cortex are inadequately shown and need special preparation and study.

---

* Cleland has a suggestive note on the flocculus in "Memoirs and Memoranda of Anatomy," i., p. 174, received while this article is passing through the press.

§ 91. Prop. LVII. *Cerebellar cortex* [illegible].—This forms a layer of remarkably uniform thickness covering the folia, including those of the lingula. It is outlined only in Fig. 4711 but can readily be imagined in the others. Its structure is described in the next article on Histology of the Brain.

§ 92. Prop. LVIII. *Cerebellar* [illegible].—In a median section of the organ there would appear to be only [illegible], the former branching in a tree-like manner, whence the name *arbor vitæ*. But there are reasons for thinking that the primitive cerebellar cortex has been [illegible] and is represented by four pairs of masses which are exposed in sections from the meson to the middle of either lateral lobe. They are figured and described in the following article, and are here merely enumerated in their order from the meson laterad: Fastigatum, globulus, embolus, dentatum: the last is the largest and most easily recognized.

§ 93. Prop. LIX. *Peduncles.*—At and near the mesal the connections of the cerebellum with the adjoining segments are thin; the lingula is relatively [illegible] (Fig. 4719) and the [illegible] (Figs. 4684 and 4711); but laterally it has massive continuations constituting three pairs of peduncles: a cephalic (prepeduncles) to the mesencephal, a caudal (postpeduncles) to the metencephal and myel, and an intermediate (medipeduncles) to the pons, part of the same segment.

§ 94. Prop. LX.—The peduncles constitute a continuous mass of fibres at either side, but their relative positions and extent are pretty well determined by various methods, anatomical, microscopical, and experimental. The medipeduncle is the largest and most lateral. It is mainly continued from the lateral lobe of the cerebellum to the pons, where the fibres cross the mesal, intercalating with their opposites and forming a relation with the cinerea, which will be considered in the following article. The postpeduncle mainly connects the vermis with the restis, while the prepeduncle connects chiefly the dentatum with the mesencephal and parts farther cephalad.

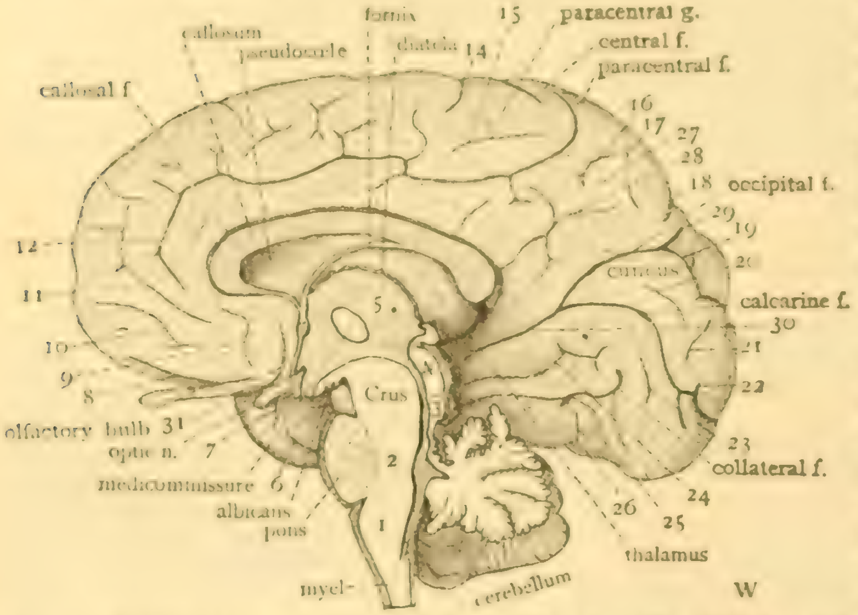

FIG. 4718.—Mesal Aspect of the Right Hemicerebrum of a Male Child, at Term. 478. × .84. Other aspects of the same specimen are shown in Figs. 4715, 4714, and 4776. 1, Postoblongata; 2, preoblongata; 3, postgeminum; 4, pregeminum; 5, thalamus, its mesal surface forming the lateral wall of the diacœle; the [illegible] surface is designated by the line from the word thalamus. These are parts of one and the same [illegible] 6, [illegible]; 7, [illegible] fissure; 8, olfactory fissure; 9, 10, 11, unidentified fissures on the mesal surface of the frontal lobe; perhaps some represent [illegible]; 12, [illegible] fissure, continuous with the paracentral; 13, [illegible]; 15, [illegible]; 16, 17, [illegible] fissures in the precuneus (27); 18, cephalic stem of [illegible] fissure; 19, a ventral branch of the occipital fissure; 20, 21, [illegible] fissures; 22, [illegible] branch of the [illegible] fissure [illegible]; 23, 24, fissures in the [illegible] gyre; 25, 26, fissures in the [illegible] gyre; 28, the [illegible] fissure; 29, dorsal end of the occipital fissure; 30, [illegible] occipital and calcarine; 31, a shallow fissure [illegible]. See § 89.

Preparation.—The fresh brain was [illegible] in brine, and the head was hardened in alcohol [illegible].

Defects.—The specimen [illegible] and is therefore wider and thinner than [illegible]. The [illegible] The thalamus is not distinctly seen. The cerebellum [illegible] Fig. 4776. The hypophysis is lacking, and the [illegible].

chiefly the dentatum with the mesencephal and parts farther cephalad.

§ 95. MESENCEPHAL.—Synonyms: Mesencephalon, midbrain. Tabular arrangement of parts. Chief parts: gemina ("optic lobes"). Cavity: mesocœle (aqueduct of Sylvius). Floor: crura. Sides: gemina. Roof: gemina and valvula. [illegible] Lateral recess: aqueduct ("central" tubular gray). Commissures and decussations: postcommissure, trochlearis.

§ 96. Prop. LXI. In early embryonic stages the mesencephal is the most conspicuous region of the entire brain, but consists of a single, thin-walled vesicle with a relatively large cavity (Fig. 4691). As the parietes thicken, two furrows appear upon the dorsal aspect: a mesal, demarcating the left elevation from the right, and a transverse, subdividing each of these into a cephalic and a caudal portion (Fig. 4697); these result, in the adult mammalian brain, the formation of four approximately similar elevations, whence the names *corpora quadrigemina*, *corpora quadrigemina*, *optic lobes*, etc. In the present article they are called *gemina* (twin bodies) (Figs. 4721 and 4723). They constitute the larger part of the mesocœlian roof.

§ 97. Points illustrated upon Fig. 4723 (see p. 130) under *Diencephal.*—A. The segmental overlapping of the diencephal at the side of the mesencephal and of the prosencephal at the side of that; see § 62, B.

B. The division of the caudatum (the entocœlian portion of the striatum) into a cephalic, enlarged *caput* and a caudal, slender *cauda*.

C. The unlike topographical relations of these two parts, in that the caput is [illegible], while the cauda has a slender, marginal (tæniate) band at its mesal side, the tænia, having peculiar connections with other parts.

D. The location of the diacœle between the two thalami and its continuity with the aula.

E. The presence of the medicommissure (seen somewhat better in Fig. 4727).

F. The relation of the callosal genu to the intercerebral fissure and the pseudocœle: but for the callosum the fissure and the pseudocœle would be continuous, as would also the hemiseptum with the general mesal wall of the precornu.

G. The demarcation of the mesal, entocœlian surface of the thalamus from the dorsal, entocœlian surface by a rough edge just dorsad of the habena; here it is represented by the narrow, white line between the two black ones, and designated as the habena; it is really a ripa along the dorsal side of the habena; see also Fig. 4718.

H. The presence of three shallow furrows on the dorsal surface of the thalamus; a dorso-mesal, just dorsad of the habena, the habenal sulcus; a lateral, corresponding nearly with the mesal edge of the tenia, the tenial sulcus; an intermediate and oblique, corresponding with the lateral margin of the fimbria (removed), the fimbrial sulcus.

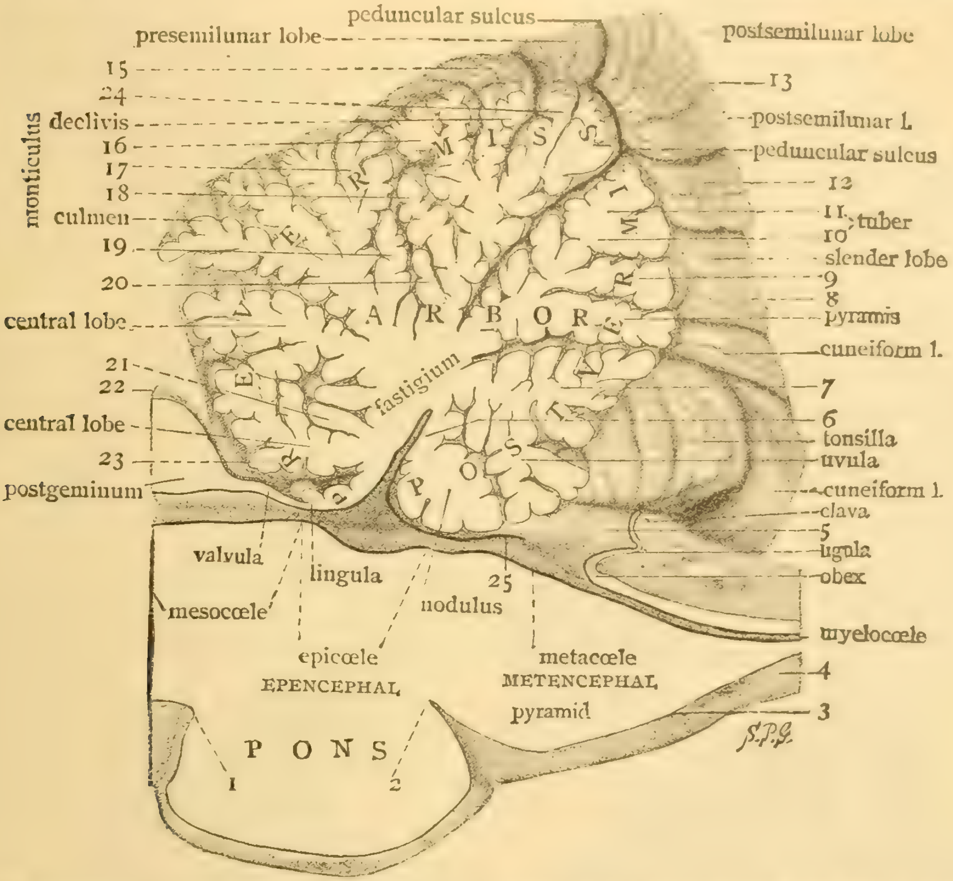

FIG. 4719.—The Metepencephal (Cerebellum, Oblongata, and Pons) of a Child at Term, Showing the Approximately Mesal Aspect of the Right Half. 478; × 3. (This is the same specimen that is shown in Fig. 4718, where, however, no attempt was made to represent details, and the cerebellum is more nearly in its "natural attitude." 1, Prepontile recess; 2, postpontile recess (*foramen cæcum*); 3, presumed caudal end of the pyramid; between 3 and 4 there might be—but were not seen—indications of the pyramid decussation (Figs. 4689 and 4712). 5, slight elevation of the metacœlian floor; the triangular darker area just ventro cephalad represents the postfovea. 6, the dorsal extension of the epicœle into the cerebellum, the hypercœle, or "cerebellar ventricle;" 7, dorsal part of the uvula; 9, dorsal part of the pyramis (*cerebelli*); 10, 11, two divisions of the tuber; 22, retreating dorsal surface of the postgeminum; 24, dorsal folia of the prevermis; 25, metatela (*velum medullare posterius*). the other numbers designate folia or interfoliar sulci which have not been identified or need not be specified in this connection. See § 87.

Defects.—The plane of section passed slightly sinistrad of the meson; hence certain features are not exactly what would have appeared upon a precise medisection. On the cut (unshaded) surfaces the alba and cinerea are not distinguished, the latter having been bleached by the alcohol. The pons section does not show the fibres of the raphé. The cavities were not alinjected and hence are unnaturally small. The meninges were removed; so there is no indication of the dorsal attachment of the arachnoid to limit the subarachnoid space and the obex, ligula, and metatela are supplied from other specimens, but the extent of the metapore (Foramen of Magendie) is not shown. The cacumen cannot be found in the specimen; perhaps its absence should have led to the selection of another preparation as a basis for the figure.

I. The demarcation of the dorsal surface of the thalamus, which is pial and ectocœlian, from the adjoining surface of the caudatum and tenia, which is endymal and entocœlian, by a sharp, irregular line at the mesal edge of the tenia, constituting a ripa. (This line was introduced into the figure; it is absent in the original, as in all similar figures known to the writer, excepting Fig. 16, in Meynert's "Psychiatry," where it is called "*linea aspera*," without, however, any reference to its morphological significance; see Fig. 3885).

J. The vague and unsatisfactory representation of the parts at the porta. This region has yet to be cleared up in respect to the relation of the pial and endymal surfaces; it was his inability to show these relations clearly upon original preparations that led the writer to employ the present figure provisionally.

§ 98. Prop. LXII. *Valvula.*—A caudal portion of the mesocœlian roof retains nearly its primitive tenuity and constitutes a transparent lamina, the valvula, between the gemina and the lingula. Its cephalic part presents some slight corrugations, either a mesal furrow and a pair of lateral ridges, the frenulums (Fig. 4724), or—as in some figures—a mesal ridge as well. The fibres of the trochlearis nerve decussate (perhaps not entirely) in the valvula.

§ 99. Prop. LXIII. The *aqueduct.*—In all mammals the originally spacious mesocœle (Figs. 4690 and 4691) becomes reduced to a slender passage, the aqueduct or *iter a tertio ad quartum ventriculum.* As may be seen from Figs. 4684, 4711, and 4718, it is expanded or trumpet shaped at the cephalic end, and irregular in form at the caudal; the intermediate, longer part varies considerably in different individuals, being sometimes nearly cylindrical, but usually a transection presents points in two, three, or four directions, lateral, ventral, dorsal; the departures from the cylindrical shape are more frequent and distinct in the postgeminal and valvular portion (see Figs. 4711, 4724, and 4725), and may be regarded as vestiges or suggestions of the potentially tripartite condi-

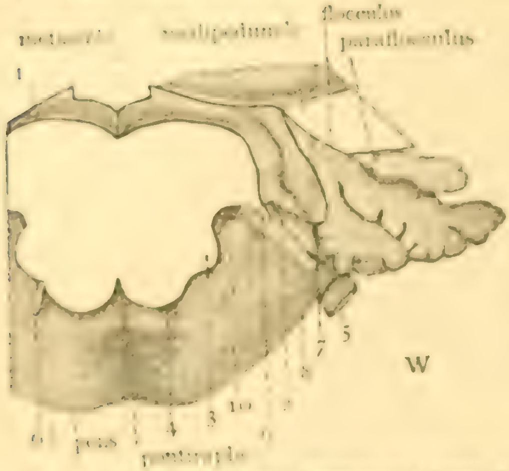

Fig. 4722.—[illegible]

[illegible]

tion which is actually present with birds and frogs (Figs. 4700 and 4701).

§ 100. Prop. LXIV. *Lemniscus and brachia.*—The lateral slope of the mesencephal presents three megascopic features, the lemniscus, postbrachium, and prebrachium, shown in Fig. 4724; in the former the fibres run approximately cephalo-dorsad, in the latter obliquely dorso-ventrad;

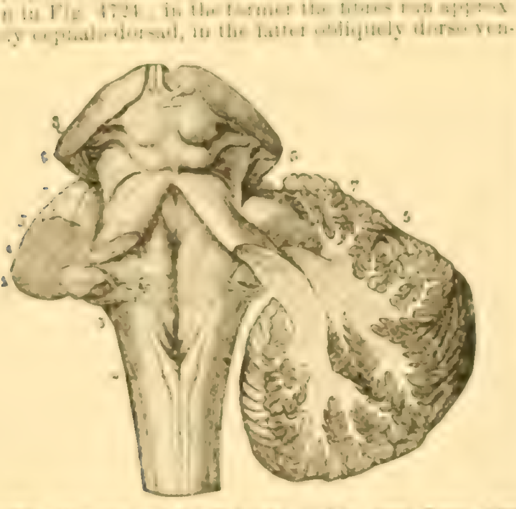

Fig. 4721.—Transection of the Pedunculus, × 1.5. From Quain, after [illegible]

[illegible]

their course and connections are considered in the following article, as is also the extent of the [illegible] called [illegible]. The lemniscus and its connections have been discussed at considerable length by Spitzka in the New York *Medical Record*, xxvi., 393, October 11, 18, 25, and November 1, 1884.

§ 101. Prop. LXV. *[illegible]*.—This is the least

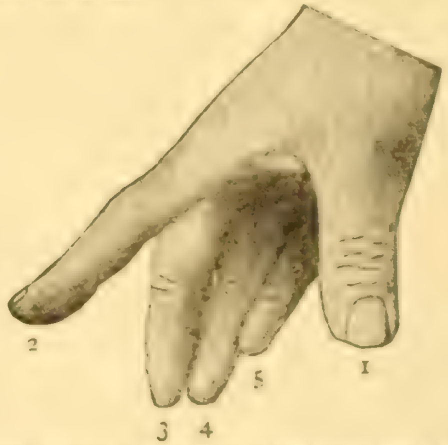

Fig. 4722.—Illustration of the Direction and Relative Size of the [illegible] by the Digits of a Right Hand. [illegible]

modified of all portions of the encephalic "central tubular gray"; its approximate extent at the level of the valvula is indicated by the [illegible] outline.

§ 102. Prop. LXVI. *The crura (crura cerebri).*—Excepting the parts already named, the mesencephal consists

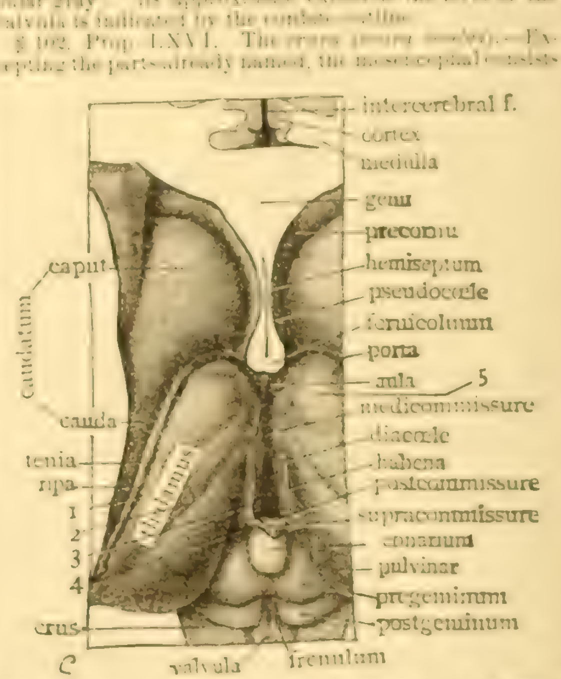

Fig. 4723.—Dorsal Surfaces of the Caudatum, Thalamus, and Mesencephal. [illegible]

[illegible]

mainly of a pair of fibrous masses (Figs. 4689 and 4712) containing the [illegible] motor and sensory conductors between the prosencephal and the metepencephal, thus between the body and the organ of mind. Each crus consists of two regions, a ventral, the crusta, and a dorsal, the tegmentum: Figs. 4724 and 4728.

§ 103. Prop. LXVII. *Intercalatum* (*substantia nigra, locus niger*).—A transection through the crus at almost any level reveals a dark mass (Figs. 4725 and 4728) of crescentic outline, approximately dividing the section into a ventral third and a dorsal two-thirds. Its lateral and mesal borders correspond to the furrows called *sulcus lateralis and s. oculo-motorius.* The name commonly employed refers to the distinctly dark color (due to pigment in the cells) of the mass in man and some apes; but the absence of color in other mammals has led Spitzka to propose (letter to the writer, December 28, 1887), a name referring to its more constant character of intercalation between the ventral crusta and the dorsal tegmentum.

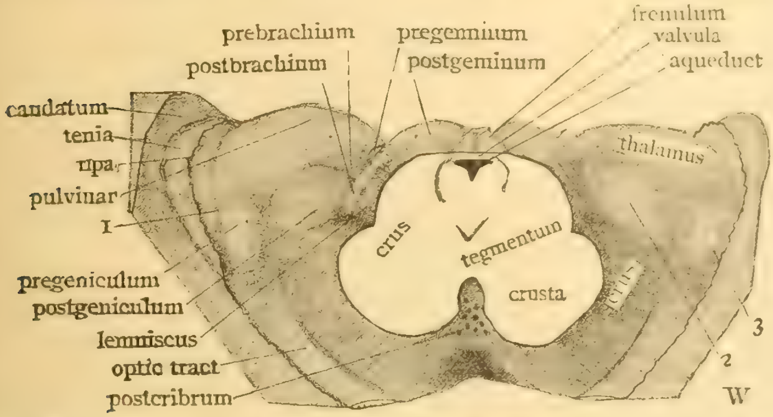

Fig. 4724.—Caudal Aspect of the Mesencephal and Part of the Diencephal. 2360; × 1.5. 1, Tenial sulcus; 2, right postgeniculum; 3, right pregeniculum

Preparation.—A well-hardened, alcoholic, adult brain was transected just cephalad of the pons, at a level indicated nearly by the line from *crus* in Fig. 4723. A block containing the thalami and adjacent parts was then cut out by incisions in various directions, the fornix peeled off, and the velum and other parts of the pia removed; the ink lines near the sides marked *ripa* indicate the lines along which the lateral margins of the velum, the paraplexuses, were torn away.

Defects.—More should have been left at the sides and ventrad. On the left, the roughly indicated curved line just laterad of the tenia was due to inadvertence, and may be disregarded. On the caudal, cut surface the heart-shaped outline was intended to indicate approximately the form of the mesocœlian entocinerea, the aqueductal "central tubular gray," but it is incomplete and perhaps not quite accurate. The intercalatum showed very faintly in the preparation and is omitted, but its location may be seen from Figs. 4725 and 4728.

§ 104. Points illustrated upon Fig. 4724.—A. Segmental overlapping. The thalami and geniculums project caudad beyond the intersegmental line, and the caudatum is here directly laterad of the thalamus instead of cephalad; consequently a transection through the pregeminum would divide not only the mesencephal but also both the diencephal and the prosencephal.

B. The caudal extension of the thalamus as a rounded eminence, the pulvinar on which, at the right, the word *thalamus* is placed.

C. The existence of two other eminences on this aspect of the diencephal, the postgeniculum, mesad and more distinct, and the pregeniculum, laterad and less distinct. With lower mammals, where the general mass of the thalamus is less developed than in man, the pregeniculum is not only still less prominent, but also decidedly cephalad, so that the prefixes *pre* and *post* are much more nearly appropriate.

D. The continuity of the optic tract with both the geniculums, more obviously with the pregeniculum.

E. The nearly complete concealment of the pregeminum, in this view of the parts, by the postgeminum; the former is seen at the left to project slightly.

F. The location and forms of the postbrachium and prebrachium; the former is between the two geminums, the latter just cephalad of the pregeminum; as they pass ventrad they embrace, as it were, the postgeniculum.

G. The location of the lemniscus, just caudad of the postbrachium.

H. The T-shaped section of the aqueduct, the reduced representative of the mesocœle.

I. The thinness of the mesocœlian roof, here constituted by the valvula, with a mesal furrow and lateral ridges, the frenulums.

J. The relatively extreme thickness of the mesocœlian floor, constituted by the crura.

K. The division of each crus into a ventral crusta and a dorsal tegmentum, the boundary between these two regions being defined partly by the lateral furrow, opposite the word crus, on the left, and partly by a pigmented tract, the intercalatum, not here seen, but shown in Figs. 4725 and 4728.

L. The deep ventral depression between the crura, constituting an intercrural area.

M. The presence at the cephalic end of this area of several rather large foramina for the transmission of arterial branches, whence this part is called postcribrum ("posterior perforated space").

N. The trefoil outline of the mesencephalic transection due to the ventrimesal and the two lateral depressions.

O. The obviously and unquestionably pial and ectocœlian character of all the natural mesocœlian surfaces.

P. The equally unquestionable continuity of these surfaces over the geniculums to the pulvinar.

Q. The absence of anything like a ripa on the visible surface of the thalamus until we reach the sharp and irregular line so marked at the left.

R. The endymal and ectocœlian character of the slender natural surface of the caudatum.

S. The continuation of this endymal surface upon the visible length of the tenia.

T. The significance of the ripa as not only a boundary between contiguous pial and endymal surfaces, but as indicating where the margin of the paraplexus or some membranous continuation of it has been torn away.

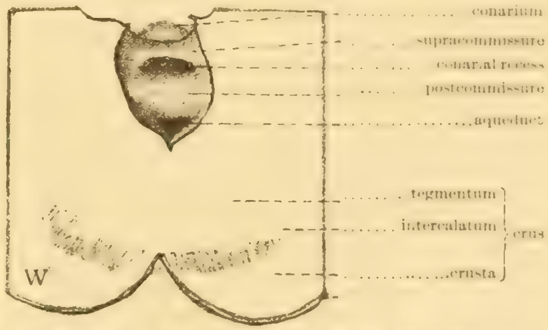

Fig. 4725.—The Postcommissure and Adjacent Parts. 2239; × 1.5.

Preparation.—The diencephal was transected just caudad of the medicommissure, and the cephalic aspect of the caudal part sliced down to near the level of the postcommissure; the diatela was torn away to admit more light. The figure should be compared with the mesal sections (Figs. 4684 and 4711), and with the dorsal aspect of the region (Figs. 4723 and 4728).

§ 105. Prop. LXVIII. The *postcommissure.*—The cephalic margin of the mesocœlian roof is of moderate thickness, and curved dorsad so sharply as to present a cephalic convexity (Fig. 4725) and a caudal concavity (Figs. 4684, 4711). It is probably not a true commissure but a decussation (Quain, ii., 321). Perhaps it belongs to the diencephal, or is *intersegmental* (Osborn, *American Naturalist*, October, 1887, p. 940).

§ 106. Points illustrated by Fig. 4725.—A. The appearance of the postcommissure as a cylinder; see, however, [illegible] and for the [illegible] figured by Dalton.

B. The considerable size of the medicommissure; although a large interthalamic [illegible] be apparently [illegible], it is larger than the [illegible] of the [illegible] in this specimen.

C. The existence of the supracommissure (commissura habenarum).

D. The relative position of these parts. In a less-modified condition of things the two commissures and the conarium should all lie nearly in one plane; but the presence of the supracommissural [illegible] has made the long axis of the conarium cephalo-caudal instead of dorso-ventral, and left the two commissures and the two callosa in a dorso-ventral series instead of a cephalo-caudal.

§ 107. DIENCEPHAL.—Synonyms: Diencephalon, deutencephalon, thalamencephalon, zwischenhirn, interbrain. Tabular arrangement of parts. Chief parts: thalami. Cavity: diacoele. Floor: tuber and diaterma. Sides: thalami. Roof: diatela (especially the velum). Plexus: diaplexus. Commissures and decussations: medicommissure, supracommissure, chiasma. Local expansions: albicantia, pregeniculum and postgeniculum. Perforated areas: preperforatum and postperforatum. Local elevations: taenia. Local depressions: trigonum habenae, ventral, and thalamic sulci. Local depression: sulcus Monroi. Appendages: conarium, hypophysis.

§ 108. Prop. LXIX. With the adult of man and all other mammals the primitively thin sides of the diencephal are greatly thickened and become the thalami, with the geniculums (pre- and post-) as latero-caudal elevations. The relations of the diencephal to the entire brain are well indicated in the young rabbit (Fig. 4694).

§ 109. Prop. LXX. In marked contrast with the massive sides the diencephalic roof is, for the most part, very thin, consisting apparently of the endyma only, closely attached to the ventral or diencephalic layer of the velum, from which are developed the parallel diaplexuses (Figs. 4690 and 4751) dependent at either side. Cephalad, the diatela is continuous with the auliatela or perhaps directly with the fornix dorsad of the aula and porta; caudad, it extends for some distance beyond the proper diencephalic boundary, is reflected ventrad upon the dorsal (properly cephalic) aspect of the conarium, and is then continuous with the supracommissure, and the conarium itself (Fig. 4711). The conarium and hypophysis are considered together in § 116.

§ 110. Prop. LXXI. The diencephalic floor is various in direction and composition. Beginning with the mesencephalic floor, the crura (Fig. 4711), there is a marked decrease in thickness in the region of the postcribrum (which may really be common to the two segments) as well as a deflection of the floor ventrad; the albicantia (Figs. 4689, 4711, and 4778) constitute lateral thickenings, and then the floor is reduced to an attenuated lamina, continuous with the valvula; this, with the shorter, the part just cephalad of the intervening and dependent hypophysis, constitute the tuber (tuber cinereum) and infundibulum. The fusion of the stems of the primitive optic vesicles to form the chiasma, and the fusion of this with the otherwise thin diencephalic floor, confers upon the latter in this region considerable thickness and firmness; but this part is again succeeded by the attenuated terma (Figs. 4711 and 4726), or rather the diaterma, in continuation from the preterma dorsad of the precommissure. Although the diaterma has a nearly dorso-ventral direction, it should properly be regarded as part of the floor, since the aula, the mesal division of the prosocoele, is morphologically cephalad of the diacoele, although actually more nearly dorsal.

§ 111. Points Illustrated by Fig. 4726.—A. The existence and completeness of the terma (lamina terminalis or l. cinerea), constituting the cephalic boundary of the mesal encephalic cavities; in the embryo it is actually the most cephalic part of the brain, but is later concealed by the projecting hemicerebrums.

B. The continuity of the terma with the chiasma, leading to the rupture of the former during the removal of the brain unless the optic nerves are early divided.

C. The extreme thinness and delicacy of the terma, which cannot be represented adequately in such a view, and is not fairly indicated in the outlines.

D. The existence of a somewhat thicker extension of the terma at each side, forming the cephalic boundary of the optic recess.

E. The pair of slightly raised bands, commonly termed the "peduncles of the corpus callosum."

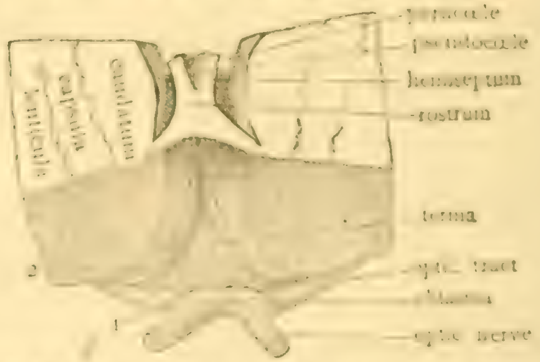

FIG. 4726.—Cephalic Aspect of the Terma ("lamina terminalis") and Adjacent Parts of a Young Adult. (× 1 [illegible].)

Preparation.—The brain was exposed by removing the skull with [illegible] and scissors so as to avoid injuring the terma. The optic nerves were divided close to their foramina of exit. After hardening in alcohol the parts adjacent to the terma were removed [illegible]

F. The convexity of the entocoelian surface of the caudatum (see also Fig. 4725).

G. The relation of the callosal rostrum to the hemiseptums, the lateral halves of the septum lucidum.

H. The somewhat unusual thickness of the hemiseptums in this specimen.

§ 112. Prop. LXXII. The mesal surface of the thalamus is divided into a dorsal and a ventral area by a slight furrow, sometimes hardly perceptible, the sulcus ("sulcus of Monro") (Fig. 4711), leading from the porta to the cephalic orifice of the mesocoele, and presenting a ventral convexity. At the dorsal margin of this surface is the habena, a slight ridge, with a dorsal convexity, extending from the porta to the supracommissure, which unites it with its opposite. Along the dorsal side of the habena is the habenal sulcus, and the two represent nearly the line of reflection of the endyma from the mesal surface of the thalamus upon the roof of the diacoele (see Figs. 4684, 4711, 4725, and 4751).

§ 113. Prop. LXXIII. Medicommissure.—Primarily separate, the opposed mesal surfaces of the thalami unite at about the fifth month of gestation according to Mihalkovics, giving rise to what is commonly called the "middle commissure" (Figs. 4684, 4711, 4725, and 4726). It is in a direct line between the porta and the aqueduct, considerably nearer the former, and just dorsad of the sulcus. The shorter, dorso-ventral, diameter is 4.5 mm., the longer, cephalo-caudal, 6-7. Sometimes it is said to be in two parts, one above the other; it is absent, according to Wenzel, ten times out of sixty-six. It consists mainly of cells (with, according to W. Krause, some fibres) and is so soft as to be commonly torn during the removal or manipulation of the brain. It is relatively larger in most other mammals; the functions are experimentally unknown, but in a man (Mall) and a cat (the writer, article Malformations of the Brain) lacking the callosum, it was larger than usual.

§ 114. Points Illustrated by Fig. 4727.—A. The size, form, and connections of the medicommissure; it is relatively smaller than in the cat, and slightly constricted about its middle; if isolated it would have the form of a pulley-wheel with a shallow groove.

B. The relations of the mesal aula to the portas and to the diacœle; of the space commonly called "third ventricle," the strictly interthalamic portion only constitutes the diacœle, while that part which intervenes between the fornix and a line drawn between the two projecting points (1) of the thalami must be regarded as the mesal division of the prosocœle; it and the two portas are sometimes embraced within the single term *Foramen of Monro,* but this name more properly applies to each porta; see the writer's article in *Boston Medical and Surgical Journal,* August 12, 1880.

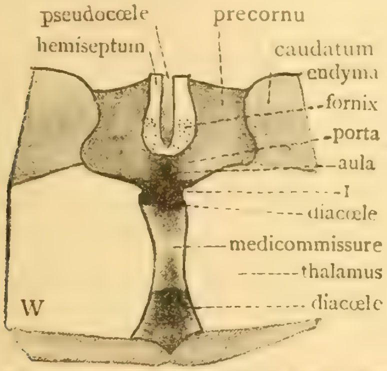

FIG. 4727.—The Medicommissure and Adjacent Parts. 2032; × 1.3. (Compare Fig. 4723, where some of the same parts are shown on a smaller scale.)

Preparation.—The brain was removed with care so as not to tear the medicommissure, and alcohol was injected *per luram* so as to harden the parietes and keep them apart. The prefrontal lobes were then removed, thus opening the precornua and exposing the caudatums; with these as guides the block containing the medicommissure was safely isolated; the thalami are cut away almost to the level of the commissure. This is the only specimen in the museum with this easily injured part complete.

C. The thinness of the lamina uniting the two halves (columns) of the fornix. This lamina must be regarded as the primitive prosocœlian terma as high as the dorsal limits of the porta, and may, therefore, be called the *prosoterma* (see a figure in the article Malformations of the Brain).

§ 115. Prop. LXXIV. The pregeniculum and postgeniculum are represented in Figs. 4723 and 4724, and described in connection therewith; the optic tract and the chiasma are shown in Figs. 4689 and 4726, and considered in connection with the optic nerves in the article, Cranial Nerves, Vol. II.

§ 116. Prop. LXXV. *Conarium* and *hypophysis.*—Excepting the lancelet (*Branchiostoma*) every known vertebrate has both these apparently functionless organs. This constancy alone would justify us in regarding them with interest, but as described under Development of the Brain, Vol. I., p. 638, the hypophysis has a double constitution and origin, from the brain (posthypophysis), and from the enteron (prehypophysis), while the number of forms in which has been traced a connection between the conarium and a rudimentary mesal eye is so great as apparently to warrant the view that it is the remnant of a primitive mesal organ of vision. Herdman thinks the hypophysis also may have been an ancestral sense organ (*American Naturalist,* 1888, p. 1127), while Max Flesch holds that the mammalian conarium is connected with the temperature apparatus.

§ 117. Prop. LXXVI. Peculiar topographical relations of the conarium.—Although directly connected with the thalami, the conarium leans caudad so as to rest upon the pregeminum; the cephalic aspect of the cerebellum rests upon the postgeminum and abuts against the conarium; finally the callosum, a cerebral commissure, has its splenial curvature upon the conarium. Between all these parts, of course, there are membranes and vessels, but if they are disregarded, the [illegible] of one segment, the diencephal, may be described as encompassed by three others, the mesencephal, the epencephal, and the prosencephal. With a brain hardened in its natural shape, a disk 2 ctm. in diameter will cover parts of all four encephalic segments; see Figs. 4684 and 4711.

§ 118. Prop. LXXVII. *Acervulus.*—The adult conarium frequently has imbedded in follicular cavities calcareous particles known by the above name, and as "brain-sand;" in the brain shown in Fig. 4711, it was so abundant as to leave a considerable cavity when removed, as shown in the *New York Medical Journal,* March 21, 1885.

§ 119. Points illustrated by Fig. 4728.—A. The form, direction, and complete separation of the albicantia; they are usually represented (as in Figs. 4689 and 4712) as hemispherical elevations; here they are seen to be elliptical in outline, their longer axes converging caudad, and the caudal ends overhanging the posteribrum; in the cat and in mammals generally the albicantial sulcus is a shallow depression or wholly absent.

B. That the hypophysis is wider than long, and consists of two parts, conveniently called *prehypophysis* and *posthypophysis*; the latter is the smaller and partly as it were let into an emargination of the former.

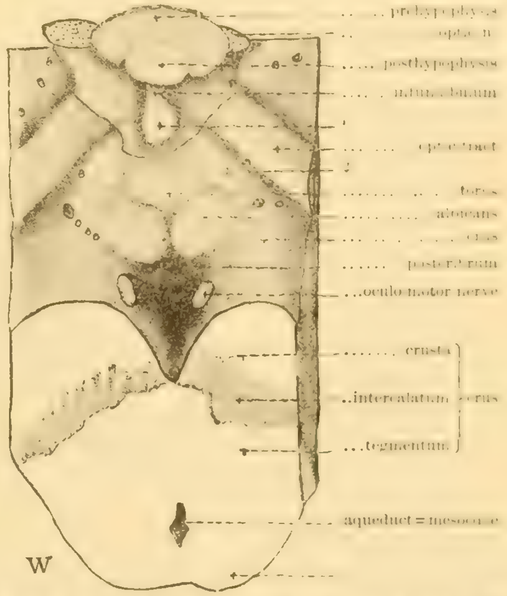

FIG. 4728.—The Torus (*tuber cinereum*) and Adjoining Parts. 706; × 1.5. (The same region is shown in Figs. 4689 and 4712, upon a smaller scale.) 1, Expanded proximal end of the infundibulum, covering the lura, which is exposed in Fig. 4689; 2, a slight elevation between the torus and the optic tract. The irregular line across the torus and optic tracts represents the cut or torn edge of the pia, which adheres quite firmly to the chiasma. The black spots represent the foramina in the posteribrum and elsewhere through which vessels passed; the triangular region laterad of the chiasma is a part of the precribrum ("anterior perforated space").

Preparation.—The brain was removed with great care, the hypophysis being extricated from its fossa by dividing the dural folds in several directions with the sharp point of a scalpel, and then introducing the blunt-pointed syringotome. This is the only preparation in the University museum to which the hypophysis remains attached. Its [illegible] by the movements of the alcohol during hardening was prevented by passing a fine entomological pin through it and the chiasma, which is very firm.

Defects. The natural surfaces of the crura should have presented a more fibrous appearance (somewhat as in Fig. 4712), and another preservative than alcohol would have differentiated the colors on the cut surface. The albicantia have perhaps the appearance of overlapping the posteribrum too far, but this is more nearly correct than the usual representation, as for example, in Figs. 4689 and 4712. The left intercalatum should be shown more nearly like the right.

C. The expanded base of the infundibulum (1).

D. The raised, unnamed area (2) at either side of the torus.

E. The demarcation of the crura from the tegmentum by the intercalatum.

F. The slight, angular extremities of the [illegible] (appendix), which otherwise is almost circular in outline.

§ 120. PROSENCEPHALON.—Synonyms: Prosencephalon, fore-brain, secondary fore-brain. Tabular Arrangement of Parts: Chief parts: hemicerebrums. Cavity: prosocœle (including the aula and the following in pairs: porta, paracœle, cella, precornu, medicornu, and postcornu). Floor: [illegible]. Sides: caudatum, hemiseptum. Roof: [illegible], callosum. Commissures and decussations: callosum, precommissure, fornicommissure. Enlargements: callosum, etc. Intercalatum, porta. Detached [illegible], lentiform. Cinerea: [illegible] elevations: [illegible], hippocampus, calcar, occipital eminence, collateral eminence, [illegible] eminence of the [illegible]. Total elevations: gyres, insula. Total depressions: fissures. False cavity: Pseudocœle. Plexuses: proplexus (including auliplexus, portiplexus, paraplexus). Line of plexal intrusion: rima. Ripatiæ parts: tænia, fimbria. Atrophied parts: prosoterma, hemiseptum, pars.

§ 121. Prop. LXXVIII. The prosencephal comprises the two lateral masses, hemicerebrums, the mesal parts by which they are connected, and a pair of olfactory bulbs, with their crura.

122. Prop. LXXIX. The olfactory bulbs with their crura (Figs. 4684, 4689, and 4718), at and after birth, are relatively so small as to be commonly regarded as insignificant appendages of the cerebrum, or even as mere nerves; but their constancy throughout the vertebrate branch (even *Amphioxus* is said to have a single, unsymmetrical olfactory lobe), their great size among many lower members of the branch and even with many mammals, their mode of development, their direct connection with the hemicerebrums (Figs. 4708 and 4782), their relation with the precommissure in most mammals, and the persistence with all mammals excepting man and perhaps the apes of a cavity, the rhinocœle, continuous with the paracœle, justify their recognition as of considerable morphological significance. As intimated in § 15, it is not impossible that they may prove to be primary, and the "cerebral hemispheres" secondary. For the present, however, and in this part of this article, it can only be added that from the slightly enlarged bulbs are given off the true olfactory nerves to the nasal mucosa; see article Cranial Nerves, Vol. II.

§ 122. Points illustrated by Fig. 4766.—A. The existence of the paracœle, medicornu, precornu, paraplexus, and porta in the cat substantially as in man.

B. The absence of a postcornu.

C. The larger relative size of the precornu.

D. The continuation of the precornu through the olfactory crus into the bulb, as a perfect rhinocœle slightly enlarged at the extremity, as in most mammals other than man.

E. The bifid condition of the medicornu is exceptional; it commonly ends roundly or with a single blunt point.

§ 123. Prop. LXXX. Primarily the cerebrum is a pair of lateral extensions of a small mesal rudiment, the first (cephalic or "anterior") encephalic vesicle; this forms their only bond of union with one another and with the other segments; their walls are thin and vary little in thickness or composition. Secondarily, the two hemicerebrums are closely connected by the callosum and other commissures; between the cerebrum and the crura (and thus the oblongata, the myel, and indirectly the entire body) are developed extensive fibrous communications, the capsules or "internal capsules;" the parietes are for the most part extraordinarily thickened, the most notable, and physiologically the most important of these increments constituting what are commonly called the "corpora striata" from the appearance presented on sections of alternating stripes of alba and cinerea. Each striatum, however, is now recognized as composed of an entocelian ("intraventricular") portion, the caudatum, and an ectocelian ("extraventricular") portion, the lentiform ("lenticular" or "lentiform nucleus"), separated by the capsula already mentioned (see Figs. 4722, 4726, 4751 and 4772).

§ 125. Prop. LXXXI. The striatum.—With all Reptiles, Birds and Mammals, and at a very early period (Figs. 4692, 4709, 4710, 4725, 4726, 4727, 4746 and 4768), the lateral wall and floor of the paracœle present a more or

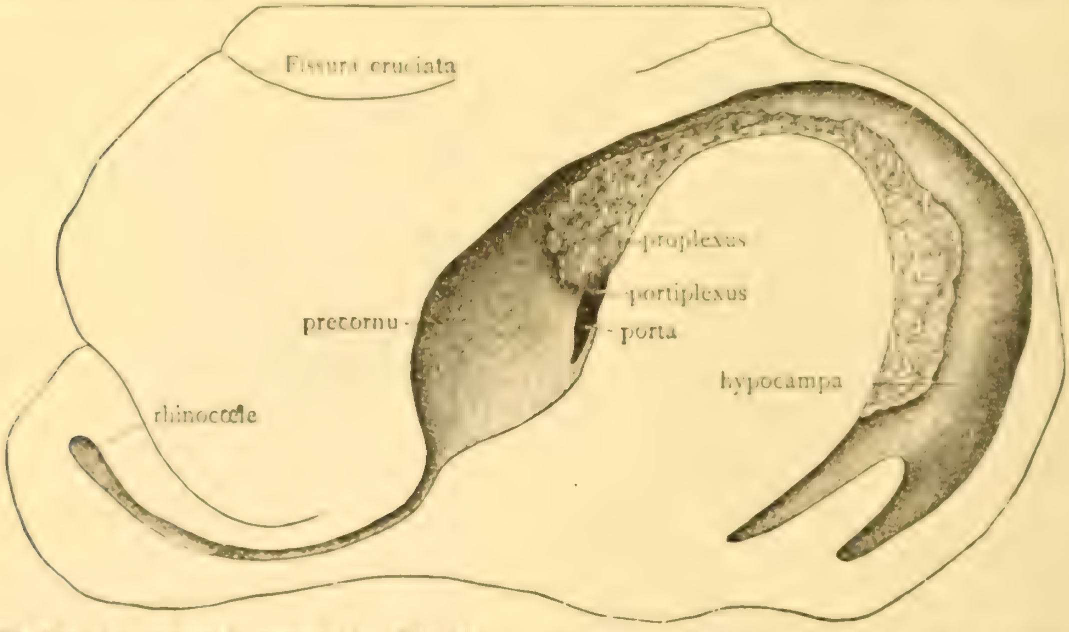

FIG. 4766.—The Left Paracœle and Rhinocœle of a Cat. [illegible]

[illegible]

less distinct elevation; in man, and some other mammals the form is such as to suggest the application of *caput* to the cephalic (precornual) portion, and *cauda* to the tapering continuation along the medicornu, thus of *caudatum* to the entire mass. It is a modification and differentiation of the entocinerea, and may perhaps be regarded as the colliculus collocated with the Sylvian fissure (Fig. 4709).

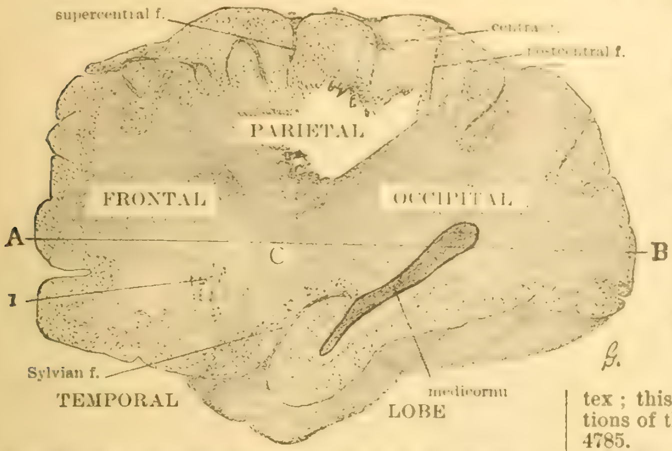

FIG. 4730.—The Right Hemicerebrum of a Male Negro, Dissected to Show the Location of the Capsula. 2397; × .5.

Preparation.—The fresh hemicerebrum was supported on a bed of cotton on its lateral surface, a large, thin-bladed knife, kept wet with alcohol, was used to remove thin slices from the mesal aspect until a distinct patch of alba was encountered opposite the porta; from this as a centre (C) oblique incisions were made in three directions, cephalad, caudad, and dorsad, thus removing thin wedge-shaped slices until, excepting the cortex, cinerea was visible only in scattered patches (1); the preparation was photographed and then divided along the line A B, and the dorsal surface of the ventral part photographed (see Fig. 4731).

Defects.—The brain was far from fresh and so soft that the sections were made with difficulty and certain important points as to the distribution of the alba and cinerea about the medicornu could not be determined. A more satisfactory preparation could be made by first dividing the entire hemicerebrum along the line A B, and then removing the wedge-shaped slices, after which the dorsal and ventral parts could be joined if desired. All this could also be accomplished more easily upon a brain so preserved as to indicate the cinerea and alba more perfectly than alcoholic specimens.

§ 126. Prop. LXXXII. The *lenticula.*—Between the caudatum and the cortex the greatly thickened hemicerebral wall presents (*a*) the medullary lamina called *capsula* (§ 127); (*b*) next the cortex, a sub-circular disk of cinerea, the *claustrum* (better shown in Fig. 4795); and (*c*) the *lenticula*, consisting of three zones, all more or less striated, the ental the smallest, and the ectal, also called *putamen*, the largest (Figs. 4731 and 4732). The lenticula, like the claustrum, may be a dismemberment of the cortex. This entire region, from caudatum to operculums, is of great morphological as well as physiological interest and should be studied in the other mammals.

§ 127. Prop. LXXXIII. *Capsula* and *corona.*—As already stated (§ 124) the capsula or "internal capsule" is the thick layer of fibres between the caudatum and thalamus mesad and the lenticula laterad; it is continuous with the crura caudad, and expands in the substance of the cerebral alba in such a way as to be called there *corona* (*radiata*). The histological and physiological aspects of the capsula and corona are considered in the following article, and in Vol. I.; here an attempt will be made only to indicate their topographical relations by explanations of the accompanying figures (4730, 4731, and 4732).

§ 128. Points illustrated upon Fig. 4730.—A. The existence of a stratum of alba, white, medullary or fibrous nervous tissue, the capsula, between the lenticula laterad and the caudatum and thalamus respectively meso-cephalad and meso-caudad.

B. The completeness of this albal interval between the three cinereal masses, excepting in the cephalo-ventral region (1), where the amygdala, caudatum, and lenticula are loosely connected.

§ 129.—Points illustrated upon Fig. 4731.—A. The general relations of the alba (medulla) to the ectocinerea (cortex).

B. The locations of the two great masses of entocinerea (central tubular gray), the caudatum and the thalamus.

C. The intermediate position of the lenticula, as a blunt wedge-shaped mass between the caudatum and thalamus.

D. The position of the capsula ("internal capsule") as a stratum of alba between the lateral lenticula and the other two masses, and constituting a fibrous path for motor and sensory conduction between the cortex and the crura.

E. The existence of two zones in the lenticula, the more lateral being distinguished as *putamen*; a third would have appeared at a level farther ventrad (Fig. 4732).

F. The existence of a thin, cinereal lamina ectad of the lenticula, between it and the cortex; this is the claustrum; it and the cortical corrugations of this region are shown upon a larger scale in Fig. 4785.

§ 130. Points illustrated upon Fig. 4732.—A. the existence and relative positions of four important masses of connecting fibres, the *callosum*, *forniculumns*, *precommissure*, and *chiasma*, differing from one another in either their direction or their appearance upon this section. The most ventral, the chiasma, is mainly a decussation (as described in Vol. II., article Cranial Nerves. The next, precommissure, is a true commissure, connecting corresponding regions of the temporal (and frontal ?) lobes; at the meson it is seen as a raised transverse band, but laterad, on account of its deflection caudad, it is divided

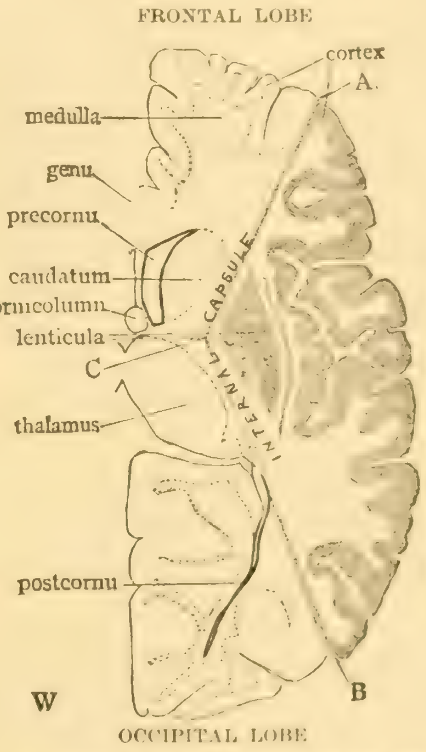

FIG. 4731.—Longisection of the Right Hemicerebrum (Fig. 4730) at the Level of the Aula. × .05; from nature 2397 and from Gray.

Preparation.—See Fig. 4730. The mesal outlines of the removed frontal and occipital regions were adapted from Gray. The plane of section corresponds nearly with the direction of the dotted line from *aula* on Fig. 4732.

obliquely, and appears as an elliptical [illegible] area. The two hemicerebrums have at this level a nearly dorso-ventral direction, appearing as equal bands just dorsal of the precommissure (the band forms the [illegible] most clearly upon the right), but they are curved in such a way as to be divided obliquely in two places—one at the level of the precommissure and the other about one centimetre [illegible]. Finally the callosum, a true commissure, uniting corresponding regions of the cerebrum, is divided in the direction of its fibres.

B. The general relations of parts and cavities at this important level. Two segments are represented—the diencephal (thalamus, chiasma, etc.) and prosencephal (the remainder) and much the larger part. Of the cavities, the mesal space between the chiasma and precommissure is the cephalic part of the diacoele, the dorsal portion being the optic recess. The prosocoele is represented by the aula, the mesal space dorsal of

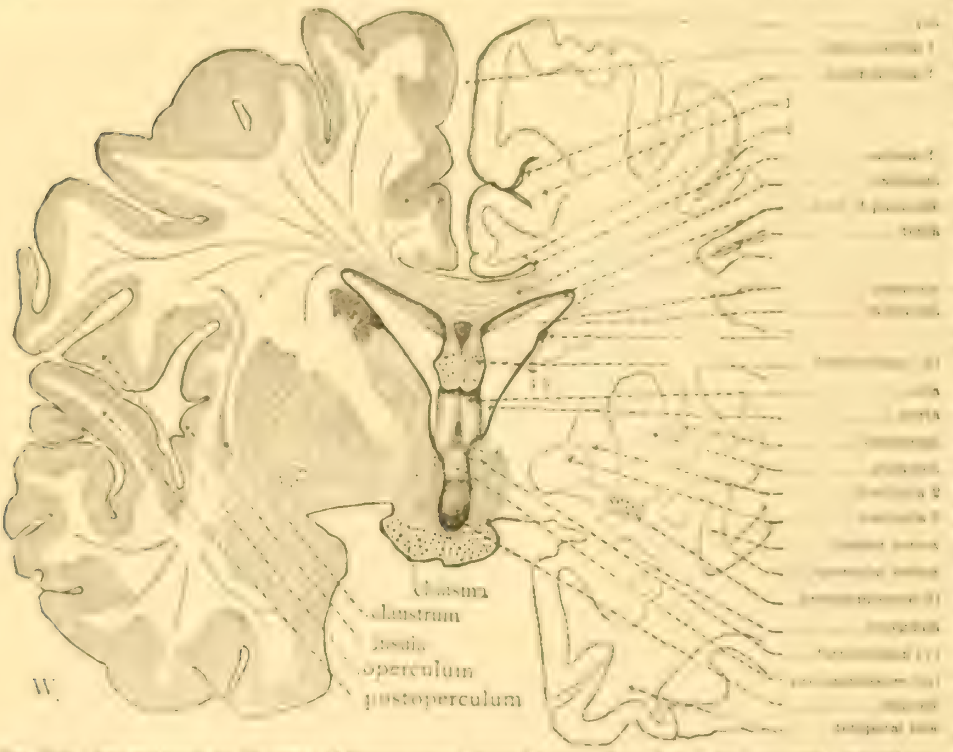

FIG. [illegible].—[illegible]

and including the precommissure; by the considerable lateral cavities, *paracoeles*; and by the intervening *portas*. All these are true encephalic cavities, but the dark, triangular area still farther dorsad is the pseudocoele, a space included as a result of secondary changes (§ 62 E and Fig. 4765). Three kinds of surfaces are included, viz.: entocoelian, lined by endyma; ectocoelian, covered by pia; and pseudocoelian, with no distinct membrane. There is cinerea (cortex, caudatum and thalamus), and what may, for the sake of a general term, be called [illegible] the lenticula and the claustrum, probably [illegible] of the [illegible].

C. The extension of the hemicerebrum nearly equally in three directions from the place of its morphological center, the porta; were this brain not somewhat depressed by its own weight, the width and height would be nearly the same.

D. The thickness of most of the parietes as compared with the earlier fetal conditions shown in Figs. 4708 and 4760, the hemicerebrums and the terma, however, have retained their tenuity in great degree.

E. The absence of the fornicula, which was seen in a young brain (Fig. 4758), and is constant in the cat (Fig. 4760); whether it is replaced or merely obscured in the human adult is not known.

F. The overlapping of the precommissure at the sides of the cephalic part of the caudatum upon the thalamus.

G. The relations of the several layers of alba and cinerea between the thalamus and the lateral surface of the cerebrum. The capsula (?) has an oblique direction, dorso-laterad, between the thalamus and caudatum, and the lenticula (see Fig. 4760). The lenticula itself comprises three more or less distinct segments, each extending farther dorsad than the one mesad of it; and presents the alternating lines of white and gray which led to the application of *striatum* to the united lenticula and caudatum. The thin lamina of cinerea between the putamen, the most lateral division of the lenticula, and the insular cortex is the claustrum; and the alba between it and the lenticula is commonly, but inappropriately, called the "external capsule."

H. The relations of the insula to the parts just named, and to the several plications which constitute the operculum (see Fig. 4696).

I. The relation of the cinereal mass called *amygdala* to a fissure opposite the [illegible] of postoperculum, which has thence been named the amygdaline fissure (Figs. 4766 and 4770).

§ 131. Prop. LXXXIV. The *precommissure* (anterior commissure).—In all medisections of the brain (Figs. 4684, 4711, 4738, and 4766) nearly dorsal of the chiasma is to be seen a marked thickening of the parietes, which remain thin ventrad (chiasma) and dorsad (precommissure); this thickening is the precommissure, a compact bundle of nerve fibres, transverse laterad with a slight ventral and caudal deflection, into the temporal lobes of the cerebrum (Figs. 4772 and 4743). With most other mammals it divides, at a little distance from the meson, into two portions, a temporal, alone perhaps represented in man, and an olfactory, which passes cephalad to the olfactory bulbs, with, especially in the lower mammals, a subdivision to the frontal lobes. This olfactory portion is probably primary and of greater morphological importance than the other.

§ 132. Prop. LXXXV. Besides the precommissure, a medisection displays two extensive lines of cut surface (Figs. 4684, 4698, 4711, and 4766), indicating that there was a continuity of the apposed mesal surfaces of the two hemicerebrums. Of these the dorsal, more extensive and more substantial, is the *callosum* (Figs. 4732, 4733, 4743, and 4744); the ventral is the *fornicommissure* or mesal part of the fornix (Figs. 4734 and 4737). The development of these parts is considered in Vol. I. 539, and the writer of that article has since published important papers respecting them and the precommissure. Here space will permit of only brief descriptions of the adult conditions with special reference to the points shown in the figures.

§ 133. Prop. LXXXVI. The *callosum.*—When the fresh hemicerebrums are divaricated, as in Fig 4733, the bottom of the intercerebral fissure is seen to be formed by a white mass which unites them for more than the middle third of their length; upon hardened brains this, the callosum (*corpus callosum, trabs cerebri*, etc.), is easily determined to be fibrous, and somewhat firm in consistency, and to extend into the hemicerebral masses. At about the middle of its cephalo-caudal extent, the trend of the callosal fibres is almost directly laterad, but at the cephalic and caudal ends, especially the latter, the direction is oblique, giving rise to the conditions known as *preforceps* and *postforceps* (Figs. 4688, 4690, and 4691). The rounded cephalic region of the callosum is called *genu*, and the caudal, *splenium*. As seen in medisections (Figs. 4684, 4711, and 4718), the genu obviously represents a folding of the callosum upon itself, the ventral continuation being the *rostrum*, which, in man and perhaps in apes, is connected with the terma by the thin *copula*. The gentle curve of the genu gives to the cephalic part of the pseudocœle a rounded outline.

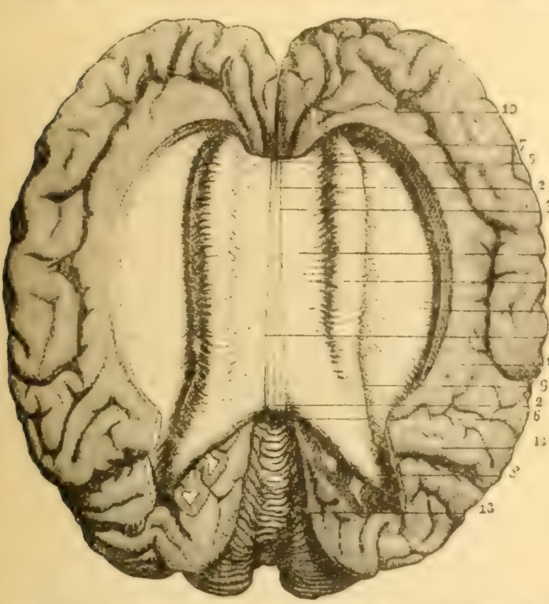

FIG 4733.—The Dorsal Aspect of the Callosum, Exposed by Divaricating the Hemicerebrums. From Quain, after Sappey and Foville; × 0.5. 1, Dorsal surface of the body of the callosum; 2, mesal ridge or raphé; 3, lateral ridges, bounding furrows in which, sometimes at least, are lodged the precerebral arteries; 4, lateral ridge, said to be formed by the arching of the callosum over the paracœle; 5, cephalic curved margin, genu; 6, caudal curved margin, splenium; 7, preforceps, callosal fibres passing cephalad into the frontal lobes; 8, postforceps, fibres entering the occipital lobes; 10, cephalic portion of the callosal gyre, the line crossing the cephalic end of the supercallosal fissure; 11, callosal fissure; 12, caudal part of the callosal gyre, the line crossing the paracentral gyre; 13, cephalic surface of the cerebellum, the number being just caudad of the occipital fissure

Preparation.—While fresh the dorsal portions of the hemicerebrums were separated widely; the curved margin of the callosal gyre ("*gyrus fornicatus*") has been detached and pushed laterad so as to expose more completely the extension of the callosal fibres into the hemicerebrum; caudad this gyre has been divided.

§ 134. Prop. LXXXVII. The *splenium.*—This region of the callosum is much less easy to understand than the genu from the study of normal adult brains, but most of the difficulties are removed or diminished by the study of fœtal and hydrocephalous specimens (Figs. 4734 and 4757). From these it is clear that, like the genu, the splenium represents a flexion of the callosal sheet upon itself so that there is a dorsal lamina, a ventral lamina, and a caudal connecting portion; commonly the dorsal and ventral portions are in close contact, but in hydrocephals (Fig. 4734), as in the fœtus at a certain stage, they are separated by a considerable interval; in these cases the pseudocœle has a greater extent and a somewhat rounded caudal end.

§ 135. Points illustrated upon Fig. 4734.—A. The complete separation of the fornix and callosum as far as the splenium, which is thus a common bond between them, although usually, and perhaps properly, reckoned as a constituent of the callosum only.

B. The concomitant extension of the pseudocœle and of the hemiseptum.

C. The large size of the porta.

D. The wasted appearance of the visible gyres, in contrast with those of Chauncey Wright (Fig. 4779).

§ 136. Points illustrated upon Fig. 4735.—A. The lapping of the cerebrum upon the diencephal, so that the transection of one includes the other.

B. The folding of the pia covering the now apposed dorsal surface of the thalami and the ventral surface of the cerebrum so as to constitute the velum (see Fig. 4751), but since this figure does not represent the lapping of the prosencephal upon the diencephal at the *sides*, or the

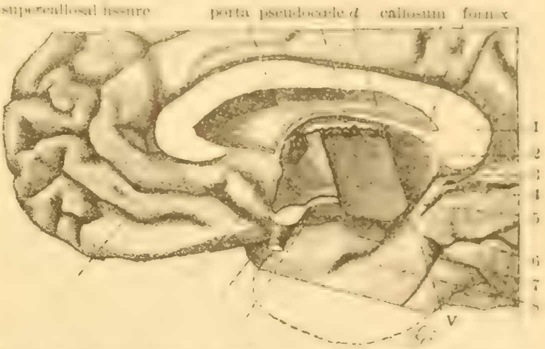

FIG. 4734.—Mesal Aspect of Part of the Left Hemicerebrum of an Adult Hydrocephalus. 747; × 7. The dorso-ventral line *d v*, indicates the transection plane represented in a figure in the article Malformations of the Brain. 1, Splenium; 2, ventral surface of fornix; 3, subsplenial gyres; 4, 5, ?; 6, collateral fissure; 7, uncus; 8, hippocampal fissure. The tip of the temporal lobe, included by the interrupted line just cephalad of *v*, indicates what was removed to expose the parts shown in Fig. 4752.

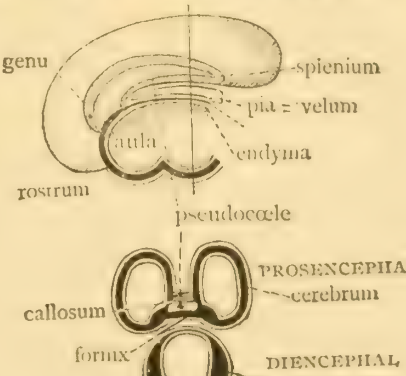

FIG 4735.—Diagrams Illustrating the Relations of the Callosum, Fornix, and Pseudocœle, the Constitution of the Velum, and the Superposition of the Prosencephal. Modified from diagrams published by the writer in the *New York Medical Journal*, February 16, 1884.

Defects.—The aula, the mesal part of the prosocœle, is shown of equal size with the diacœle, and on the same level; this is not the case, so far as the writer is aware, with any vertebrate in which the callosum and fornix attain dimensions such as are indicated in the figure (see Fig. 4766), but so far as concerns the special objects of the figure, the above inconsistency may be ignored. Unlike most of the figures the substantial nervous parietes are represented by the heavy black line, the pia and endyma by lighter ones.

formation of the rima and paraplexus, the pia of the two segments is continued independently around each.

C. The theoretical constitution of the [illegible] tract is (1) the pseudo[illegible], though not always actual, continuation of the [illegible] at the sides; (2) the [illegible]; (3) the [illegible] pia, one or both layers according to the closeness of their adhesion.

D. The relations of the callosum, fornicommissure, and paraplexus: the two former represent two lines of secondary junction between the apposed mesal surfaces of the hemicerebrums; they are coëxtensive at the splenium and [illegible] in front of the cephalic end; the space thus

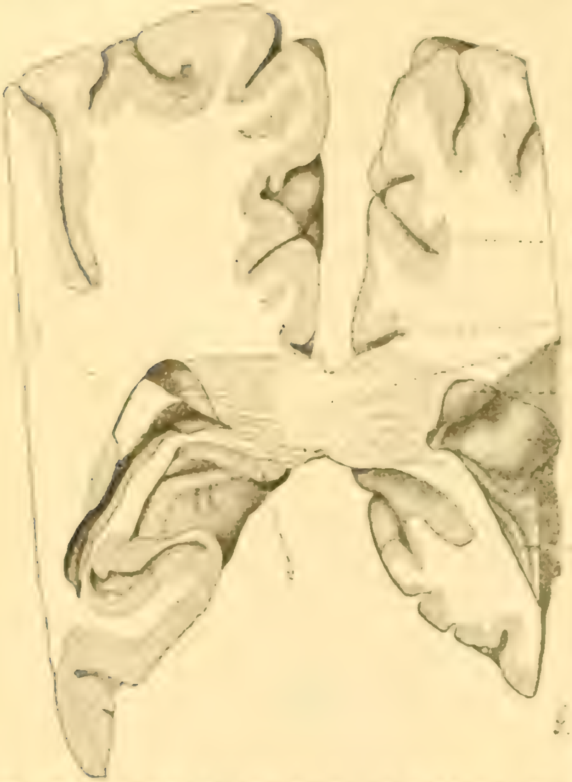

FIG. 4756.—Transection of an Adult Brain Through the Splenium. [illegible]

Preparation.—[illegible] New York Medical Journal [illegible]

Fulcrum.—[illegible]

interrupted, like the lumen of a partition, is the pseudocele or "fifth ventricle." It is really narrow, but the relations are as indicated.

E. The general constitution of the fornix more fully described in § 139.

§ 137. Prop. LXXXVIII. For the most part the callosum extends dorsad of the paraplexus (thus constituting their actual though not primary roof), but the fibres extending obliquely cephalad and caudad from the genu and splenium are parts of the mesal wall of the precornua and postcornua respectively, while those which compose the ventral lamina and the splenium are parts of the paracœlian floors, continuous with the fornix (Figs. 4756 and 4755).

§ 138. Points illustrated by Fig. 4756.—A. The continuity of the splenium with both the floor, roof, and caudo-mesal wall of the postcornua; some of the fibres pass dorsad, some ventrad into the hippocamp, while others, constituting the postforceps, extend caudad into the calcar, dorsocaudad into the occipital eminence, and ventro-caudad into the collateral eminence.

B. The unusual distinctness of the occipital eminence, this being, in fact, the preparation in which it first attracted the writer's attention (see Fig. 4764).

C. The prominence of the calcar; both seen, of course, greatly foreshortened; of the left hippocamp only a segment of the caudal convexity appears in this preparation, with the collateral eminence just beyond (compare Fig. 4750).

§ 139. Prop. LXXXIX. *Fornix* is a collective noun, a comprehensive name applied to a congeries of parts, each of which has its own name, and all of which, with a single exception, may exist in lower vertebrates and in man or other mammals, in certain anomalies, without the formation of the fornix as a whole.

§ 140. Prop. XC. *Fornicolumna.*—In each hemicerebrum there is a bundle of fibres ascending from the albicans and thalamus, passing just caudad of the precommissure, forming the cephalic boundary of the porta, diverging presently from its opposite, pursuing a curved direction along the floor of the medicornu and ending in the temporal lobe; in the mesal region where it is most compact and exposed, this is called an "anterior pillar of the fornix;" herein fornicolumna.*

§ 141. Prop. XCI. *Hippocamp.*—In each hemicerebrum there is a corrugation of the entire thickness of the parietes, resulting in the formation of a total fissure, the hippocampal (§ 204, C) and an entocœlian eminence, or colliculus, the hippocamp, along the medicornu; the hippocamp is thickened also, and intimately associated with the fibres of the fornicolumna already mentioned.

§ 142. Prop. XCII. *Fimbria.*—In each hemicerebrum between the hippocamp, with its corresponding cortex and the rima or line of intrusion of the paraplexus, there is a zone consisting of white fibres, and forming, as it were, a margin for the hippocamp (Figs. 4746, 4752, and 4755). This is the fimbria, corpus fimbriatum, *taenia hippocampi*.

§ 143. Prop. XCIII. The fornicolumna and its caudal curved extension, the hippocamp and the fimbria, are simply portions of the paracœlian parietes, mainly of the paracœlian floor; they are continuous with the mesal wall, lamina septum (Fig. 4751), and thus indirectly with the roof (callosum); excepting at the ventral end, in the tip of the temporal lobe, however, their substantial continuity with the callosum and roots and other portions of the paracœlian parietes is interrupted by the rima. It would be perfectly legitimate, therefore, to designate the irregular, elongated portion of either paracœlian floor, composed of hippocamp, fimbria, and fornicolumn by a special name, *e. g.*, [illegible].

§ 144. Prop. XCIV. *Fornicommissure.*—The parts composing either hemifornix pertain each to its own hemicerebrum, and in brains where the callosum is undeveloped (see article Malformations of the Brain), these have no connection across the meson dorsad of the aula and porta, representing the primitive mesal cavity of the prosencephal. But as the callosum itself is a line of secondary union of apposed mesal surfaces of the hemicerebrums at one level, so at a more ventral level, contiguous cephalad with the primitive precommissure, at each side of which is the fornicolumna, and continuous caudad with the ventral lamina of the splenium, the two hemifornices are united by a lamina of greater or less thickness, the fornicommissure. This is not, at least in man, apparently a true commissure, or even fibrous in structure, and a name like *fornical fusion* might be more appropriate.

---

* The application of "pillar" or "column of the fornix" to the [illegible]

§ 145. Prop. XCV. *Septum lucidum.*—Like the fornix, this is composed of two independent parts of the two hemicerebrums (Figs. 4723 and 4735); each half (hemiseptum) is a portion of the mesal wall of the paracœle which has been demarcated from the rest by the formation of the callosum and fornicommissure; the thinness in man is by no means common among other vertebrates, so that the adjective *lucidum* is not only superfluous but inappropriate.

§ 146. Prop. XCVI. *Pseudocœle* ("fifth ventricle").—This is the space between the two apposed halves of the septum (hemiseptums); it was originally merely a part of the intercerebral interval or fissure, but is isolated therefrom, partly in other animals, but completely in man, by the continuity of the callosum with the fornix at the splenium and at the copula (Figs. 4711, 4723, and 4735).

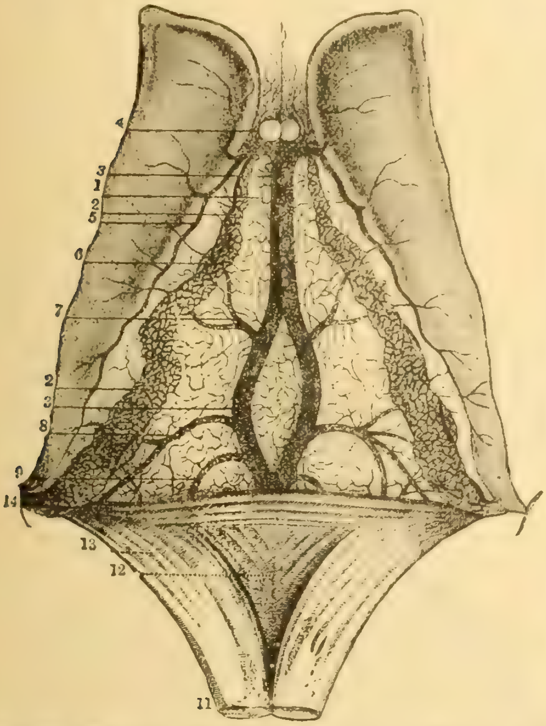

Fig. 4737.—The Velum and Lyra, × 1.5. From Quain, after Sappey and Vicq d'Azyr. 1, The narrower cephalic part of the velum; 2, left paraplexus, the margin of the velum which enters the paracœle as the paraplexus; 3, left velar vein, partly covered by the right; 4, fornicolumns, with small veins said to come from the callosum and septum, the precornual veins; 5, temal vein; 6, medicornual vein; 7, thalamic vein; 8, vein from left medicornu; 9, postcornual vein; 11, body of fornix, transected and reflected; 12, lyra; 13, on the lateral part of the fornix; 14, splenium. (The names here employed for the veins are those adopted by the writer of the article Blood-vessels of the Brain, in this volume.) See § 149.

Preparation.—With a preparation such as is represented in Fig. 4746, if the fornix were transected at its middle (*f*), the caudal half turned caudad, and the cephalic half, with the attached hemiseptums, removed down to the middle of the height of the portas, the appearances would be nearly as in the present figure.

Defects.—The relation of the parts shown to the rest of the brain would be clearer if there were included at least an outline of one side, or of the adjoining region. The temas are omitted, between which and the fornical margins, fimbrias, the paraplexuses enter; at the mesal side of each paraplexus should be a line, a ripa, indicating where the endyma covering the plexus was torn or cut in the separation of the fimbria. The whole, especially the lyra, is somewhat idealized.

§ 147. Prop. XCVII. Now, since the lateral connection of each hemifornix with the adjacent parts (tenia and caudatum) of the paracœlian parietes is merely membranous, and since, especially in man, the hemiseptums are so thin as to be easily torn, it is not, perhaps, strange that the conjoined hemifornices should have been described as constituting a single organ (Fig. 4737), and given a single name, *fornix*; but the morphological constitution of the cerebrum cannot be clearly perceived, unless the fornix be recognized as representing parts of the two hemicerebrums, dissociated in some degree from other parts of the same, and associated somewhat markedly with each other.

§ 148. Prop. XCVIII. *Lyra.*—When the fornix is transected through the columns (Fig. 4737) and turned caudad the exposed ventral surface, including the splenium, is seen to present lines which have been rather fancifully compared to the strings of a harp; the lyra is not a part, but merely a surface.

§ 149. Points illustrated upon Fig. 4737.—A. The general form of the velum, a double fold of pia between the thalami and the superposed cerebrum, one of the layers belonging to each of the two segments (Fig. 4735); the great veins are between the two, and others enter them from adjoining organs. The free lateral margins of the velum project into the paracœles as the paraplexuses (Fig. 4740), and its rounded apex hangs in the aula and the two portas as the auliplexuses and portiplexuses (Figs. 4742 and 4743).

B. The triangular form of the fornix; the cephalic, or "ascending" part, consisting of the two parallel fornicolumns, constituting the so-called "anterior pillar;" it expands caudad, the sides being incurved instead of nearly straight, as with the cat, and at the splenium is quite wide. Each lateral half here is practically composed of the corresponding hippocamp and fimbria, which, as they continue along the medicornu, are sometimes called the "posterior pillar."

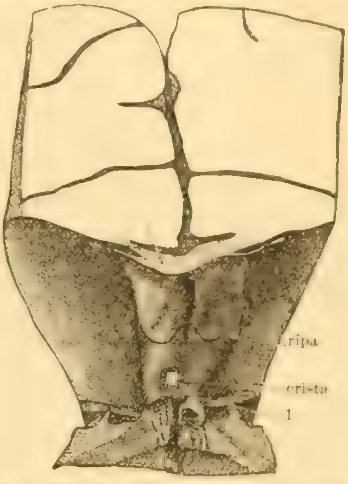

Fig. 4738.—The Fornicrista and Adjacent Parts of a Child at Term. × 1.5.

Preparation.—After transection at about the middle of the diacœle, the thalami were torn from their continuity with the fornix, leaving the irregular surface at and ventrad of 1. The lateral parts were then removed as indicated in the drawing. The paraplexus was torn from the margin of the fimbria, constituting the lateral part of the fornix; the short line at the right, ripa, is from the fimbria, crossing the intervening space, paracœle. On the left the similar line begins more nearly at the middle of the fornix, and crosses first the callosum itself, and then the callosal fissure. Before photographing, the crista was touched with white paint.

Defects.—The brain was ill preserved, and broke apart during dissection; the shading is too heavy.

C. The nature of the lyra. This is neither a separate part, nor a surface of the callosum, but the triangular, intermediate area of the ventral surface of the fornix, marked by lines which have been fancifully compared with the strings of a musical instrument. The line from 12 ends at the meson, the location of the fornicommissure or thin part connecting the thicker lateral portions.

D. The double relation of the splenium to the callosum and the fornix. The larger part, body, of the callosum consists of fibres which pass laterad, dorsad of the paracœles, constituting their roof; at the splenium some fibres pass dorsad, some caudad, some ventrad, and others in intermediate directions; now all the constituents of the fornix form parts of the floors rather than the roofs of the paracœles, and at the splenium fornix and callosum become continuous.

§ 150. Points shown on Fig. 4738.—A. The presence, in this new-born brain, of a mesal body upon the prosoterma, a little ventrad of the middle of the height of the aula, representing apparently the part which is constant in the cat (Fig. 4710).

B. The dorsal limitation of the aula and the two portæ by the line of reflection of the endyma constituting a ripa.

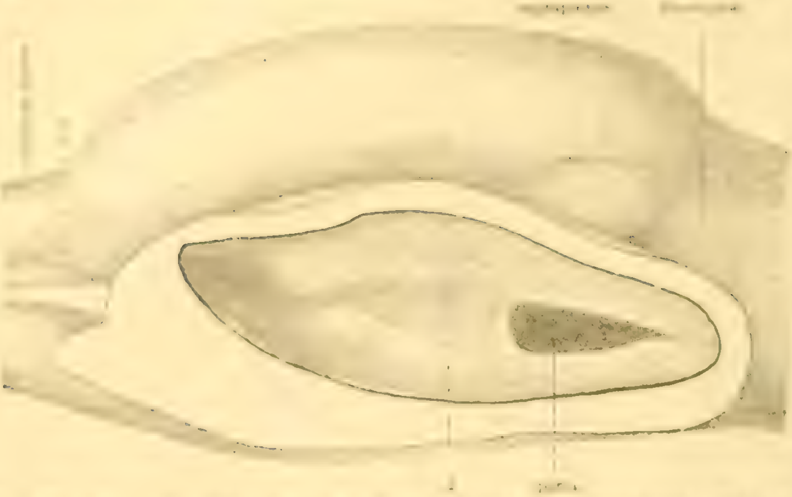

FIG. 4739.—[illegible] Cryptobranchus [illegible] of the Left [illegible] Exposed. × 6. [illegible]

C. The narrowness of the body of the fornix as compared with that of the cat and most other mammals.

D. The division of the cauda-ventral surface of the fornix, by the ripa mentioned under B, into an entocœlian area covered by endyma and forming the cephalic wall of the aula and the two portæ, and an ectocœlian area covered by pia, the dorsal or fornical layer of the velum.

§ 151. Prop. XCIX. The prosocœle's cavities, their connections, parietes, and circumscription.—As shown in Figs. 4692 and 4695, the primitive prosocœle is the single mesal, subspherical cavity of the first encephalic vesicle, a cephalic ("anterior") extension (or division?)* of the primary fore-brain (prosodiencephal). With some "fishes" this cavity remains practically undivided; but with all air-breathing vertebrates at least, Mammals, Birds, Reptiles, Amphibia, and Dipnoans, there are three main divisions, a mesal, the aula, and two lateral, the paracœles ("lateral ventricles") together with the rhinocœles ("olfactory ventricles") which, notwithstanding their constancy and presumptive, morphological importance, may be disregarded in the present connection. The more or less constricted communication between the aula and either paracœle is the porta ("Foramen of Monro").

§ 152. Prop. C. The *porta*, in a little modified condition, may be seen in the large salamander, Cryptobranchus (also called Menopoma and "hell-bender"), from the Ohio River and its tributaries. When the lateral wall of the adjacent hemicerebrum is removed (Fig. 4739), the paracœle is seen to communicate with a mesal space (aula) and thereby with its opposite and with the diacœle, through a considerable orifice, the porta. Its caudal end is narrower than the cephalic, but it is seen to be completely circumscribed by ordinary nervous walls.

§ 153. Points illustrated by Fig. 4739.—A. The simple condition of the prosencephal in this amphibian; each hemicerebrum is an elliptical, thin-walled sac, the cavity of which, the paracœle, communicates through a porta with the aula and so with the diacœle.

B. The large size of the porta, its length equalling about one-third that of the entire cerebrum; its cephalocaudal direction as compared with that of mammals, birds and reptiles, where—especially in mammals—it is dorso-ventral.

C. The absence of a rima; the prosoplexus enters the aula from the supraplexus and sends a prolongation through either porta into the paracœle, where it lies freely.

§ 154. Prop. CI. The rima.—With man, however, and with most of the other forms above named,* along a line beginning always at the porta and extending for a greater or less distance, the proper nervous parietes of the paracœle are interrupted for the intrusion of a pial extension, the paraplexus; this line of intrusion is the rima (chief part of the "great transverse fissure") already mentioned in § 42 and shown in Figs. 4705 (Macropus), 4729, 4740, 4746, and 4753.

§ 155. Points illustrated by Fig. 4740.—A. The location and general form of the paracœle; unfortunately, however, the postcornu is unusually short, and foreshortened by the way in which the preparation is viewed; but the sharp curve of the medicornu is well seen, and the projection of the precornu cephalad from the porta.

B. The absence of any indication that even in the embryo the precornu was continuous with a rhinocœle, as in the cat (Fig. 4729), and in mammals generally.

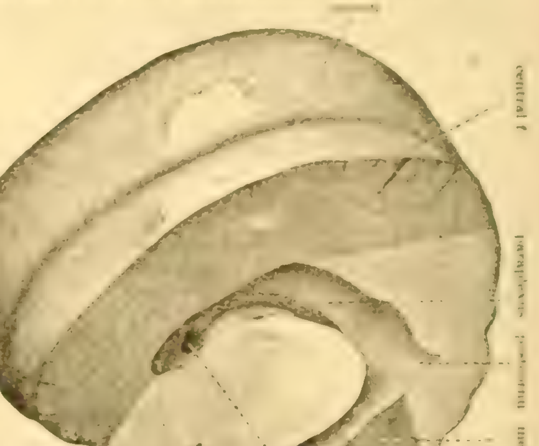

FIG. 4740.—The Left Paracœle ("lateral ventricle") Viewed Obliquely from the [illegible] × [illegible] (Fig. [illegible]) (This figure was [illegible] N. Y. Med. Journ. [illegible] 1886 [illegible])

Preparation.—[illegible]

C. The indistinctness of the colliculi, calcar, collateral eminence and occipital eminence, whether this is natural

---

* [illegible]

* [illegible] Amer. Naturalist, June, 1887.

(owing to hydrocephalus) or due to the pressure of the alinjected alcohol it is impossible to say.

D. The location and size of the porta, which is shown on a larger scale in Fig. 4742.

E. The location of the paraplexus and of the rima through which it enters, covered, however, by the endyma (Fig. 4765).

§ 156. Prop. CII. The ease with which the two margins of the rima are separated by the tearing of the membranes during the removal or examination of the brain has occasioned a somewhat general impression that (1) there is a natural "great transverse fissure" communicating between the encephalic cavities and the ectal surface of the brain; (2), the porta is merely a part of this fissure. The whole subject has been considered at some length by the writer (*New York Medical Journal*, May 10, 1884, pp. 513–516) and here the following figures may be allowed to illustrate the principal points.

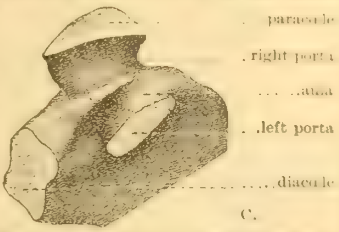

FIG. 4741.—Cast of Aula, Portas, and Part of Diacœle. × 1.5. The main object of the figure is to demonstrate the complete circumscription of the porta, and its independence of the rima (§ 41). The material used was a mixture of wax and gutta-percha. The mesal ridge which represents the aulic recess just dorsad of the precommissure, Fig. 4743. The figure should have been so placed as to make this ridge vertical.

§ 157. Prop. CIII. The porta is completely circumscribed, so that a cast has a definite outline, viz., that of an elongated ellipse, its longer diameter, 4–6 mm., its shorter 1–3 (see Figs. 4741–4743).

§ 158. Points illustrated upon Fig. 4743.—A. The existence, form, size, and complete circumscription of the two portas ("Foramina of Monro").

B. The extent of the aula, the mesal division of the prosocœle, and the cephalic or prosocœlian constituent of the "third ventricle." It includes the interval between the portas, extending ventrad so as to include the precommissure, only part of which appears in the figure.

C. The existence of the aulic recess, a subtriangular depression between the precommissure and the two fornicolumns; the line from the word *aula* ends in this recess; on the cast shown in Fig. 4741, it is a ridge.

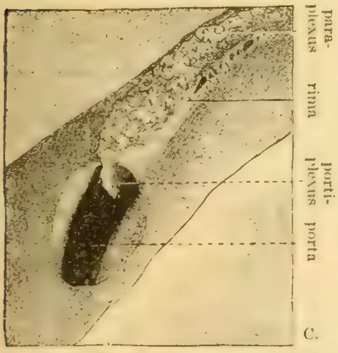

FIG. 4742.—The Left Porta and Adjoining Parts of the Alinjected Brain shown in Fig. 4740. 385; × 3. The form of the precornual orifice of the porta appears more distinctly, and the endyma is seen clearly to be reflected upon the portiplexus from the adjoining surfaces. Just dorsad of the line from *rima* are a few artificial rents in the endyma.

D. The peculiar curvature of the fornicolumns. They converge dorsad, curving at the same time caudad, so as to appear as cut ends in this transection; ventrad they diverge, are twisted somewhat, and again curve caudad, so that their cut ends should appear again just dorsad of the optic tracts, as shown in Fig. 4732.

E. The relation of the precommissure to the fornicolumns, which pass just caudad of it. In a figure including a greater width of this region, the cut ends of the precommissure would appear at the side, as in Fig. 4732.

F. The reflection of the endyma upon the plexuses from the fornix and thalami, at two points upon each side; such lines of reflection constitute a ripa.

G. The continuity of the hemiseptums with the callosum dorsad and the fornix ventrad.

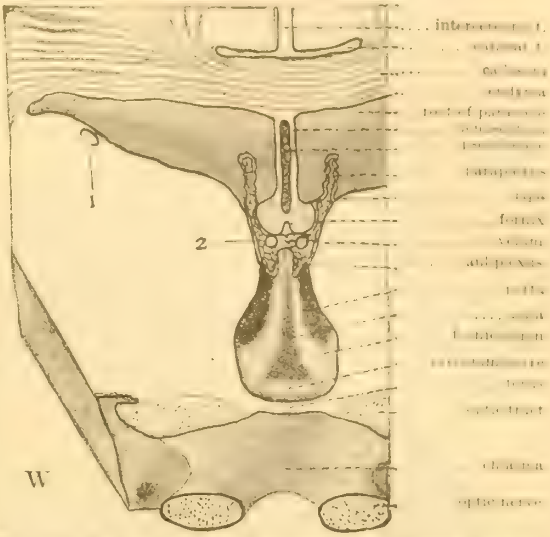

FIG. 4743. The Two Portas, as Seen from the Aula, Looking Obliquely Dorso-cephalad. 2345; × 1.5. (Compare with Figs. 4742 and 4744.) 1, Tenial vein; 2, velar vein; the number rests upon the thalamus.

Preparation.—From a brain, the arteries of which had been injected with the red glue mixture, and the cavities with alcohol, a transection was removed, 12 mm. thick, so as to include the chiasma; for security of handling it was trimmed down so as to include little more than the parts represented. The optic nerves were divided obliquely, to show their cut ends more fully.

Defects.—The alba and cinerea are not distinguished, and the figure is not upon a scale large enough to show certain details as to the connections of the velum and plexuses. The divided ventral ends of the fornicolumns were inadvertently omitted, but may be seen in Fig. 4732. A still greater enlargement of the right porta is shown in the article Malformations of the Brain.

§ 159. Points illustrated upon Fig. 4744.—A. The existence of the two portas, and their obviously natural

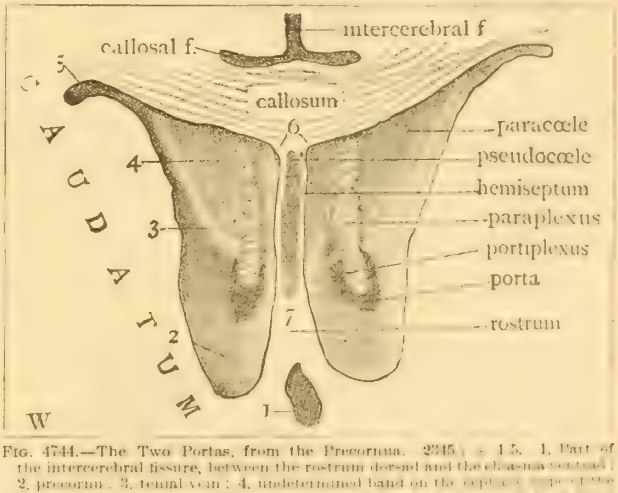

FIG. 4744.—The Two Portas, from the Precornua. 2345; × 1.5. 1, Part of the intercerebral fissure, between the rostrum dorsad and the chiasma ventrad; 2, precornu; 3, tenial vein; 4, undetermined band on the [illegible] of the thalamus; 5, dorsal part of right paracœle; 6, the short [illegible] point to the locations of veins (septal ?) at the angle of junction of the hemiseptums with the callosum; 7, dorsal of the junction of the hemiseptums with the rostrum is a small (septal ?) vein at either side.

Preparation.—See under Fig. 4743. The slice including the portas is 12 mm. thick; the caudal (aulic) aspect is shown in Fig. 4743, the cephalic (precornual) in this.

Defects.—The shading does not indicate with sufficient distinctness that the entire surface, and plexus at either side dorsad of the porta, [illegible] caudad beneath the callosum, and is not continuous with the [illegible]. As in Figs. 4742 and 4743, the lines representing the callosal fibres are [illegible]. Other preparations and figures upon a still larger scale are needed, in order to exhibit the somewhat intricate relations of the parts about the porta. The morphological importance of the entire aulic region can hardly be overestimated.

conditions. This point, already shown in several previous figures, is here reiterated because this aspect of these callosa is almost [illegible], and [illegible] a distinguished French anatomist, Mathias Duval, has declared (*Progrès Médical*, Nov. 22 and 29, 1879) that when one finds a communication between the middle and lateral ventricles in an adult human brain it results from an artificial perforation: see the writer's comments in "Amer. Assoc. Proc., 1884," p. 506, and *N. Y. Med. Journ.*, May 10, 1884.

B. The [illegible] of the callosum in two places, viz., dorsad near the genu and ventrad through the rostrum; the part of the [illegible] or [illegible] here shown. The [illegible] continued by the general curve of the callosum (see Figs. 4711 and 4718).

C. The continuity of the [illegible] with the corresponding [illegible]; so far as the porta is concerned the former may be compared to a [illegible] partition, and the latter to a door post (see also Figs. 4726 and 4727).

§ 160. Prop. CIV. The portal boundaries are as follows: caudad, the thalamus (perhaps the tenia); cephalad, the [illegible]; ventrad, the junction of the two; dorsad, the endyma reflected from the thalamus and fornix column upon the intruded portiplexus (Fig. 4745). So long as this endyma retains its adhesions, so long the circumscription of the porta is complete.

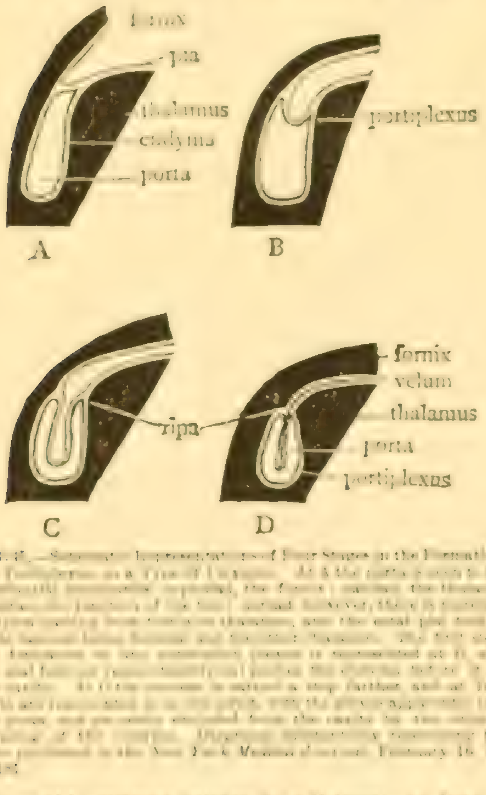

FIG. 4745.—Schematic Representations of Four Stages in the Formation of the Portiplexus as a Type of Plexuses. [illegible] New York Medical Journal, February 16, 1884, p. 18.

§ 161. Prop. CV. The exact conditions and relations of the rima, paraplexus, tenia, fimbria, and thalamus near the porta have not been as yet clearly made out. Preparations should be made with special reference to their elucidation, and figures upon a very large scale. Excepting the metapore ("Foramen of Magendie") no part of the brain involves so many and so important morphological questions; see the difficulties and doubts admitted under Fig. 4755.

§ 162. Prop. CVI. The colliculi. This collective term is applied to the rounded eminences and ridges which project into the paracœles ("lateral ventricles") from their parietes. They are the caudatum (corpus striatum), hippocamp ("*Hippocampus major*"), calcar ("*Hippocampus minor*"), collateral eminence, occipital eminence, and amygdaline eminence. Excepting, perhaps, the first and the last, each of these represents a corrugation of the entire thickness of the parietes, the entad elevation (colliculus) being collocated with an ectal depression (fissure); this collocation is indicated in the list of total fissures, § [illegible].

§ 163. Points Illustrated upon Figs. 4746 and 4747.—

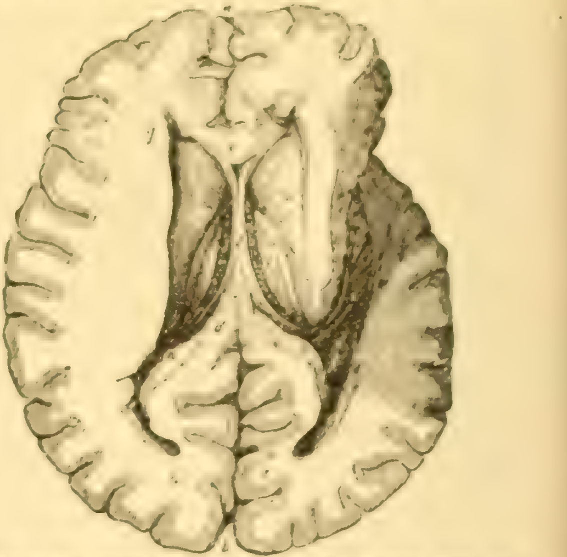

FIG. 4746.—The Paracœles ("lateral ventricles") Exposed from the Dorsal Side. [illegible]

A. The general relation of the paracœles to the cerebrum in the adult (compare Figs. 4692 and 4709).

B. The thickness of most of the parietes as compared with the fetal condition, as seen in Fig. 4708.

C. The existence of special ental elevations, colliculi, viz., the caudatum (*k*), the calcar (*o*), the hippocamp (*g*), and the collateral eminence (*u*).

D. The apparent representation of the thalamus as a constituent of the paracœlian floor, as if it were an additional colliculus; for explanation of this appearance see § 172.

E. The presence of the "white line of Vicq d'Azyr," a thin stratum of a white color between the strata of the cinerea (cortex) in the occipital region.

F. The peculiar curve of the [illegible] and hippocamp, whence the latter is sometimes called *Ammon's horn*.

G. The terminal expansion and digitation of the hippocamp, *pes hippocampi*; see Fig. 4752.

H. The relation of the collateral eminence as a more or less elevated triangular interval between the hippocamp and the calcar.

§ 164. Prop. CVII. The *callosal eminence*.—Besides the colliculi named in § 162, all of which are more or less distinct in at least some adult brains, there is one which is perfectly obvious in some fœtuses (Fig. 4748, 1), and which, from its apparent collocation with the callosal fissure (Fig. 4757), may be called, provisionally, the callosal eminence. It, the hippocamp and the occipital eminence form an irregular triradiation. Its commencement and disappearance require further observation, but its unbroken continuity with the hippocamp confirms the idea that the callosal and hippocampal fissures are essentially parts of one, merely deflected by the splenium of the adult.

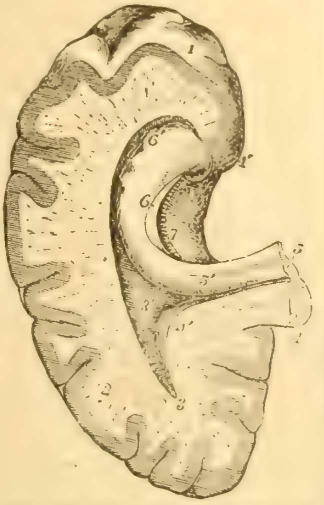

Fig. 4747.—The Left Hippocamp and Adjoining Parts. × 5; from Quain (altered from Hirschfeld and Leveillé). 1, Apex of the temporal lobe; 1', uncus; 2, cut surface of the cerebral medulla surrounded by the cortex; 3, at the apex of the postcornu; 3', collateral eminence; 4, part of the splenium, nearly medisected; 4', points to the calcar; 5, cut end of the lateral portion of the fornix which is continued at the hippocamp; 5', and the fimbria (6); 6, the fimbria; 6', the terminal expansion of the hippocamp, called *pes hippocampi*; 7, dentate gyre ("*fascia dentata*"). See § 163.

Preparation.—The left occipito-temporal region of the cerebrum was separated from the rest, together with a part of the splenium and fornix, and the dorsal and lateral parietes of the postcornu and medicornu sliced away so as to expose nearly the entire extent of the cavities.

Defects.—The specimen had not been alinjected, and the figure looks somewhat diagrammatic; especially as to the dentate gyre (7); the actual extremity of the medicornu does not appear (see Fig. 4752). There is no indication, along the free margin of the fimbria, that one surface of this lamina was covered by pia and the other by endyma, and that they were continued in and upon the removed paraplexus.

§ 165. Prop. CVIII. The relative size of the colliculi is not the same in the adult as in the fœtus. This is clear from the comparison of Fig. 4748 with Figs. 4736, 4740, and 4746. The callosal eminence may disappear wholly; the occipital is seldom recognized; the collateral is certainly less prominent in the adult than in the fœtus (Fig. 4748).

§ 166. Points illustrated upon Fig. 4748.—A. The contiguity of the margins of the fimbria and the tenia (the edge of the caudatum) with just room for the entrance of the paraplexus, and the concomitant complete exclusion of the thalamus from the paracœlian floor (compare Figs. 4746, 4749, and 4751).

B. The existence of an ental ridge (1) at this period, continuous and corresponding with the hippocampal and callosal fissures; whether it extends still further cephalad, as in Fig. 4757, cannot be ascertained from this specimen.

C. The branching off of a ridge corresponding apparently to the occipital fissure, and representing the adult occipital eminence.

D. The existence of two intermediate ridges, apparently the calcar and collateral eminence.

§ 167. Prop. CIX. With all mammals other than man (and perhaps the apes) the margins of the rima are, throughout their whole extent, separated only so far as to permit the intrusion of the paraplexus; nor does this adhesion yield at all in cases of hydrocephalus, observed by the writer in dogs and cats.

§ 168. Prop. CX. With the human fœtus, also, up to the estimated age of four months (Figs. 4748 and 4749), at least, the tenia and the fimbria are closely apposed, as closely, that is, as they can be and yet allow the plexal intrusion; at this age, therefore, the human thalamus is as perfectly excluded from the paracœle as it is in mammals generally.

§ 169. Points illustrated by Fig. 4749.—A. That, at this age, the paracœles extend much farther dorsad than in the adult, far beyond the level of the callosum.

B. That the paraplexus is relatively more extensive.

C. That the caudatum is relatively larger.

D. That the margin of the fimbria reaches the groove between the caudatum and the thalamus, which probably represents the tenial sulcus of the adult.

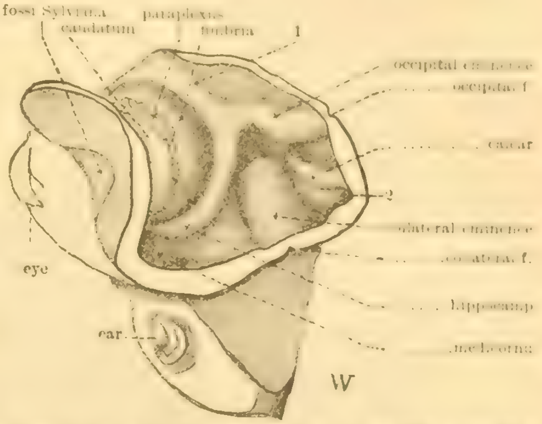

Fig. 4748.—Left Hemicerebrum, Laid Open, of a Fœtus Weighing 88 grams (3 ounces), Measuring 15 ctm. from Heel to Bregma, and Estimated at 14 Weeks. 2683; × 1.5. See § 166.

Preparation.—The fœtus was received fresh; the head was cut off and pinned by the neck to a cork loaded with sheet lead; a shawl-pin was inserted as a handle at one side of the head. A slit was made through the scalp at the lateral angle of the prefontanelle, and the guarded cannula adjusted so that ninety-five per cent. alcohol should enter the paracœle gently, with opportunity for egress at the side of the cannula. After six hours the alinjection was discontinued, but the specimen remained in alcohol for two days, when the scalp was removed and the specimen placed in ten per cent. nitric acid. After three hours the calva was so far decalcified that it could be cut away with the scalpel and scissors without jarring the very delicate brain. The left hemicerebrum was then exposed as indicated, and the nape of the neck removed to expose the collateral fissure. Upon a larger scale some of the points would have appeared more clearly.

E. That the thalamus is therefore absolutely excluded from the paracœlian floor, without even the appearance of representation which exists in the adult.

§ 170. Prop. CXI. But with all human adults (perhaps also with the new-born, and possibly with fœtuses during the latter months) the tenia and fimbria, for most of their length, are separated by an interval, 2–7 mm. in width, narrowing at the porta and in the medicornu. This interval is filled by (1) the paraplexus, which usually retains its attachment to the fimbria rather

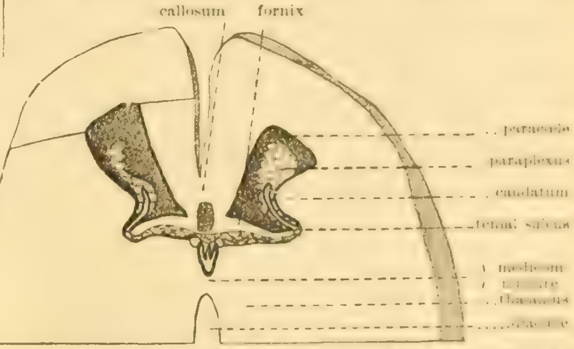

Fig. 4749.—Transection of the Brain of a Fœtus, about 16 ctm. from Nates to Bregma, and Estimated at Four Months. 1816; × 1.5. See § 169.

Preparation.—The fœtus was received in alcohol, not very well preserved. The calva was cut away with scissors, and the dura and pia removed. The entire brain was then transected at the level of the medicornu in situ, but only the dorsal half of the divided surface is included in the figure; it is the cephalic aspect of the caudal part. The two lines crossing the right hemicerebrum indicate the plane of the section shown in Fig. 4764.

than the sprout; (2) an extension of the contents from the margin of the tela; (3) in some cases, perhaps, a membranous [illegible] through the [illegible] of the [illegible] itself; the parts have the appearance (Figs. 4736 and 4751) of having been stretched by the expansion of the adjacent thalamus, which is very much in the human adult.

§ 171. Points illustrated by Fig. 4750.—A. The completeness of the paracoelian floor, irrespective of the thalamus, which he made to appear in Fig. 4746 between the paraplexus and the tenia.

B. The existence of ridges (2, 3, 5, and 7) not yet commonly recognized, and perhaps not invariably present.

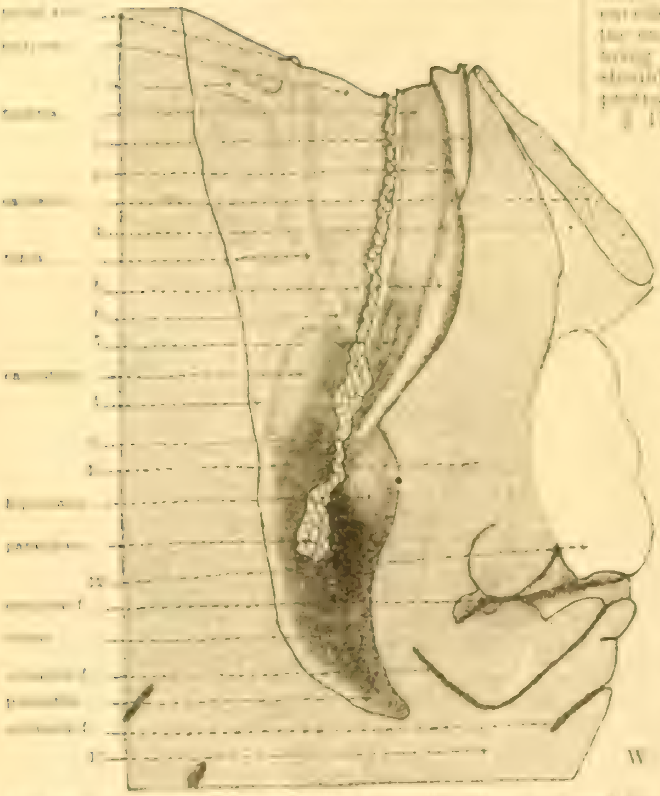

FIG. 47[illegible].—The Caudal Part of the Left Paracoele, Viewed from the Dorsal Side, and [illegible]. [illegible] 2, 3, 5, 7, [illegible] ridges of the floor [illegible]; 12, the surface of the hippocampal gyre; [illegible]

[illegible]

C. The approximate coincidence of the band marked *fornix* (?) with the subjacent fornical vein.

§ 172. Plate CXII. The common impression as to the appearance of the thalamus may be ascribed to two sources, viz.: (1) Since the endyma is thin and transparent, and often more or less closely attached to the dorsal surface of the thalamus, one might (unless already well grounded in morphological principles from the study of embryology and comparative anatomy) regard the thalamus as a constituent of the paracoelian floor in the same sense as is the caudatum or the hippocampus; but since the entire dorsal surface of the thalamus is, from its beginning, ectocoelian and separated from the entomedian mesal surface by the fimbria and its sulcus, and a line of ependymal reflection, rima, its appearance as a genuine portion of the paracoelian parietes is as little to be admitted without further inquiry as would be the alleged appearance of the cerebellum in the same place. (2) The delicacy of the membranes, the readiness with which they are detached along a rima, the rough handling to which brains are commonly subjected during the ordinary processes of removal and examination, the slight degree in which preservatives can reach the parts in question when the entire organ is merely immersed as usual, and, finally, the fact that some specimens prepared for macroscopic purposes do not well preserve the ependymal attachments: all these conditions conspire to bring it about that the endyma across the velar rima should be torn, and the dorsal surface of the thalamus protrude through the rent, as in Fig. 4746.

§ 173. Points illustrated upon Fig. 4751.—A. The main point is the continuity of the floor of the paracoele ("lateral ventricle") irrespective of the dorsal surface of the thalamus, and the concomitant exclusion of this diencephalic mass from this portion of the prosencephalic cavity; but so many other points are shown incidentally that the figure will be described in detail.

Beginning at the dorsal side of the figure, the intercerebral fissure is seen to separate the apposed mesal surfaces of the hemicerebrums. The arachnoid dips into this fissure to a certain depth, so as to pass around the ventral margin of the falx (not shown in the figure), since this has (as seen in Fig. 4711) a curved margin, and becomes narrower (dorso-ventrally) cephalad; the extent of the arachnoidal fold varies at different levels; in the specimen here figured, for example, which is about 1 cm. thick at the level of the callosum, the arachnoid crosses 5 mm. dorsad of the callosum on the caudal aspect and 8 mm. on the cephalic. The pia, however, follows the apposed hemicerebral surfaces to and into the callosal fissure at either side and is continuous upon the dorsal surface of the callosum. Of the vessels the figure includes only the two parallel precallosal arteries (4). The callosum itself presents a slight mesal elevation, which is more distinct at the cephalic side of the section and of a somewhat different color; there is no distinct evidence of the longitudinal striæ or of the furrow caused apparently by the pressure of the arteries, and described by the writer in the *N. Y. Med. Jour.* for April 5, 1884, p. 374.

The callosum extends laterad and likewise dorsad to form the roof of the paracoele, and it is to be noted that the lateral portion of this cavity would be opened by a horizontal section at the level of the dorsal surface of the callosum. Hence, as remarked by Dalton (*Medical Record*, April 19, 1884) and confirmed by the writer (*N. Y. Med. Jour.*, April 5, 1884, p. 374), the appearance commonly described and figured under the name of "centrum ovale majus" seldom, if ever, exists. For the condition of things in fœtal brains see Fig. 4749, § 169.

Ventrad of the callosum is the fornix, connected therewith by a thin septum, the hemiseptum at either side of a mesal cavity, the pseudocoele. The lateral margin of the fornix is formed by the fimbria (corpus fimbriatum).

At the extreme left of the figure the lateral wall of the paracoele is seen to be formed by a cinereal mass, the caudatum. By reference to Figs. 4723 and 4736 it will be seen that this narrows rapidly from the cephalic end (caput) as a slender prolongation (cauda); but this cauda is really twisted somewhat upon its longitudinal axis so as to constitute, in at least part of its course, not only the side but a part of both the roof and floor of the paracoele. In the figures just mentioned the roof portion and part of the lateral is removed, leaving only the floor portion. Along the mesal border of the cauda there passes a vein (3), the tenial vein, which may be regarded as indicating the boundary between the caudatum and the thalamus.

Projecting mesad of the vein is seen a lamina, consisting evidently of the paracœlian endyma, and also, at least near the caudatum, of some nervous substance; this is, or includes, the white band named *tenia* in this article, but commonly called *tænia semicircularis* or *stria cornea*.

All the parts so far described are unquestionably constituents of the prosencephal; the remaining portions shown in Fig. 4751 belong to the diencephal. The walls of the diacœle are the thalami, of which the figure includes only the portions dorsad of the level of the medi- and postcommissures (see Fig. 4711).

The mesal surface is covered by endyma, which is continued over the low ridge called habena ("habenula") seen from the mesal aspect in Fig. 4711, and from the dorsal in Fig. 4732. Just dorsad of the habena is a slight furrow, the habenal sulcus; here the endyma meets the pia covering the dorsal aspect of the thalamus, and is reflected with it dorsad and then mesad toward the opposite side. Instead of passing horizontally across the interval between the thalami, however, the endyma is deflected over the two vascular plexuses (folds of pia or vessels therefrom) which hang in the diacœle. The habena and its sulcus, more accurately, perhaps the latter, constitute the boundary line between the mesal, entocœlian, endymal surface of the thalamus and the dorsal, ectocœlian, and pial surface, which extends dorso laterad.

Between the dorsal surface of the thalamus and the ventral surface of the fornix (including, of course, the fimbria), the pia is freely separable, and appears to consist of but a single layer, but laterad it is traceable to the paraplexus, and it is almost inconceivable that a plexus should be formed of a single layer of pia as a free edge covered by endyma.* When, however, this fornico-thalamic pia is traced mesad, it is found to separate into two layers, a dorsal, belonging to the fornix, a ventral, constituting part of the diacœlian roof (diatela) with a pair of arteries, a pair of veins, and numerous smaller vessels in the intervening space. The ventral layer is not separable (in man) from the diacœlian endyma, but the dorsal not only may be detached from the fornix in an alcoholic specimen, as may the pia from most of the surfaces which it covers, but here, excepting at the margins, the disjunction was almost spontaneous, and there is a distinct space (8) between it and the fornicommissure, bounded at the sides by the thicker (hippocampal) constituents of the fornix. This double curtain of pia is the velum (interpositum), which belongs equally to the diencephal and to the superposed prosencephal; were it possible in separating the two segments, the dorsal layer should accompany the cerebrum, and the ventral remain attached to the thalami; the continuity of the two is seen at the aula and the two portæ, as well as along the entire margin of the paraplexus; see Figs. 4735 and 4745.

Corresponding with the margin of the fimbria, the dorsal surface of the thalamus presents a shallow groove, the fimbrial sulcus ("sulcus choroideus" Fig. 4732); laterad from this the surface is nearly regular, and overlaid partly by the paraplexus and a membrane apparently endyma only, and partly by the thin but more substantial lamina (tenia ?) already described as an extension of the caudatum.

The entire dorso-mesal surface of the thalamus, instead of being homogeneous, as it has been sometimes figured and described, may be divided, first and most sharply into a mesal, or entocœlian, and a dorsal, or ectocœlian, portion, the boundary between the two being the habena and its sulcus. The dorsal surface itself presents a twofold division into a subfornical (B) and a parafornical (C and D), separated by the fimbrial or choroid sulcus. Finally, the parafornical area is covered partly by the endyma and plexus and partly by the tenia, and may thus be distinguished as subplexal (C) and subtenial (D), there being occasionally a furrow, the tenial sulcus between them. The desirability of discriminating between

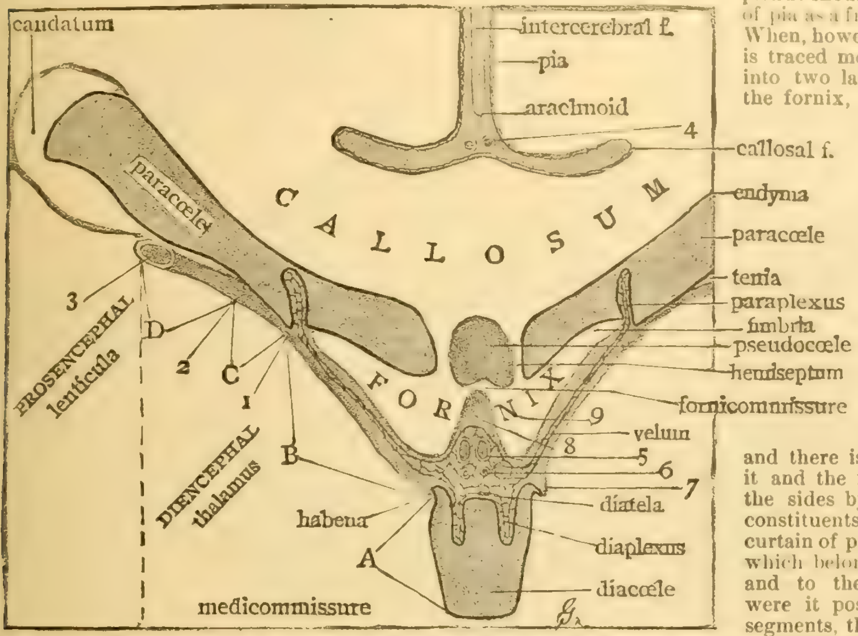

FIG. 4751.—Transection, Partly Schematic, of the Fornix and Adjacent Parts at a Level Corresponding with the Interval Between the Medicommissure and the Postcommissure. 1824; × 2.5. 1, Fimbrial sulcus ("sulcus choroideus); 2, tenial sulcus (in some specimens); 3, tenial vein; 4, precerebral arteries; 5, velar veins; 6, velar arteries; 7, habenal sulcus; 8, interval (natural ?) between the fornicommissure and the velum; 9, lateral part of the fornix (hemifornix); A, mesal, endymal surface of thalamus; B, C, D, zones of its dorsal surface; B, subfornical; C, subendymal; D, subtenial.

The figure represents the caudal surface of the transection; the observer is looking cephalad, and his right coincides with the right of the specimen and the figure; the two sides are substantially identical but less is shown upon the right; the meson of the figure, the anatomical middle of the various parts and cavities represented, is dextrad of the middle of the area covered by the figure. Throughout the figure the cavities are shaded and the blank areas represent transected surfaces. The arachnoid is represented by a narrow, straight line, the pia by a corrugated line, and the endyma by a heavy line; the endyma is made to adhere closely to the entocœlian surfaces, but the pia and arachnoid are separated slightly from the parts which they cover.

Preparation.—See Fig. 4736, representing another transection of the same brain. The cœlian parietes were thoroughly hardened before the brain was removed from the skull, and the membranes and plexuses have retained their connections notwithstanding much handling and considerable transportation. There is some distortion and dislocation of the loosely connected parts about the fornix, but it has been possible to clear up most of the doubtful points by comparison of the two sides and with adjoining sections. So far as respects the exclusion of the dorsal surface of the thalamus from the paracœle, the preparation affords unequivocal evidence.

Defects.—As in several other figures representing transections of plexuses, it has been assumed that a plexus consists of a fold of pia covered by endyma; for present purposes it matters not whether there is a complete fold of the pia, or merely an extension of vascular loops. The ventral lamina of the velum is made too low. The medicommissure, the dorsal margin of which is included at the ventral side of the figure, did not actually appear in this section, which was just caudad of it, but is introduced as a readily recognized landmark.

---

* The expression is qualified in view of the conditions at the margin of the metapore ("Foramen of Magendie"), where the pia is supposed to either terminate or become continuous with the endyma, and where a plexus might apparently be developed.

these lesions will appear in connection with Fig. 4755, which reveals different and perhaps anomalous conditions [illegible] described.

So far as this preparation is concerned, there is absolutely no indication of entrance to any part of the thalamus dorso-laterad of the fimbrial sulcus; on the contrary, the endyma [illegible] continuously about each paraplexic [illegible], in turn, the ental surface of the thalamus, the [illegible], the tenia, the paraplexus, the fimbria, the [illegible] portion of the fornix, and the [illegible] septum, back again to the callosum.

§ 174. Points illustrated upon Fig. 4752.—A. The existence of substantial walls of nervous substance about

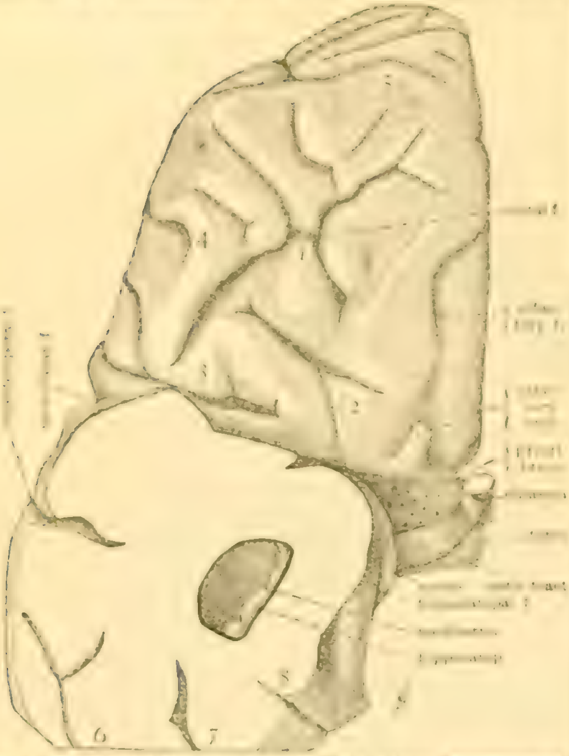

FIG. 4752.—Ventral (ectal) Aspect of the Right Fronto-temporal Region of the [illegible] [illegible] [illegible] [illegible] [illegible]
(Natural size.) See Fig. 4751.

the medicornu at the distance of 1 ctm. from the tip of the temporal lobe.

B. The coincident non-extension of the rima ("great transverse fissure") to the extremity of the medicornu as implied in most anatomical works, *e.g.*, Quain, ii., 346.

C. The existence of digitations at the ventral end of the hippocamp (pes hippocampi).

D. The non-extension of the hippocamp to the extremity of the medicornu, as stated in Quain, ii., 345.

E. The dilatation of the medicornu in hydrocephalus.

F. The efficacy of alinjection in maintaining the size of an encephalic cavity and preserving the contents of its parietes.

G. The nearly typical zygal, or H shape, of the orbital fissure; see Fig. 4750.

§ 175. Page CXIII. The rima extends from the porta to near the extremity of the medicornu, but for about 1 ctm. from its extremity the margins are substantial, Fig. 4752. The transition to the rima is constituted by the slender part, pala, which connects the two rimal margins, fimbria and tenia (Figs. 4753 and 4754). This thin portion has, as seen, a shape like the blade of a turf-cutter. It was figured and described by the writer in 1884 (N. Y. *Med. Jour.*, April 5th, Fig. 48, p. 376) and in 1886 ("Anatomical Technology," 490). In the preparation was prepared for it, the pala is not distinctly shown in any of the figures in this article, but in Fig. 4753 it would constitute the thin lamella at the ventral end

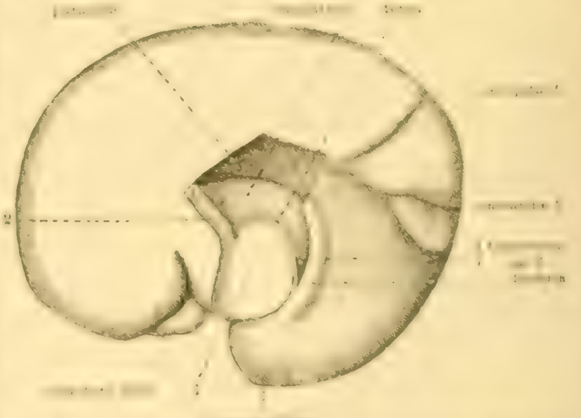

FIG. 4753.—[illegible] [illegible] [illegible] [illegible] [illegible]

of the fimbria; in the diagram, Fig. 4754, the pala is seen in transection at B.

§ 176. Points illustrated upon Fig. 4753.—A. The early and distinct formation of the medicornu; see also a figure in the article Malformations of the Brain.

B. The continuity of the two margins of the rima, the fimbria and tenia, near the tip of the temporal lobe, the place of their union, at and after birth, being somewhat distinct, the pala.

§ 177. Page CXIV. With some specimens the interval between the paraplexus and the caudatum seems to be

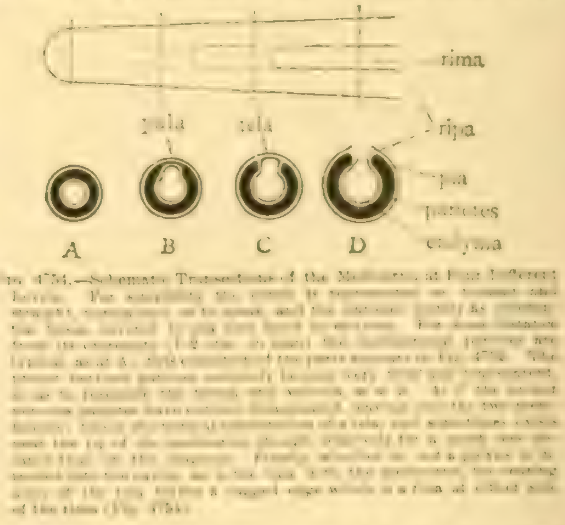

FIG. 4754.—Schematic Transections of the Medicornu at Four Different Levels. [illegible] [illegible] of the rima (Fig. 4755).

occupied by a somewhat substantial lamina, separable from the thalamus, continuous with the caudatum, and perhaps merely a special development of the tenia, but requiring further investigation (Fig. 4755).

§ 178. The point illustrated upon Fig. 4755 is the continuity of the paracoelian floor from hippocamp to caudatum without the intrusion of the thalamus. This figure is to be studied in connection with the transection (Fig. 4751) and the dorsal view of the floor in Fig. 4746.

There are, however, differences between these and other preparations which are not easy to explain, excepting upon the general supposition that a region in which the conditions are, apparently, peculiar to the human brain, might naturally be expected to present individual peculiarities and even anomalies.

§ 179. Prop. CXV. There seems to be considerable variation in the details of the parts involved in the apparent representation of the thalamus within the paracœle; this is perhaps to be expected, since the conditions that have made the usual statements possible constitute a great and perhaps peculiar modification of the primitive and typical relations, indeed, almost a malformation.

It is hoped that the foregoing descriptions and figures may at least serve to induce anatomists to investigate the subject in all its bearings.

§ 180. Prop. CXVI. The *cerebrum* proper comprises the prosencephal less the olfactory bulbs and crura.*

in pairs; 2, although its sides are formed by cortex, the bottom is alba, the callosum; 3, although the pia has the usual relation, the arachnoid, instead of passing directly across, dips into it to a greater or less depth on account of the falx (Figs. 4711 and 4751); 4, it is, in one sense, a superfissure (§ 261) since in its depths are concealed the callosal fissures. Respecting points 2, 3, 4, however, see, in the article Malformations of the Brain, cases where the callosum is undeveloped, or the cerebrum forms a scarcely divided mass.

§ 183. Prop. CXIX. *Cerebral lobes.* For topographical convenience, and not because they represent perfectly natural divisions, either anatomical, histological, or physiological, each hemicerebrum may be regarded as forming six lobes, as indicated in the fissural diagrams (Figs. 4769 and 4770).

§ 184. Prop. CXX. One of these lobes, the *insula* (*lobus opertus*, "central lobe"), is nearly or quite covered in the adult brain by folds (operculums) from the adjoining lobes (Figs. 4767 and 4778); excepting at part of the ventral side the insula is surrounded by an irregular furrow, the circuminsular fissure (Figs. 4783 and 4785); on the mesal aspect the insular lobe may be regarded as bounded approximately by the hippocampal and callosal fissures.

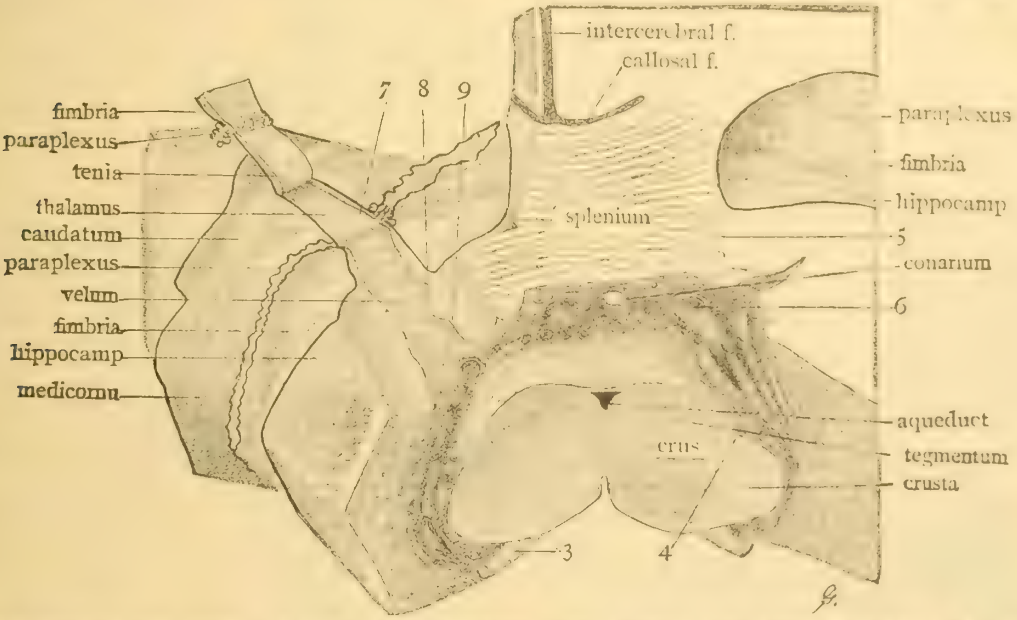

FIG. 4755.—Dissection, Partly Schematic, of the Floor of the Left Paracœle ("lateral ventricle") Caudal Aspect (2345 and 2347; × 1.5). Compare in part with Fig. 4724. 4. Lateral sulcus of the mesencephal; 3, oculo-motor nerve; 5, line of somewhat sudden deflection of the splenial fibres caudad into the occipital lobe; 6, large vein; 7, fimbrial sulcus; 8, angle between the fimbria and the hippocamp; 9, hippocampal fissure.

Preparation.—The arteries were injected with the red glue mixture, and the cavities with alcohol. When hardened, a thick slice was taken by a transection at about the middle of the length of the callosum and another at the splenium, just shaving off the tip of the conarium. The ordinary transection of the brain stem between the mesencephal and epencephal was modified by carrying two sections cephalo-mesad, meeting at the base of the valvula. On the right of the cerebrum the parts were left undisturbed excepting that the paraplexus was raised so as to expose the floor of the cavity. On the left, a thin slice of the hemicerebrum is left attached to its opposite by the pia. In order to expose the paracœlian floor as completely as possible from this point of view, the sections had to be made in many directions. The paraplexus was trimmed down for a certain distance; then a wedge-shaped piece was cut from the thick caudal wall, hippocamp, etc., including part of the thinner floor, fimbria, thus exposed the velum, the double fold of pia between the dorsal surface of the mes- and diencephal and the ventral surface of the fornix. Very cautiously then the two parallel incisions were carried across the floor to and into the caudatum constituting the lateral wall; the strip so enclosed was then lifted; it included (1) a piece of the fimbria; (2) the disconnected part of the paraplexus; (3) a strip of the thin lamina intervening between the plexus and the caudatum; in 2347 all these were found separable from the dorsal surface of the thalamus, substantially as in the transection, Fig. 4751; in 2345 there were complications which should form the subject of monographic consideration.

Defects. The defects of the figure are due mainly to the attempt to combine the appearances presented by two different preparations.

§ 181. Prop. CXVII. The cerebrum consists (Fig. 4688) of two lateral, hemispherical masses, the *hemicerebrums* ("cerebral hemispheres") united primarily by the walls of the aula from which they were developed as lateral protrusions, and also by secondary junctions (or extensions of junctions) the fornix and callosum (Figs. 4698, 4733, 4735, and 4751).

§ 182. Prop. CXVIII. The interval between the apposed, mesal surfaces of the two hemicerebrums is the *intercerebral fissure* ("interhemispheral," "sagittal" or "great longitudinal") (Figs. 4698, 4732, 4735, and 4736); it differs from ordinary fissures in the following respects: 1, It is mesal or azygous, while all others are lateral or

§ 185. Prop. CXXI. The other five lobes have more or less complete natural boundaries on either the lateral or mesal surface, but not on both. The primary division is by the line of the central fissure (Fig. 4759) into a frontal region and an occipito-temporo-parietal region. The former, although commonly accepted as a single lobe, is so extensive as to be conveniently subdivided by a line continued dorso-cephalad from the presylvian fissure into a *postfrontal* and *prefrontal* lobe, the latter including the orbital surfaces.

---

* To include under the name *cerebrum* the thalami and gemina is to disregard the plain facts of development and comparative anatomy; it is sometimes convenient, however, to group the thalami with the striata (caudatums and lenticulas) under the physiological term "basal ganglia."

§ 186. Prop. CXXII. The region caudo-ventrad of the central fissure line is divided first by the occipital fissure into a parietal and an occipito-temporal portion, and the latter again into a temporal and an occipital lobe by a line from the preoccipital fossa (Fig. 4769,) to the end of the sylvian on the lateral surface, and to the convexity of the splenium on the mesal. In a general way, but by no means accurately, these lobes coincide with the cranial bones for which they are named.

§ 187. *List of the Interlobar Fissures with the Lobes Bounded by them.* (*Figs.* 4768 *and* 4769.)

Fissure.	Aspect.	Lobes.	Figures.
Central	Lateral	Frontal and Parietal	[illegible]
Sylvian	Lateral	Frontal and Temporal	[illegible]
[illegible]	Lateral	[illegible] and [illegible]	[illegible]
[illegible]	Lateral and ventral	Parietal and Temporal	[illegible]
[illegible]	Lateral	[illegible]	[illegible]
Callosal and the [illegible]	Mesal	[illegible]	[illegible]
[illegible]	Mesal	[illegible]	[illegible]
[illegible]	Ventral	[illegible] and Temporal	[illegible]

§ 188. Prop. CXXIII. *Transitory fissures.*—In the article Development of the Brain (Vol. I., p. 640) these are mentioned, but not distinctly represented in the illustrations; what appear to be transitory corrugations of the thin hemicerebral parietes are shown in Figs. 4756, 4757, and 4758; the first is noteworthy from the fact that the left hemicerebrum (Fig. 4697) of the same fœtus presents no depressions corresponding with 1, 2, 3 on the right. The writer has not yet encountered a brain in which, as stated in the article above named, the temporary fissures have vanished before the permanent ones appear, leaving the surface smooth. The subject is interesting and important, and requires much further observation and study of well-preserved specimens.

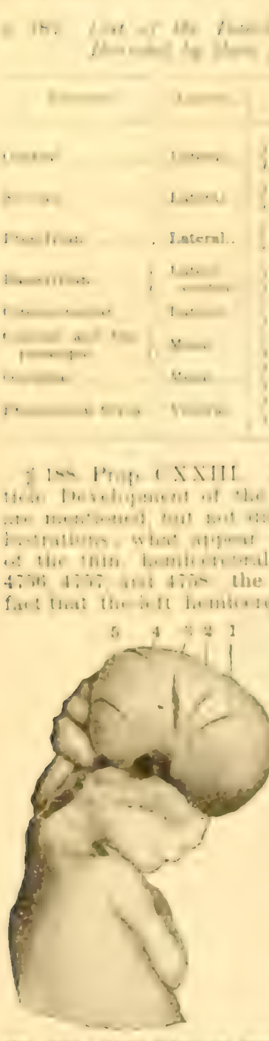

FIG. 4756.—Right Side of the Brain of an Embryo Measuring [illegible] from [illegible] and Estimated at 11 Weeks. [illegible] 1-4 [illegible] in Fig. 4697, [illegible]

§ 189. Points illustrated upon Fig. 4756.—A. The condition and relative size of the encephalic segments at this period; see Fig. 4697.

B. The presence of distinct, lateral fissures which are absent from the other hemicerebrum; notwithstanding their depth, they are probably transitory, at least the three radiating from near the Sylvian fossa.

§ 190. Points illustrated by Fig. 4757.—A. The primary continuity of the hippocampal and callosal fissures, and of the frontal extension marked 1.

B. The existence of several early fissures, some of which are probably transitory.

C. The continuity of the callosum, fornicommissure and terma.

D. The degree of separation of the callosum and the fornix at this period, and the concomitant form and extent of the pseudocœle.

§ 191. Prop. CXXIV. What is perhaps a transient fissure has been observed by the writer to be accurately coincident with the lambdoidal suture in three fœtuses estimated at from three to seven months; see *Journal of Nervous and Mental Disease*, August, 1886.

§ 192. Points illustrated upon Fig. 4758.—A. The distinct collocation of a fissure and suture at this period.

B. The early appearance (or late disappearance?) of

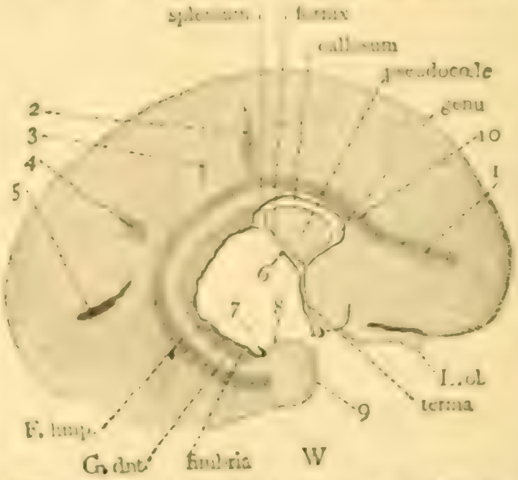

FIG. 4757.—Mesal Aspect of the Left Hemicerebrum of a Fœtus Measuring 16.8 ctm. from Heel to Bregma and Estimated at 18 Weeks. [illegible] 1, [illegible] extension of the primitive callosal fissure; 2, 3, 4, 5, small but distinct radial fissures, some of which probably transitory; 6, point of reflection of the [illegible] from the fornix at the dorsal end of the porta; 7, point of reflection of the endyma at the tip of the [illegible] upon the other margin the [illegible] which has been removed; 8, region which would have become the [illegible]; 9, tip of the temporal lobe; *F. hipp.*, the hippocampal fissure; *G. dnt.*, the dentate gyrus (*fascia* or *fascia dentata*); *L. ol.*, olfactory lobe.

Preparation.—The fœtus was [illegible] and the head [illegible] the entire head was [illegible] the brain was so tender that the [illegible] were broken [illegible]

Defects.—The terma is shown too thick; the [illegible] of the specimen did not permit determining the location and form of the [illegible] and [illegible]

this, the lambdoidal fissure; excepting, perhaps, the dorsal end of the occipital, the rest of this region is smooth.

C. The peculiar sharpness of outline, and the depth of the fissure as compared with its length; both these features reminding one of the supposed transitory fissures (Figs. 4756 and 4757, § 188).

§ 193. Prop. CXXV. The entire ectal surface of the adult hemicerebrum presents alternating depressions, *fissures*, and elevations, gyres (or "convolutions").

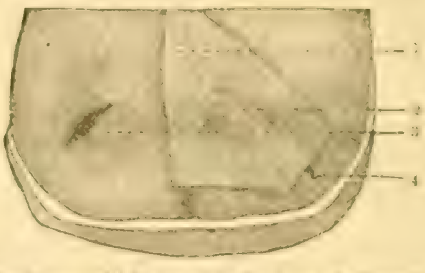

FIG. 4758.—Dorso-caudal Region of the Cerebrum of a Fœtus Measuring [illegible] from Heel to Bregma, and Estimated at Six Months. [illegible] This figure was published by the writer in the *Journal of Nervous and Mental Disease*, August, 1886; see Fig. [illegible] 1, Sagittal suture; 2, lambdoidal suture; 3, right lambdoidal fissure; 4, left [illegible] fissure.

Preparation.—The entire fœtus had been preserved in alcohol. From the left side the [illegible] were removed, excepting a narrow strip along the suture; on the right there was left a trapezoidal area, twelve by twenty-five millimetres, including part of the sagittal and lambdoidal sutures.

The fissures vary in depth from one millimetre to thirty, and in length, from one centimetre to ten. The intervals between the fissures (and thus the width of the gyres) vary greatly, but an adult brain seldom presents an unfissured surface more than 20 millimetres in width.

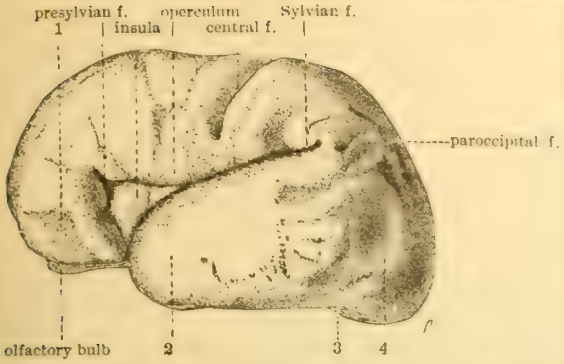

Fig. 4759.—Left Fœtal Hemicerebrum. 1820; × 1. 1, Orbital region, unfissured; 2, temporal lobe, unfissured; 3, slight furrow, the preoccipital fovea; 4, circular depression, unidentified. See § 196.

Preparation.—The fresh hemicerebrum was placed in a mixture of alcohol and glycerine, equal parts; after two days half the mixture was replaced by alcohol; after two days more alcohol alone was used, and renewed on the following day. The original mixture seemed to prevent the usual distortion of fœtal brains, and to facilitate the removal of the pia. Unfortunately the age and size of the fœtus were not recorded.

Notwithstanding considerable variations in different brains, and in different parts of the same brain, one can hardly fail to be impressed with the approximate uniformity of the interfissural spaces (when viewed squarely, as suggested under Fig. 4771) as if the fissures were produced mechanically by the extension of the surface within a confined space; see also the writer's observation upon the fissures of dogs, *Amer. Assoc. Proc.*, 1873, p. 248.

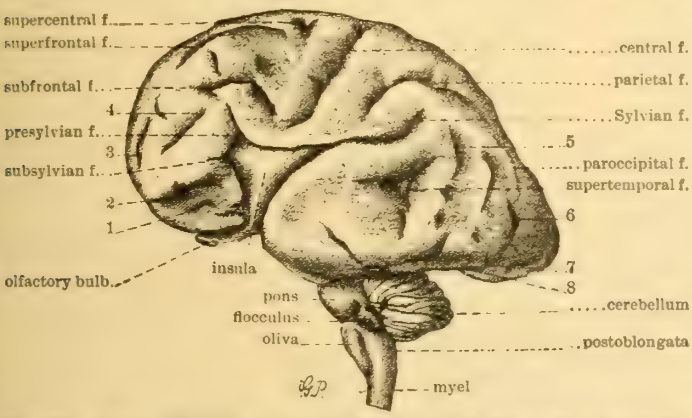

Fig. 4760.—Lateral Aspect of the Left Half of the Brain of a Fœtus, Size and Age Unknown. 2278; × 1. 1–8, Fissures not identified with certainty. See § 197.

Preparation.—The brain was medisected while fresh and this half placed in alcohol upon its mesal aspect; it has become thinner and wider than natural, but exhibits the fissures more perfectly on this account.

§ 194. Prop. CXXVI. Fissures should be studied before gyres, because: 1, They are simpler, being represented by lines instead of planes; 2, they are more commonly entirely independent of other fissures; 3, they are comparable with the rivers of a region which are employed as boundaries of the subdivisions; 4, themselves structureless, they really represent the locations of a greater amount of cinerea than lines of equal width and extent on the gyres, and have thus a greater, presumptive, physiological significance, although there seems to be a difference of opinion as to the functions of the intrafissural cinerea.

§ 195. Prop. CXXVII. For the elucidation of the intricacies of adult fissures, *fœtal brains are much more serviceable than those of monkeys.* This, in contravention of the view and practice of Meynert (*Psychiatry*, p. 7), was insisted upon by the writer (*Amer. Assoc. Proc.*, 1886), and *American Naturalist*, Oct., 1886, p. 902). Some of the peculiarities and complexities of the monkey brain are represented in Fig. 4788.

§ 196. Points illustrated by Fig. 4759.—A. The early appearance of the Sylvian, presylvian and central fissures, and of a depression which was to become the paroccipital. See the ventral surface of this specimen (Fig. 4782).

B. The nearly uncovered and slightly fissured condition of the insula at this period; the faint dorso-ventral line just caudad of the end of the line from *insula* represents the just commencing transinsular fissure, seen distinctly in Fig. 4715.

§ 197. Points illustrated upon Fig. 4760.—A. The condition of the insula and operculums at this stage. The former is distinctly elevated, but as yet perfectly smooth, while in the otherwise less advanced brain shown in Fig. 4759 it has a slight transinsular furrow. The subsylvian fissure is just forming as the ventral boundary of the preoperculum.

B. The demarcation of the subfrontal gyre by the subfrontal fissure.

C. The non-continuity of the parietal and paroccipital fissures.

D. The non-appearance of the precentral and postcentral fissures.

E. The peculiar triangular depression which seems to represent the commencement of the supertemporal fissure.

F. The presence of three fissures or series of fissures caudad of the supertemporal, the middle of which may represent the exoccipital (§ 274).

G. The interruption of the central fissure near its dorsal end; so much as appears in the figure is continuous, but near the mesal margin of the hemicerebrum is a slight depression separated from the longer lateral portion by an isthmus; this condition in the fœtus is noteworthy in view of Heschl's observations (§ 246).

H. The small size of the cerebellum, the freedom of the flocculus therefrom, and the prominence of the oliva.

§ 198. Points illustrated by Fig. 4761.—A. The existence of three independent furrows between the callosum and the margin of the hemicerebrum along the line of what is commonly called the calloso-marginal fissure.

B. The distinctness at this period of the four total or collicular fissures, occipital, calcarine, collateral, and hippocampal.

C. The independence of the occipital and calcarine.

D. The extension of the calcarine alone nearly or quite as far as the point reached in some other brains by the occipital alone or by the compound fissure, occalcarine (§ 214, G).

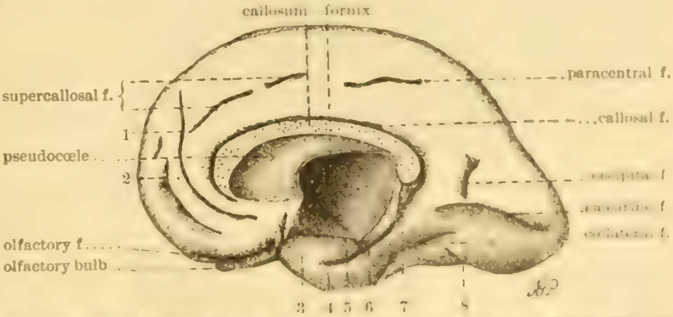

Fig. 4761.—Mesal Aspect of the Left (Reversed) Hemicerebrum of a Fœtus, Size and Age Unknown. 2278; × 1. The lateral aspect of the left half of the same brain is shown in Fig. 4760. 1, 2, 8, Undetermined fissures; 3, tip of temporal lobe; 4, ventral end of hippocampal fissure; 5, uncus; 6 (should have been extended a little farther so as to reach the light band), fimbria; 7, dentate gyre (*fascia dentata*).

§ 199. Plate CXXVIII. *Total and partial fissures.*—Of the permanent fissures some affect merely the cortex and the adjacent white and are therefore sometimes called partial fissures; the central, for example, though constant and deep, is only a partial fissure. But others represent corrugations of the entire parietes so that the ectal depression, fissure, is opposite and obviously correlated with an ental elevation, colliculus; the fissures commonly enumerated as total are the hippocampal (Fig. 4760), calcarine (Fig. 4763), and collateral (Fig. 4764); the Sylvian may be correlated with the caudatum (Fig. 4769); the [illegible] and occipital are total fissures in the fœtus (Figs. 4758 and 4763), and the ental correlative of the latter is sometimes recognizable in the adult (Fig. 4760).

§ 200. Plate CXXIX. *Classification of the permanent fissures.*—The following grouping of the fissures is approximately natural and has been found convenient by the writer; at the best, however, any such arrangements are provisional.*

A. Total fissures, representing a corrugation of the entire paracœlian parietes; *e.g.*, calcarine.

B. Partial fissures with some structural correlative; *e.g.*, olfactory.

C. Partial fissures nearly or quite constant and demarcating recognized gyres; *e.g.*, central.

D. Inconstant, intragyral fissures; *e.g.*, medifrontal.

§ 201. *A List of the Total Fissures with their Ental Correlatives (Colliculi), and the Figures Exhibiting the Conditions.*

Fissures.	Colliculi.	Figures.
1 Calcarine	Calcar	4758, 4762, 4763
2 Occipital	Occipital eminence (in the fœtus only)	4758, 4763
3 Collateral	Collateral eminence	4764, 4765
4 Hippocampal	Hippocamp	4757, 4761, 4763, 4765, 4762, 4767, 4768
5 Callosal	[illegible] (in the fœtus, presumably absent in the adult)	4758, 4759, 4762, 4765, 4766
6 Sylvian	Caudatum (?)	4769

§ 202. Points illustrated by Fig. 4762.—A. An early stage in the formation of the Sylvian fissure, the presylvian fissure being represented by a mere notch.

B. The incomplete separation of the calcar and the occipital eminence.

C. The size of the postcornu relatively to that of the entire hemicerebrum.

§ 203. Points illustrated by Fig. 4764, in addition to A and B, specified under Fig. 4749, § 169.—A. The contiguity of the two margins of the rima excepting for the intruded paraplexus.

B. The consequent absolute exclusion of the ental space from the [illegible].

C. The depth and peculiar form of the hippocampal fissure (Fig. 4768).

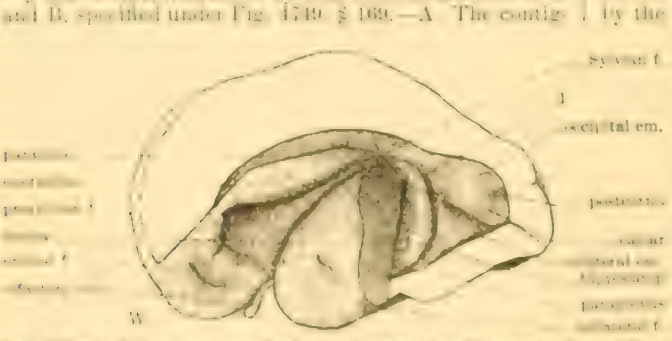

Fig. 4762.—Left Hemicerebrum of a Fœtus [illegible]. Opened from the mesal aspect. [illegible]

D. The corrugation constituting the collicular calcar and calcarine fissure.

E. The equally distinct corrugation of the occipital fissure, at this period with the adjoining collateral occipital eminence, sometimes called "bulb of the posterior cornu."

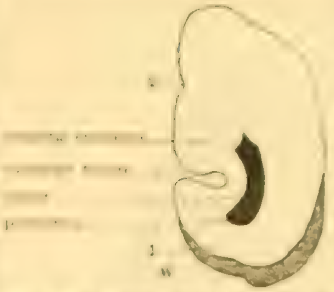

Fig. 4763.—Transection of the Left Occipital Lobe of a Fœtus [illegible] × 1.5. The fissure is [illegible] represented as in Fig. 4763 A.

§ 204. Points illustrated in Fig. 4765.—A. The mesal wall of the postcornu presents a ridge, the calcar, and the mesal surface of the occipital lobe a furrow, the calcarine fissure; as seen in Figs. 4763 and 4764, the ental depression and the ectal elevation are obviously correlated.

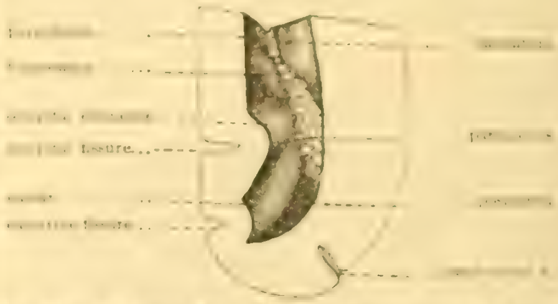

Fig. 4764.—The Caudal Part of the Right Hemicerebrum of a Fœtus Measuring 14 cm., from Vertex to Coccyx, and Hardened in a Mixture 1876. × 1.5. See § 203.

Preparation.—This is part of the specimen shown in Fig. 4749, where the mode of preparation is described; the postcornu was exposed by removing the parietes [illegible]. The plexus was partly cut away [illegible].

B. The precornu presents an ental elevation, the caudatum, and a depression nearly opposite, the Sylvian fissure; but the correlation of the two is not quite clear and the conditions are complicated by the formation of the intrafissural (or intergyral) elevation called insula.

C. Here as in the postcornu there is no doubt respecting the correlation of the ental elevation or colliculus, the hippocamp and the ectal furrow, the hippocampal fissure. In addition, the proper nervous parietes are interrupted along a line, the rima, and the paraplexus is formed by the intrusion of the pial process covered by the endyma; the margins of the rima are specialized and become the fimbria and tænia (on the figure the tænia is not indicated as separate from the caudatum), see § 154.

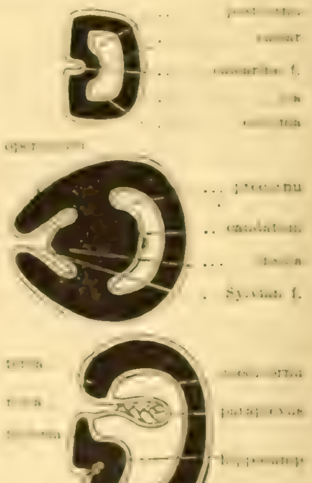

Fig. 4765.—Schematic Transections of the Three Cornua [illegible].

---

* [illegible]

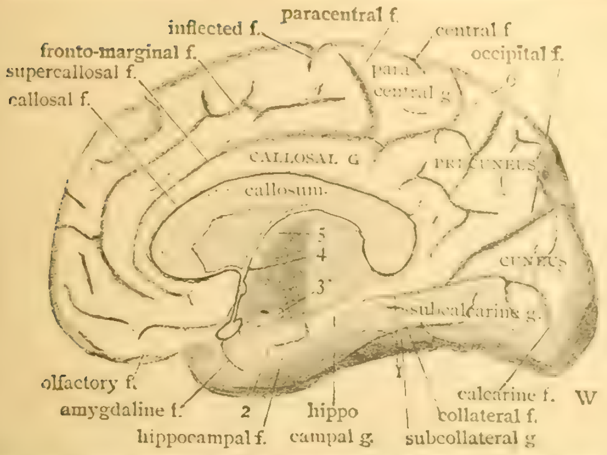

Fig. 4766.—Mesal Aspect of the Left (reversed so as to appear the right) Hemicerebrum of an Adult Male Mulatto. 322; .5. 1, Occalcarine fissure, the common stem of the occipital and calcarine; 2, uncus; 3, optic tract, divided obliquely; 4, fornicommissure; 5, retreating ventral surface of the fornix; 6, paracentral fissure. See § 207.

Preparation.—The entire brain was hardened by continuous alinjection while in the cranium: this and all the other views of it (Figs. 4767, 4770, 4777, 4786, and 4787) are based upon photographs.

Defects.—Most of the fissure lines are too faint: the emargination of the ventral outline just cephalad of the optic nerve is too decided.

§ 205. Prop. CXXX. With children born at term the main fissures are always well defined, and in some cases there seems to be little difference between infant and adult cerebrums in respect to fissural complexity, although the insula is always less developed and less completely covered by the operculums (see Figs. 4715 and 4776). Such brains are often more readily obtained and removed than those of adults and if well preserved and carefully handled may materially aid both study and investigation (see Figs. 4774 and 4776).

§ 206. Prop. CXXXI. Adult cerebrums commonly present individual peculiarities which prevent their serving as types or standards; the writer has found such in every brain examined; even that of a mulatto, simple in several respects, has peculiarities and complexities not as yet fully understood (see Figs. 4766, 4767, 4778, and 4779).

§ 207. Points illustrated upon Fig. 4766.—A. The form of this adult mulatto brain, unaltered save by shrinkage.

B. The continuity of the supercallosal and paracentral fissures.

C. The extent of the fronto-marginal fissure.

D. The complexity of the precuneal fissure.

E. The length of the collateral fissure.

F. The invisibility of the hippocampal fissure excepting at its dorsal end, where it is continuous with the callosal around the splenium, and at its ventral end where it lies between the uncus and the main part of the hippocampal gyre. The margin of this gyre between the tip of the uncus and the splenium is sometimes regarded as one side of the hippocampal fissure, but this is not strictly correct, any more than it would be to regard the crest of a hill as one of the walls of a ravine in its farther slope.

G. The appearance of the dorsal end of the central fissure, dorsad of the splenium.

H. The distinctness of the amygdaline fissure.

I. The sharp ventral deflection of the calcarine fissure, which passes across the margin so as to appear upon the lateral aspect (Figs. 4767 and 4786).

§ 208. Points illustrated upon Fig. 4767.—A. The form of this adult, mulatto, left hemicerebrum, unaltered save from alcoholic shrinkage.

B. A simple, almost typical condition of certain fissures, *e.g.*, central and Sylvian, in a large part of their course, combined with great and unusual peculiarities of the same or other fissures.

C. The visibility of the insula; see Figs. 4778 and 4779.

D. The separation of the preoperculum from the postoperculum by the confluence of the proximal parts of the pre- and subsylvian fissures.

E. The union of the subfrontal fissure, deeply with the

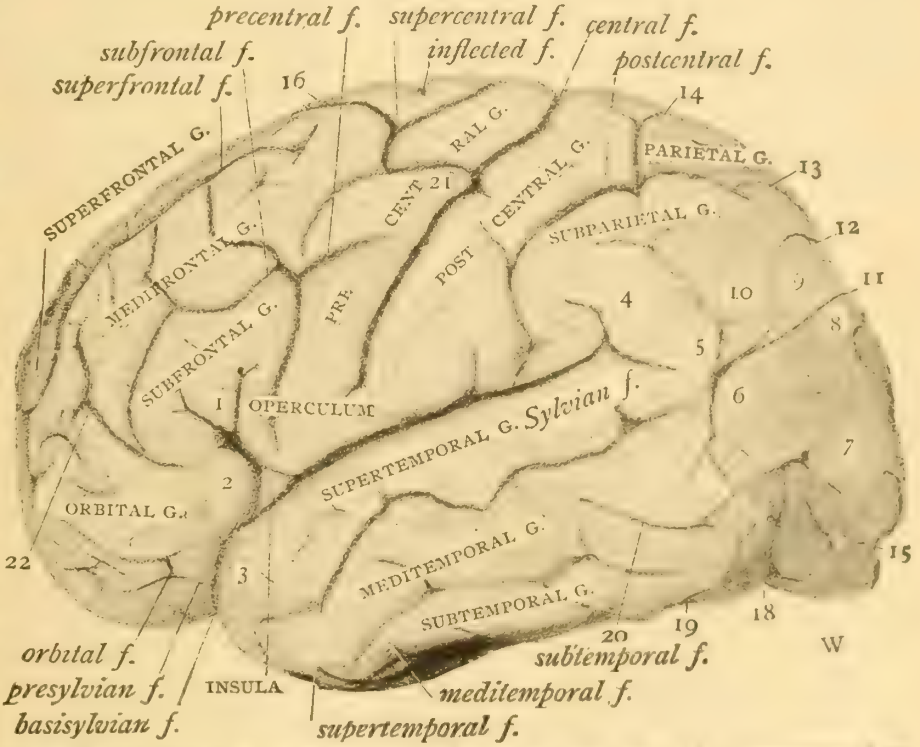

Fig. 4767.—Lateral Aspect of the Left Hemicerebrum of a Mulatto (Fig. 4766). 322; .8. 1, Preoperculum; 2, suboperculum, 3, postoperculum; 4, what is commonly called the "supramarginal gyre;" 5, may represent part of what is called the "angular gyre;" 6, a supergyre overlapping the concealed caudal part of the [illegible] occipital gyre; 8, 9, portions of the unidentified supergyre that overlaps the lateral part of the [illegible] gyre; 10, gyre at the caudal (apparently dorsal) side of the dorsal, deflected end of the supertemporal [illegible] dorsal end of the occipital fissure (this is, however, invisible, and the straight fissure that [illegible] between 8 and 9, and curves ventrad at 6, may probably be the exoccipital or Wernicke's [illegible] "ape-fissures;" it has apparent, though not real, connections with the occipital and [illegible]. 12, curved fissure in the same supergyre, superficially connected with the supertemporal. 13, [illegible] cipital fissure; 14, dorsal fork of the postcentral fissure; 15, caudal extremity of the [illegible] independent; 16, cephalic radius of the triradiate supercentral fissure, see Fig. 4772; 18, 19, 20, [illegible] temporal fissures; 21, just ventrad of the strait between the central and [illegible] (see Figs. 4771 and 4777); 22, the most cephalic of three distinct fissures crossing the medifrontal gyre.

presylvian and the three transfrontal fissures, the most cephalic of which is marked 24, and superficially with the short fissure connecting the precentral with the supercentral.

F. The apparent narrowness of the superfrontal gyre, which nevertheless, as seen from the dorsal aspect, is of considerable width; in fact the narrowest portion of the superfrontal is just as wide as is the subfrontal measured in line with the stem of the compound presylvian and subsylvian fissures; this is a forcible exemplification of what is expressed under Figs. 4771 and 4772.

G. The great length of the supertemporal fissure, and its apparent dorsal branching in four directions; its true and deep continuation is explained between 5 and 10.

H. The continuation of the calcarine fissure around the margin of the hemicerebrum so as to appear upon the caudo-lateral aspect as an undivided end.

I. The superficial connection of the central and precentral fissures.

J. The partial appearance of the subtemporal fissure on the lateral aspect; see, however, Figs. 4767 and 4770.

K. The forking of the Sylvian into an episylvian fissure, next 4, and a hyposylvian, next 5.

§ 212. Prop. CXXXII. The study of fissures upon actual brains is facilitated by reference to diagrams such as have been published by Pansch, Jensen, Ecker, and others;† the present views of the writer are embodied in Figs. 4768 and 4769.

§ 213. Comments upon the fissural diagrams (Figs. 4768 and 4769).—A. They represent the writer's views at this time, but are not identical with those published by him three years ago (*American Naturalist*, October, 1886), and are subject to further modification with increasing knowledge of the facts. For example, the small fissures caudad of the occipital are but little understood, and the [illegible] frontal of Giacomini may prove to be more nearly constant than now supposed.

B. The diagrams are warranted, in most respects, by the brains herein figured, although these constitute but a small portion of the material employed.

C. An attempt has been made to indicate the relative depth and constancy of the fissures by lines of three degrees of width; this grouping, however, is provisional.

D. Excepting with the orbital, paroccipital, and precuneal, the fissural lines are unbranched, and without contortions.

E. As a rule, two lines are connected only when the fissures they represent are always, or almost invariably, continuous in the adult.

F. These connections are of two distinct kinds: primary, invariable, and inevitable from the mode of formation of the parts; secondary, and more or less common, but not necessary.

G. *Invariable* and apparently inevitable fissural connections are (1) of the Sylvian with the basisylvian, presylvian, and subsylvian, all which might be regarded as its continuations or branches; (2) of the callosal with the hippocampal.

H. *Usual* connections are of the occipital with the calcarine, and of the supercallosal with the paracentral, but there are occasional exceptions.

I. *Common* connections are of the superfrontal and supercentral; the precentral and subfrontal; the precentral and supercentral; the postcentral and parietal; the parietal and paroccipital.

J. *Occasional* connections are of the precentral with the Sylvian, and of the central with the Sylvian over the margin of the operculum; in these cases, so far as known to the writer, the junction is seldom very deep.

§ 214. From the deservedly popular fissural diagrams of Ecker, the publication of which has so materially advanced the general knowledge of the subject, these differ mainly in the following respects:

A. The omission of branches and corrugations.

---

* [illegible] (see § 211.)

* Observed on both sides of the brain of an insane woman, No. 2268, Museum of Cornell University, and on the right of No. [illegible].

† The writer regrets that the [illegible] papers by Dr. C. L. Dana ("[illegible]," New York Medical Record, January 12, 1889, pp. 29–34, 18 illustrations) did not appear in time for his suggestions to be considered in this connection.

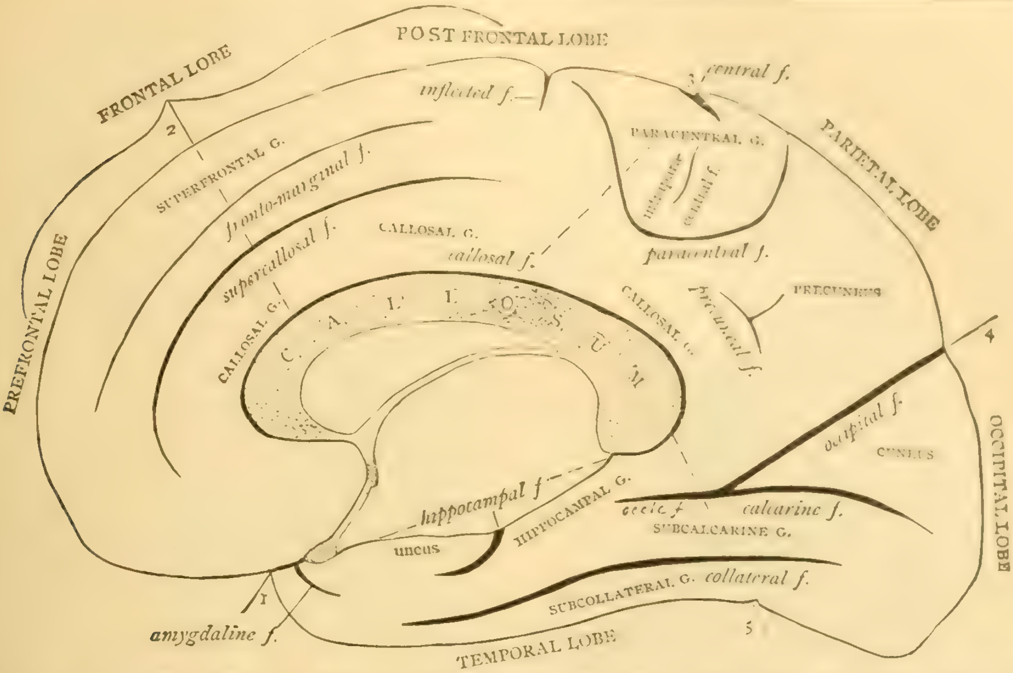

FIG. 4768.—Diagram, nearly Natural Size, of the Fissures upon the Mesal Aspect. The outline and the locations of the principal fissures are from the mulatto brain, represented in Fig. 4766, which was hardened within the cranium. The numbers 1-5, designate the five interlobar lines or boundaries, as follows: 1, fronto-temporal; 2, inter-frontal; 3, fronto-parietal; 4, parieto-occipital; 5, occipito temporal. The abbreviation *occic. f.* stands for occalcarine fissure, the stem or confluence of the occipital and calcarine fissures.

B. The inclusion of the callosal, inflected, amygdaline, medifrontal, precuneal, and subtemporal fissures.

C. The disjunction of the supercallosal from the paracentral.

D. The separation of the precentral from the subfrontal.

E. The introduction of the exoccipital as probably representing the true "ape-fissure" of Wernicke.

F. The combination of the "transverse occipital" of Ecker with the caudal portion of his "interparietal" as a distinct fissural integer, the paroccipital.

G. The designation of the apparently common stem of the occipital and calcarine as the *occalcarine*.

H. The adoption from various writers of what seem to be the best fissural names of a single word each; *e.g.*,

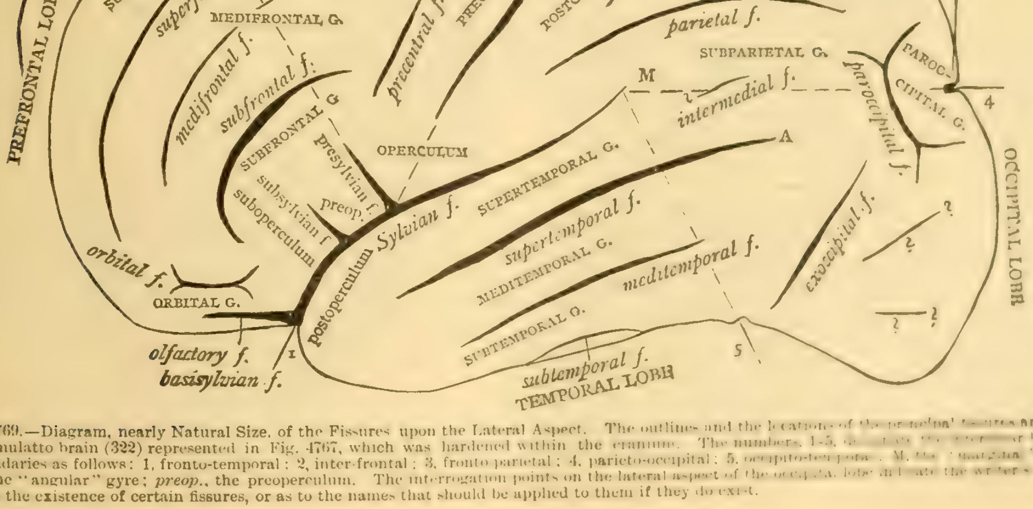

FIG. 4769.—Diagram, nearly Natural Size, of the Fissures upon the Lateral Aspect. The outlines and the locations of the principal fissures are from the mulatto brain (322) represented in Fig. 4767, which was hardened within the cranium. The numbers 1-5, designate the five interlobar lines or boundaries as follows: 1, fronto-temporal; 2, inter-frontal; 3, fronto-parietal; 4, parieto-occipital; 5, occipito-temporal. M, the [illegible] gyre; A, the "angular" gyre; *preop.*, the preoperculum. The interrogation points on the lateral aspect of the occipital lobe indicate the writer's doubts as to the existence of certain fissures, or as to the names that should be applied to them if they do exist.

from Huxley, *subcentral*; from Owen, *callosal*, [illegible] and [illegible]; from Wernicke, *frontomarginal*; from Jensen, *intermedial*; from Pansch, [illegible] and [illegible]; from Schwalbe, [illegible] and [illegible]; from Meynert, [illegible].

J. The substitution of [illegible] mononyms for polyonyms, viz., [illegible] for ascending branch of the [illegible]; [illegible] for anterior branch; [illegible] for the part ventral of the [illegible]; and the restriction of [illegible] to the [illegible] posterior branch.

J. The explanation of *lingual lobule* and *fusiform lobule* [illegible] to apply correctly [illegible] gyri and [illegible] gyri [illegible] at once associated with the fissures which respectively constitute the dorsal boundaries.

K. The use of one and the same word, *fissure*, for all the cerebral depressions excepting the two fossæ.

L. The use of one and the same word, *gyre*, for all subdivisions of the lobes, excepting the cuneus and precuneus, already well distinguished by mononyms.

§ 218. Points illustrated by Fig. 1770.—A. The relative length and width of a hemicerebrum, unaltered excepting from alcoholic shrinkage.

B. The presence of a distinct though rounded prominence between the frontal and the lateral portions of the outline, but the absence of any such boundary between the lateral outline and the occipital (see Fig. 1768).

C. The narrowness of the olfactory gyre between the fissure of that name and the mesal margin of the frontal lobe.

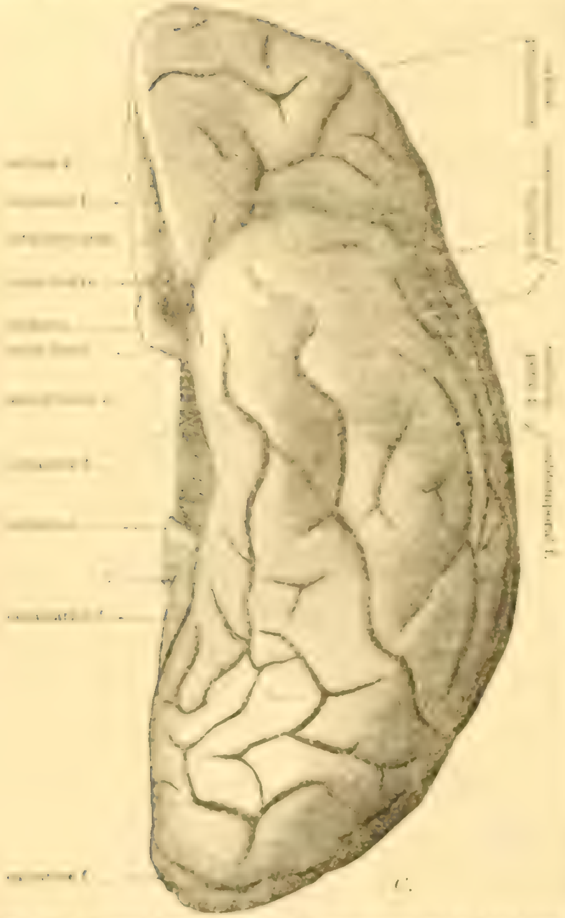

FIG. 1770.—Ventral Aspect of the Left Hemicerebrum of an Adult Male Mulatto. [illegible]

[illegible]

FIG. 1771.—[illegible]

D. The distinctly zygal form of the orbital fissure.

E. The length and distinctness of the subtemporal fissure.

F. The extension of the calcarine fissure upon the occipital end of the hemicerebrum.

G. The presence of a fissure [illegible] on the mesal surface, caudad of the [illegible] fissure.

§ 219. Points illustrated upon Fig. 1772.—A. The length and independence of the superfrontal fissure, and its close parallelism with the dorsal cerebral margin.

B. The extent of the [illegible] fissure upon the dorsal surface, outlining, with the two dorsal radii of the supercentral, a U-shaped area (resembling the sigmoid gyre about the cruciate fissure in the cat, Fig. 1698) which might, if sufficiently constant, be called the *sigmoid* gyre.

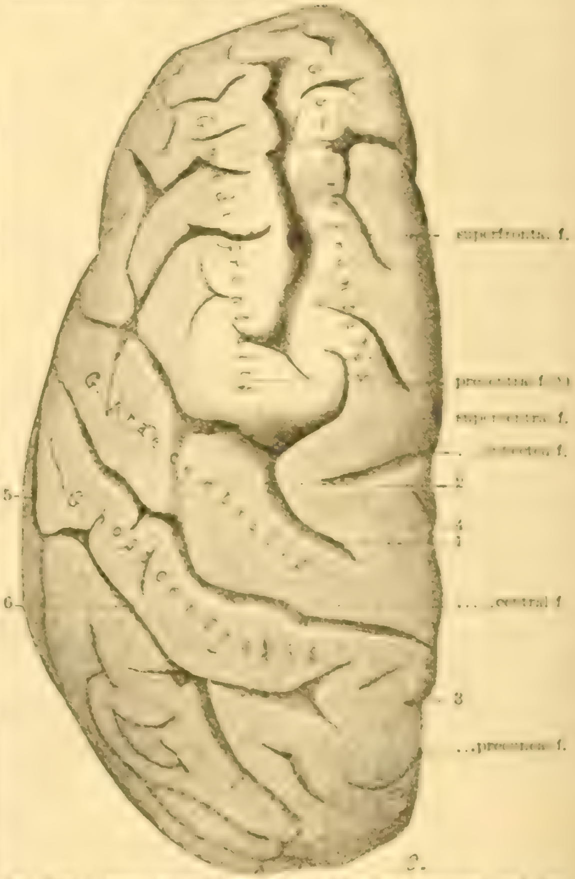

FIG. 1772.—Dorso-cephalic Aspect of the Left Hemicerebrum of a Mulatto. [illegible] 4, cephalic end of the [illegible]

C. The apparently deep communication of the central with the supercentral fissure at 2; at about the middle of this strait, however, is a distinct vadum, a shallow not more than 2 mm. below the surface, and visible in an oblique view, as in Fig. 4777.

D. The triradiate form of the supercentral fissure; one of its dorsal radii is marked (1); the ventral is apparently continuous with the precentral, but the fissure so named is shallow at each end, as stated under Fig. 4767.

E. The continuity of the postcentral fissure with the parietal, which would be reached by the extension of the line from 3.

F. The width of the superfrontal gyre when thus viewed directly, as compared with its apparent width when seen obliquely as in Fig. 4767; see Fig. 4771.

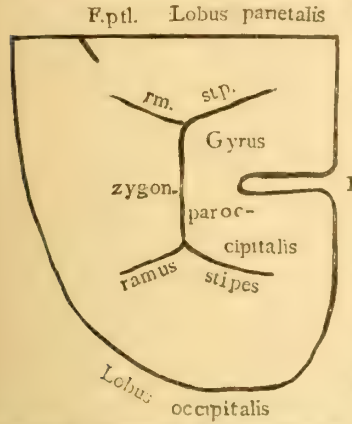

FIG. 4773.—Diagram of the Paroccipital as a Type of the Zygal Fissures (originally published in the *Journal of Nervous and Mental Disease*, June, 1886). The figure represents the dorso-caudal aspect of the occipital end of the left hemicerebrum, including the occipital lobe and part of the parietal, with the dorsal end of the occipital fissure (*F. oc.*) and the caudal end of the parietal (*F. ptl.*). The H-shaped line represents the paroccipital fissure, bounding the gyre of the same name. The bar of the H constitutes the zygon, or yoke, connecting the diverging branches at either end; from the mode of formation the mesal branch is the *stipe* or *stem* (Lat., *stipes*) and the lateral, the *ramus*.

§ 217. Prop. CXXXIII. *Fissural Integer.*—This term (introduced by the writer in 1886, *Jour. of Nerv. and Mental Disease*, xiii., No. 6) is employed herein to designate a fissure which is independent in some species or individuals, and deepest at or about the middle of its length, corresponding nearly with the place of its first appearance. Any marked and frequent shallowing of a supposed fissural integer is reason for questioning its integrality, and for seeking, in other individuals and in allied species, evidence that it really consists of two.

For a summary of the fissural connections observed by the writer, see § 213, F–J. Constant and apparently inevitable branches (*e.g.*, the presylvian and subsylvian) are not strictly integers, although conveniently treated as such. The doubts respecting the central fissure are mentioned in § 253; the relations of fissural integers, as above defined, to more extensive lines of depression which are ideally continuous or may be actually so in some animals (*e.g.*, the alleged components of Meynert's "arched fissures," and of Broca's "limbic lobe" outline, and of the feline anterior and postica fissures in respect to the ventral arched fissure of the fox [see "Anat. Technology," § 1354]) cannot be considered here.

§ 218. Prop. CXXXIV. The "interparietal fissure" of Ecker probably represents two fissural integers, the parietal and the paroccipital, because (1) in about half the cases examined by the writer there are two fissures separated by an isthmus of greater or less width; (2) when the two were continuous there was almost always a vadum at the point corresponding to the isthmus; (3) each of the two portions, whether separate or continuous, is usually deepest at or near its middle; (4) at their first appearance in the fœtus they are always completely independent.*

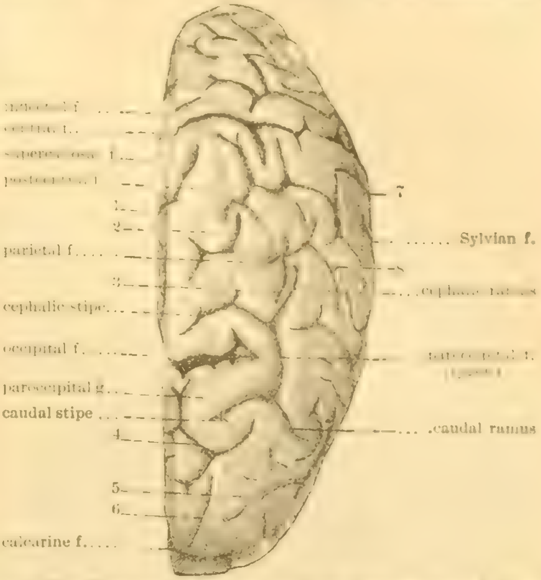

FIG. 4774.—Dorso-caudal Aspect of the Right Hemicerebrum of a Child at Birth. 478; × 1. This figure was published in the *Journal of Nervous and Mental Disease*, June, 1886. Other aspects of the same brain are shown in Figs. 4715, 4718, and 4776.

§ 219. Points illustrated upon Fig. 4774.—A. The form of a perfect and typical paroccipital fissure, very symmetrical, and completely independent of the parietal, although its cephalic ramus and what seems to be an extension of the parietal overlap and approach very closely.

B. The peculiar appearance of the entire hemicerebrum and of the central fissure from this point of view.

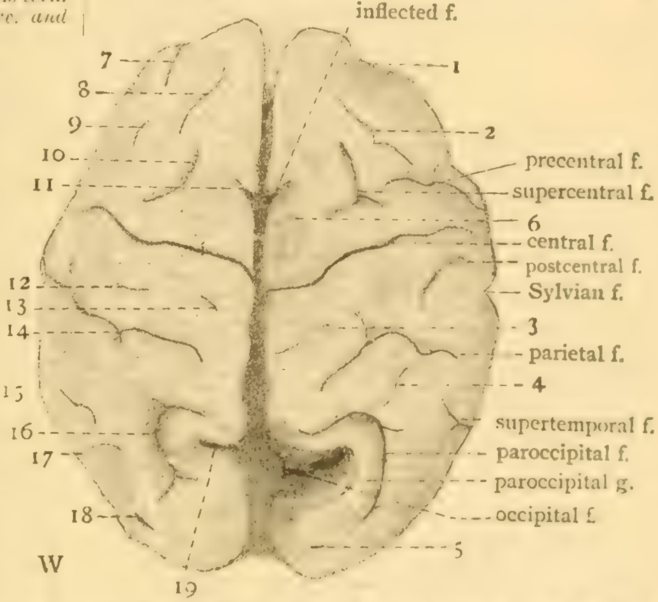

FIG. 4775. Dorso-caudal Aspect of the Brain of a Fœtus, Measuring 41 ctm. from Heel to Bregma, and Estimated at 8 Months. 734; × 1. 11. Left inflected f.; 12, 13, separate portions of the left postcentral (?); 14, left parietal (?); 16, left paroccipital; 17, left supertemporal; 18 (and 5 ?) the lambdoidal fissures; 19, left occipital f. The remaining numbers indicate fissures of doubtful identity. See § 220.

Preparation.—The arteries were injected with starch mixture; extravasation took place at several points, especially the two following: (1) into the dorsal part of the right occipital fissure, converting it into a kind of fossa at the bottom of which is seen the unaffected part of the fissure; (2) into the left paroccipital fissure, separating its walls to some extent. The essential relations of parts are [illegible].

---

* The propriety of dividing the "interparietal" is conceded by Dana, on p. 34 of the *New York Medical Record*, January 12, 1889.

§ 220. Points illustrated upon Fig. 4775.—A. The degree of fissuration at this period.

B. The early condition of the paroccipital fissure as a [illegible] depressed line with lateral branches.

C. The independence of the paroccipital fissure at this period.

D. The absence of any fissure closely resembling the "transverse occipital."

E. The presence of a short fissure, the [illegible] near the caudal end of each hemicerebrum [illegible]

F. The distribution of the inflected fissures at this period.

G. The difficulties of identifying fetal fissures in the [illegible] of those upon the frontal and parietal regions of this specimen.

§ 221. The point illustrated upon Fig. 4776, in addition to some equally well exhibited upon Figs. 4715 and 4774, is the greater depth of the paroccipital zygon at the middle of its length, a fact hardly compatible with the supposition that it is only a caudal extension of the parietal, or that the caudal stipe and ramus constitute an independent fissure, the "transverse occipital" of Ecker.

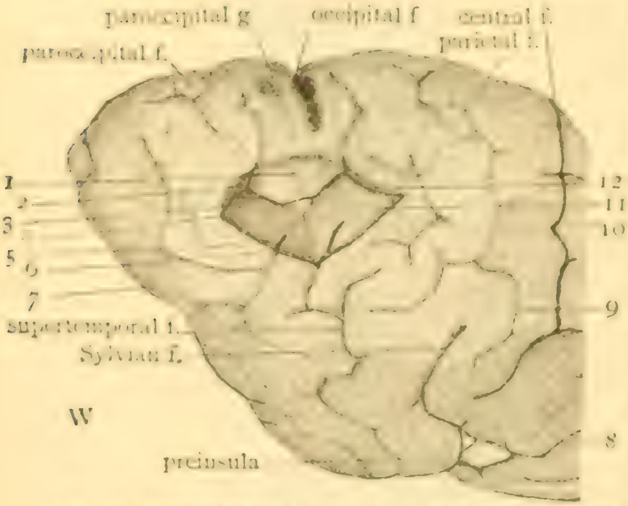

FIG. 4776.—Dorso-caudo-lateral Aspect of the Right Hemicerebrum of a [illegible] 478; × 1. [illegible] rami. [illegible]

§ 222. Prop. CXXXV.—A cerebral fissure is a narrow space vacant of brain tissue and containing only a fold of pia with blood-vessels; yet it has many and sometimes important relations, a complete account of which would embrace between thirty and forty distinct topics. Every fissure demands monographic treatment, but the limits of this article permit only one to be discussed with even approximate completeness, although another, the paroccipital, has been briefly considered (§ 217) in illustrating certain difficulties of fissural study.

§ 223. Prop. CXXXVI.—Pre-eminent importance of the central fissure.—Taking all things into account, the central fissure demands first and fullest consideration; there is indeed no fact concerning it that is not worth recording or that may not prove significant morphologically or practically valuable. The order in which the following topics are presented is far from perfect, but it may serve to indicate the many relations of these cerebral features. To save space the pronoun *it* will commonly designate the central fissure.

§ 224. The name.—It has been called, to use the Latin forms, *fissura*, *sulcus*, and *rima*, with the qualifying adjectives *centralis*, *Rolandica* and [illegible], all these having of course appropriate equivalents in the various modern languages. The writer's doubts as to the utility of discriminating at present between fissures and sulci, have been expressed in § 200, note. His reasons for preferring *central* to *Rolandic* are given in the article Anatomical Terminology.

§ 225. General location and direction.—On the dorso-lateral aspect of the cerebrum at about the middle of its length; from a point at or near the dorsimesal margin, it extends latero-cephalad at an angle of about 67 degrees with the meson, or about 134 degrees with its opposite.*

§ 226. Dimensions.—Among adult hemicerebrums in the museum of Cornell University the length of the fissure, measured in a straight line between the two ends, varies from 8 to 10.5 cm., the usual length being about 9.5 cm., or about one-fourth of the entire circumference of a cerebrum as measured in a dorso-ventral plane intersecting the fissure at about the middle of its length. If measured along the sinuosities, as if the fissure were straightened out, the length may be one-seventh greater than if measured across the curves. The greatest depth varies from 10 to 15 millimetres.

§ 227. Relation to cranial elevations.—There is no evidence of any special collocation between it and any cranial elevation in man or any other mammal; hence, though so deep, it is not a total but a partial fissure (§ 200, A).

§ 228. Constancy.—There is known to the writer no case of the absence of the central fissure in an adult or after the sixth month of fetal life.

§ 229. Topographical importance.—This is well indicated in the following vigorous declarations of Wagner and Ecker: "*Man muss sie immer zuerst aufsuchen, um sich von da in dem schwierigen Chaos der Hirnwindungen* . . . ." " . . . *Bildet sie den sichersten Ausgangspunkt für die Auffindung der Windungen.* . . . ."

§ 230. Form or course in detail.—According to Broca it normally presents two cephalic convexities with an intermediate caudal convexity. In most adults it is certainly more or less serpentine or tortuous and the regular curves are sometimes distinct; but three cephalic convexities have been observed in sufficient number to show the need of careful observation and tabulation.

§ 231. Branches.—Offshoots from the central are usually rather short and straight, starting at the summits of the curves; but in the brain presenting the most decided curvatures (Fig. 4778) there is scarcely any branching.

§ 232. Junctions.—So far as the writer is aware, connections between the central and other fissures (excepting the intercerebral, § 236) are rare, and incomplete or shallow when they occur; *e.g.*, in Fig. 4777, where the concealed vadum between the central branch and the supercentral nearly reaches the surface, and in Fig. 4778, where there is also a nearly invisible vadum just at the apparent union of the supercentral with the central. The occasional confluence of the central with the Sylvian over the margin of the operculum is commonly shallow, but sometimes quite deep, as in the right hemicerebrum of James Evans, figured by Mills, *Journal of Nervous and Mental Disease*, vol. xiii., September, 1886. The depth of such straits should always be stated.†

---

* In a fetal brain figured by [illegible] Pl. xxx.) the fis- [illegible]

† [illegible]

§ 233. Points illustrated upon Fig. 4777.—The visibility, in an oblique view, of a feature invisible in either direct view, dorsal (Fig. 4772), or lateral (Fig. 4767, 21), viz., the existence of an isthmus separating the cephalic branch of the central fissure from the caudal branch of the supercentral, and thus maintaining the continuity of the precentral gyre.

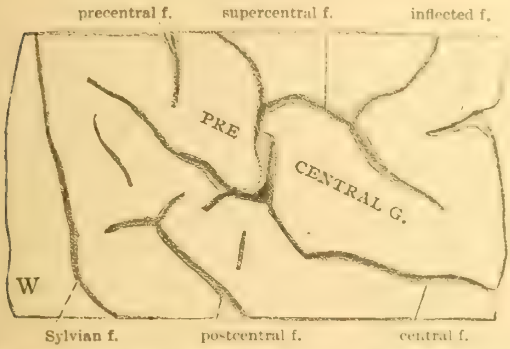

Fig. 4777.—Dorso-lateral Aspect of Part of the Left Hemicerebrum of the Mulatto Brain represented in Fig. 4767.

§ 234. Points illustrated upon Fig. 4778.—A. The unusual number of minor fissures, especially of the slight depressions which are called *fossulæ*.

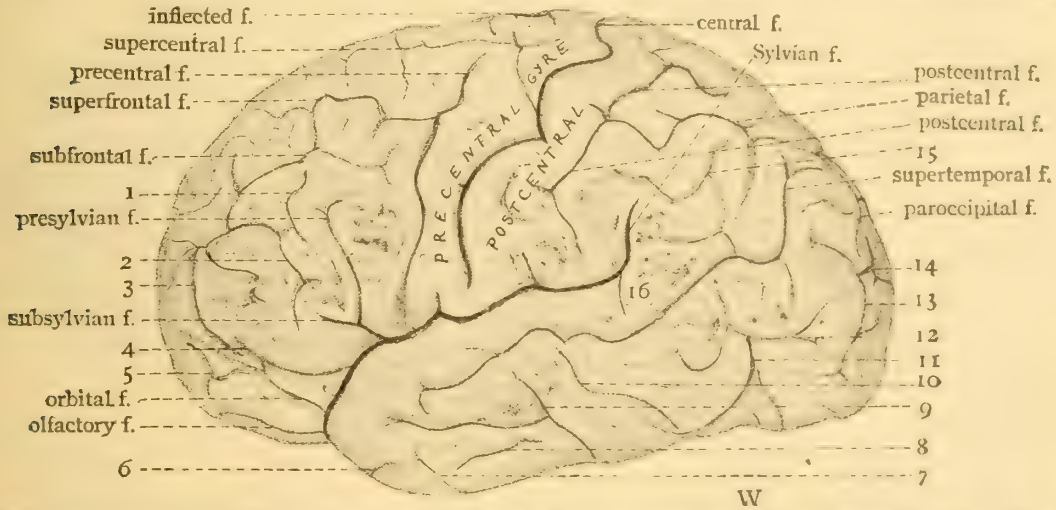

Fig. 4778.—Lateral Aspect of the Left Hemicerebrum of an Adult Hungarian Carpenter, Presenting an Unusual Degree of Fissuration. 385 6. *Preparation.*—The hemicerebrum was hardened resting upon the mesal surface, and apparently with little change in form. The right was likewise numerously fissured. Of the unidentified fissures the only ones that seem to call for comment here are 9 and 10, which are transtemporal fissures, and 16, a well-marked hyposylvian.

B. The three cephalic curves of the central fissure, and their decided character.

C. The extent of the supertemporal fissure.

D. The continuity of the postcentral, parietal and paroccipital fissures.

E. The union of the presylvian and subsylvian, and the concomitant separation of the preoperculum from the postoperculum.

F. The length of the presylvian.

G. The two dorsal branches of the Sylvian, and the distinct hyposylvian branch (16).

H. The crossing of the temporal lobe ventrad of the supertemporal fissure by two transtemporal fissures.

§ 235. Bifurcation.—Terminal division of the central fissure at either end is rare; there are but two instances of it among the brains examined by the writer.

§ 236. Relation to the mesal aspect.—Ecker and Quain imply that the central fissure usually ends at or near the dorsal margin; Gegenbaur and Schwalbe admit that it may cross the margin occasionally or even frequently. Among twenty-five adult hemicerebrums in the museum of Cornell University, January 5, 1889, with five the fissure distinctly fails to reach the margin; with four it just reaches it; with the other sixteen it extends upon the mesal surface for at least one centimetre. So far, therefore, as concerns these undisturbed preparations, the central fissure, although mainly lateral, is entitled to mesal representation in sixty-five per cent.

§ 237. Special location.—About midway between a line coinciding with the precentral and supercentral fissures cephalad, and a line coinciding with the postcentral and ventral part of the parietal caudad.

§ 238. Geometrical relations to the hemicerebrum as a whole.* A. A straight line representing the greatest length (fronto-occipital diameter) of the cerebrum usually crosses at or near the ventral end of the fissure. B. If the middle of this line be determined, the ventral end of the fissure will be found cephalad of the point at a distance equal to about one tenth of the entire line. C. If a perpendicular be drawn dorsad from the middle of this line, it will intersect the fissure at about the middle of its length. D. If the distance from the angle between the frontal and orbital outlines to the angle between the occipital and ventral outlines be measured along the mesal margin of the hemicerebrum, the dorsal end of the fissure will be found at a distance of about fifty-eight hundredths of the whole from the orbito-frontal angle. E. On the mesal aspect, if, from a line representing the greatest length of the hemicerebrum, there be drawn a perpendicular passing the caudal margin of the callosum, it will commonly meet the dorsal end of the central fissure at the margin of the hemicerebrum.

§ 239. The fissure-plane.—This term is employed to designate the entire length and depth of the fissure; the fissure-line is the ectal or superficial margin of the plane. If a hemicerebrum, hardened in the cranium, be transected obliquely along the course of the central fissure, and either half be so held that the mesal surface coincides in direction with the visual axis, the following points may be noted: A. The dorsal half of the exposed surface (including both the cut area and the intrafissural) constitutes very nearly the quadrant of a circle, rounded at the dorso-mesal angle where the fissure cuts the margin. B. The ectal (superficial) margin of the fissure plane coincides very nearly with the periphery of the quadrant. C. The ental margin, the line formed by the bottom of the fissure, is neither depressed at its middle, as with most fissures, nor even straight, but actually lower at the ends than at the intermediate region.

---

* The surgically and pathologically important relations of the central fissure to the cranium and scalp are considered in the article Surgery of the Brain; also in *The Medical Record*, January 12, 1889.

§ 240. How to distinguish from adjoining fissures.—When the precentral is separate from the supercentral, and the postcentral from the parietal, the central is not only longer than either. When these two pairs of fissures unite, however, it is the middle of the group of three fissures at about the middle of the hemicerebrum having a general dorso-ventral direction. The following characters should be noted in case of doubt: its greater depth and length; its extension across the dorsal margin into the paracentral gyre; its location relatively to the entire length of the cerebrum and the angle it forms with the meson; its more complete independence, and the usual absence of terminal forks.

§ 241. Comments upon Fig. 4779.—Pending the detailed study and description of this very interesting brain by the writer, to whom it has been generously loaned from the Museum of Harvard Medical School, with the consent of its preparator and first describer, Dr. Thomas Dwight, the professor of anatomy, the following points may be noted: A. The great length of this hemicerebrum as compared with that of the mulatto (Fig. 4767).

B. The special length of the caudal part, whether the central or the Sylvian fissure be taken as the dividing line.

C. The height of the frontal region.

D. The apparently slight extent of the prefrontal lobe; apparently, because, as is shown upon the dorsal outline (Fig. 4781), a large part of this region is invisible from the side, and is of unusual width.

E. The simplicity of the visible gyres, due to the few connections of the main fissures, and the comparative infrequency of minor ones; partly, because the mesal cephalic surface of the prefrontal lobe presents a much greater complexity.

F. The condition of the minor fissures as sharp incisions rather than as slight depressions, like those in the Hungarian brain (Fig. 4776).

G. The visibility of the insula, at least equal to that in the mulatto (Fig. 4767). Whether any of this condition is due to the pressure during hardening, which may have occasioned also a peculiar roundness of the temporal lobe, it is impossible to determine, and Dr. Dwight does not recall the condition of the parts when the brain was removed.

H. The great length of the supertemporal fissure and its dorsal subdivision.

I. The bifurcation of the Sylvian fissure, constituting perhaps an episylvian and hyposylvian as in the mulatto.

K. The complete independence of the precentral and subfrontal fissures.

L. The union of the proximal parts of the presylvian and subsylvian fissures so as to separate the pre- and postoperculum.

M. The presence of an unusual, curved fissure (14) ventrad of the postcentral.

N. The crossing of the temporal region ventrad of the supertemporal fissure by several irregular fissures (transtemporal).

O. The complication of the zygal form of the orbital fissure by a branch extending cephalad from the middle of the zygon.

P. The complete interruption of the central fissure by an isthmus which is more clearly indicated in the dorsal outline (Fig. 4781).

Q. The rounded form, fullness, or "plumpness" of the gyres, remarked by Dr. Dwight.

§ 242. Anomalies of the central fissure.—There are two conditions of the central fissure that are so unusual as to be properly termed anomalies, viz., its complete interruption, and its duplication.

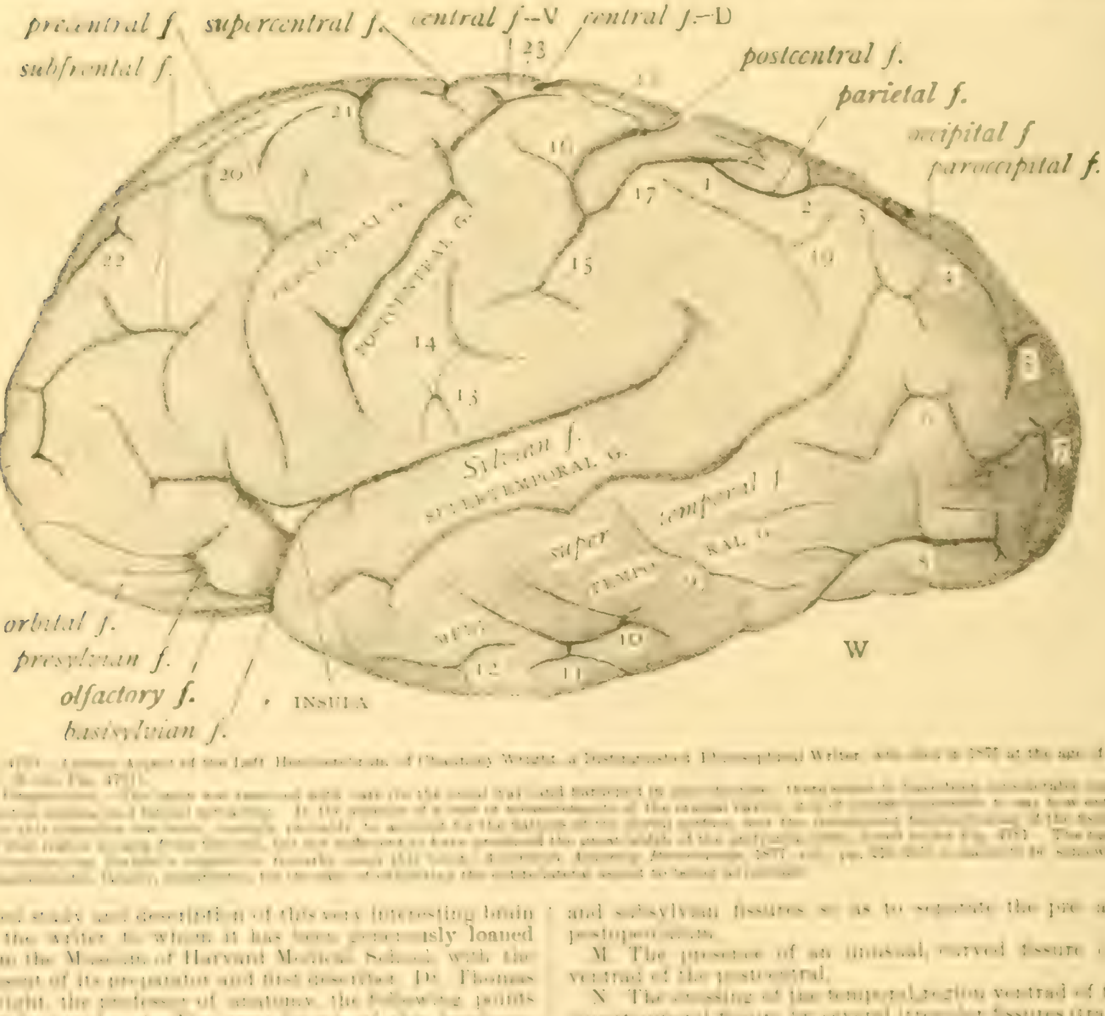

FIG. 4779.—Lateral Aspect of the Left Hemicerebrum of Chauncey Wright, a Distinguished Philosophical Writer, who died in 1875 at the age of 45. (C. Brain Fig. 4781.)

[illegible]

§ 243. Duplication.—Giacomini and Calori have each described a brain in which there are apparently two central fissures, nearly parallel and distinctly separated by an "intercentral gyre."

§ 244. Interruption.—As shown in Figs. 4779 and 4781, the central fissure is completely interrupted on both sides of the brain of Chauncey Wright, the isthmus * being fully on a level with the adjacent gyres. The brain of Dr. Fuchs, figured by Wagner, exhibited a like peculiarity, and the complete interruption has now been recorded for at least ten (perhaps twelve or fourteen) hemicerebrums, a very small proportion of the enormous number of brains examined.

§ 245. Points illustrated upon Fig. 4780.—A. The interrupted condition of both central fissures at their first formation.

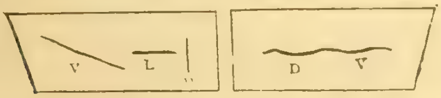

FIG. 4780.—Diagrams of the Right and Left Central Fissure Regions of a Fœtus, 56 ctm. Long and Estimated at 20 Weeks. 827 ; 2.

B. The lack of symmetry ; on the right are two parts, the right ventral (V) being 2 mm. deep at its middle and the dorsal (D) 2.5 mm.; on the left are three distinct divisions—the dorsal parallel with the meson, the lateral at right angles with it, and the ventral oblique.

§ 246. Partial interruption.—Dwight and Heschl have called attention to the not infrequent presence of a vadum or shallow in the depths of the central fissure, commonly nearer the dorsal end ; among 1,087 hemicerebrums examined, Heschl found in 152 (about fourteen per cent.) an elevation rising from one-sixth to five-sixths of the entire depth of the fissure, and suggests that the rare cases of complete interruption result from the greater development of this feature. In view of these observations the vadum should always be looked for.

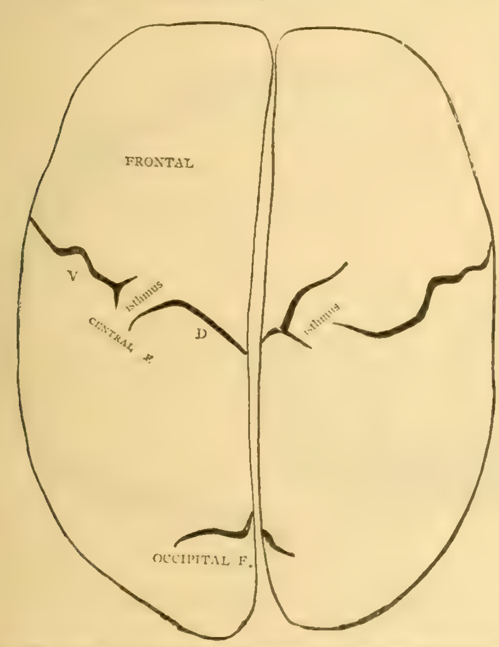

FIG. 4781.—Dorsal Outline of the Cerebrum of Chauncey Wright, Including only the Central and Occipital Fissures. × .5.

§ 247. Points illustrated upon Fig 4781.—A. The unusual width and squareness, of the prefrontal lobes, whence a direct lateral view of either hemicerebrum fails to include what is, on the whole, the most richly fissured surface ; see Fig 4779.

B. The complete interruption of the central fissure on each side by an isthmus which is level with the general surface and thus unites the precentral and postcentral gyres (see § 244).

§ 248. Time of first appearance.—Nearly all writers state that the central fissure is formed about the end of the fifth month, the twentieth week. The following observations show that there is probably some variation in this respect, or—as is perhaps equally probable—that the length of the fœtus varies considerably at the same stage of fissural development. In fœtuses 827 and 1817, respectively 56 and 65 ctm. long, the fissure is vague or absent ; in 1820, 61 ctm. long, it is distinct and deep ; in 2278, 67 ctm. long, it is well-developed, and several other lateral fissures are visible.

§ 249. Relative order of appearance.—Excluding the transitory fissures (Fig. 4756) and the lambdoidal (which may be transitory) the central is apparently the first of the lateral fissures to be developed after the Sylvian (Fig. 4759). But some of the writer's preparations indicate that this order may not be invariable ; in 2081 the parietal and supertemporal are more advanced than the central ; in 1817 there is no trace of a central, although both superfrontals are distinct. Numerous and careful observations are needed on this point.

§ 250. Form in the fœtus.—When first distinctly formed, the fissure line is nearly straight, with a slight cephalic convexity (Fig. 4759).

§ 251. Proximate cause.—According to W. Krause (as stated in *Quain*, ii., 332), in the fœtus, between the fourth and sixth months, the medicerebral vein is connected with the longitudinal sinus by a vein which atrophies later ; the writer has not been able to consult Krause's original statement, or to verify its accuracy.

§ 252. Relation to primitive fissures.—There is no good reason for regarding either of the three radiating, presumably transitory, fissures shown in Fig. 4756, as the direct precursor of the central.

§ 253. Integrality.—For the definition of *fissural integer* see § 217. The occasional, complete interruption (§ 244), the not infrequent existence of a vadum (§ 246), and the mode of appearance in one case (Fig. 4780), suggest the possibility that the central consists really of two fissural integers, commonly connected, and comparable, perhaps, with the parietal and paroccipital (§ 217). For the present, however, it seems justifiable and certainly more convenient to regard the conditions above named as anomalous, and to treat the central as a single fissure.

§ 254. Lateral variation.—Clevenger states that it is usually located farther caudad on the left side than on the right ; its relations to motor areas would lead one to expect considerable lateral variation in position, direction, and shape.

§ 255. Physiological and surgical relations.—It is completely surrounded by important motor areas, and its exact relations to the cranium and surface of the scalp are of great pathological and surgical importance ; these matters are considered in Vol. I. of this work, pp. 642-648, and in Surgery of the Brain, in this volume.

§ 256. Psychological relations.—Clevenger has a suggestive paper (*Journal of Nervous and Mental Disease*, April, 1880) on the ratio between the location of this fissure and the intelligence of the individual or species ; although unable to admit his identification with the cruciate fissure of Carnivora, or to accept all his conclusions, the writer regards the determination of the relative bulk of the precentral (frontal) region of the cerebrum and the postcentral (occipito-parieto-temporal) region as of great importance, in connection with the comparison between individuals and species in respect to intellectual power and voluntary inhibition or self control.

§ 257. Condition in other Primates.—In the apes and in all the ordinary monkeys the fissure is readily recognized ; *e.g.*, in the *Macacus*, Fig. 4788.

§ 258. Carnivoral representative.—By various authors (see "Anat. Technology," § 1370) it has been homologized with the following features of the ... superorbital, ... and ... Notwithstanding the ... relations of the ... and ... fissures to ... areas, the question of their homology (morphological identity) must be held as yet undetermined; see

---

* This term is equivalent to *pli de passage*, *annectent convolution* and *bridging convolution* ; the latter is misleading, for the interruption of a fissure has no analogy with a bridge, but rather with a dam, dyke, or isthmus, absolute size being of no moment.

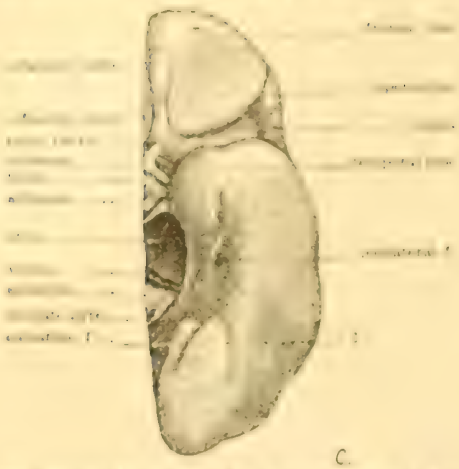

FIG. 4782.—Ventral Aspect of the Left Hemicerebrum of a Fœtus [illegible]. The lateral aspect of the same preparation is shown in Fig. 4759. See § 264.

also the writer's remarks in *Journal of Nervous and Mental Disease*, July, 1885.

§ 259. Prop. CXXXVII. *Collocation of fissures with cranial sutures.*—In the adult the dorsal end of the occipital fissure has a notably constant position at the mesal angle of the lambdoidal suture, as seen in Fig. 4684. With fœtuses of between three and seven months this suture is decidedly caudad of the occipital fissure, but is distinctly collocated with the lambdoidal fissure (Fig. 4758); this collocation does not persist after the seventh month, and it is not yet known whether the fissure disappears or changes its position. The approximate collocations of the central and other fissures with sutures are considered in the article Surgery of the Brain.

§ 260. Prop. CXXXVIII. *Supergyres and subgyres.*—The ectal surfaces of two adjoining gyres are commonly at about the same level, excepting for a marked change in the general contour of the cerebrum, as, *e.g.*, at its several ... But sometimes one gyre may be developed much more than its neighbor, and encroach upon it so as to conceal it more or less completely. The covering gyre may be called a supergyre, and the covered a subgyre.

§ 261. Prop. CXXXIX. *Superfissures and subfissures.*—These terms are employed herein to designate the fissures which result from the formation of supergyres and subgyres. The line of overlapping of a supergyre is a superfissure, as also is the line of junction of two supergyres meeting from opposite directions. A subfissure is one which is concealed by a supergyre, and invisible until the lips of the superfissure are divaricated.

§ 262. Prop. CXL. *Normal fissures and subfissures* are the circuminsular, which encircles the insula (Fig. 4783), the transinsular and others crossing the surface of the insula (Figs. 4715 and 4783), and those which indent the ectal or insular surfaces of the opercula (Fig. 4784). Unusual subfissures appear in Fig. 4787, after the removal of the unusual supergyre; superfissures are shown also in Fig. 4788.

§ 263. Prop. CXLI. The insula ("Island of Reil") and the operculum constitute normal and typical examples of subgyres and supergyres. As may be seen in Figs. 4715, 4752, 4759, 4760, 4782, and 4784, and in the diagram, Fig. 4765 (B), the insula is a part of the cortex which, at one period wholly superficial, is gradually covered, more or less completely, by converging folds of the adjacent regions. The insula thus becomes a subgyre, while the operculum, preoperculum, suboperculum, and postoperculum are supergyres. For other supergyres see §§ 271 and 276.

§ 264. Points illustrated by Fig. 4782.—A. The continuity of the insula with the lateral root of the olfactory crus.

B. The partial covering of the insula at this period.

C. The thickness and roundness of the margin of the operculum.

D. The formation, at this period, of the presylvian fissure constituting the cephalic limit of the operculum, but the non-existence of a subsylvian fissure.

E. The length of the olfactory bulb at this period, as compared with its crus, which latter is the longer in the adult.

F. The concealment of the entire olfactory fissure by the olfactory bulb. In the adult, usually, the fissure projects considerably beyond the bulb (Fig. 4689).

§ 265. Prop. CXLII. The insula has notable topographical relations with (*a*) the several opercula, (*b*) the claustrum and lenticula. Although perhaps, upon the whole, most developed in man, relatively to the size of the entire brain, it is perfectly distinct in apes and monkeys, in dogs, the porpoise, and (according to Spitzka) in several other mammals. Its comparative anatomy and its human variations are fruitful and important subjects for further observation: see the papers by Spitzka (N. Y. *Med. Record*, January 6, 1879), Eberstaller (*Anat. Anzeiger*, May 15, 1888, p. 582, and references there given), and the writer (*Jour. of Nerv. and Mental Disease*, xii., July, 1885).

§ 266. Points illustrated on Fig. 4783.—A. The location and common form of the insula.

B. The existence of fissures and intervening gyres radiating in general from its summit.

C. The division of the whole by a somewhat deep fissure, the transinsular (2), into a cephalic region, *prœinsula*, and a caudal, *postinsula*. Other views of the insula, young and adult, are given in Figs. 4759, 4760, 4762, 4767, 4779, 4782, and 4785.

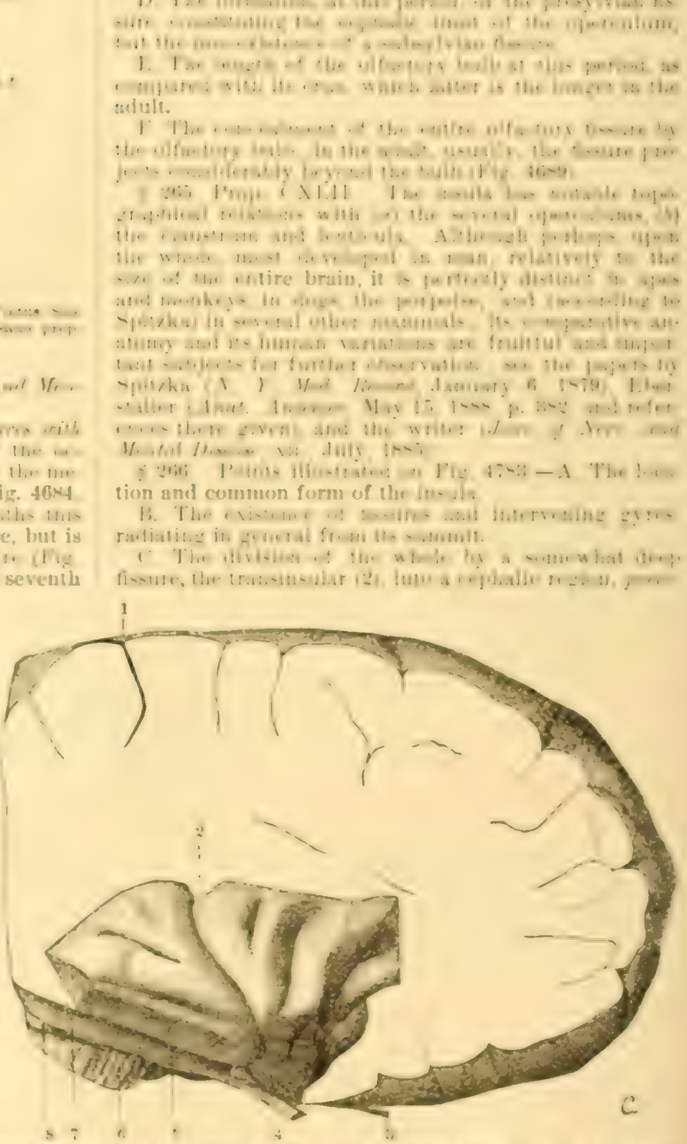

FIG. 4783.—Right Adult Insula Exposed from the Lateral Aspect. (B. G.) 1, Central fissure; 2, transinsular fissure; 3, olfactory crus; 4, optic nerve; 5, [illegible]; 6, [illegible]; 7, preoperculum; 8, postoperculum.

§ 267. Prop. CXLIII. The *operculum* is not strictly a single gyre, but includes portions of at least two, the precentral and the subfrontal. It is as if the eastern half of the southern extremity of Africa were owned by the Dutch and the western by the English, each half having its own territorial designation; we might still speak of

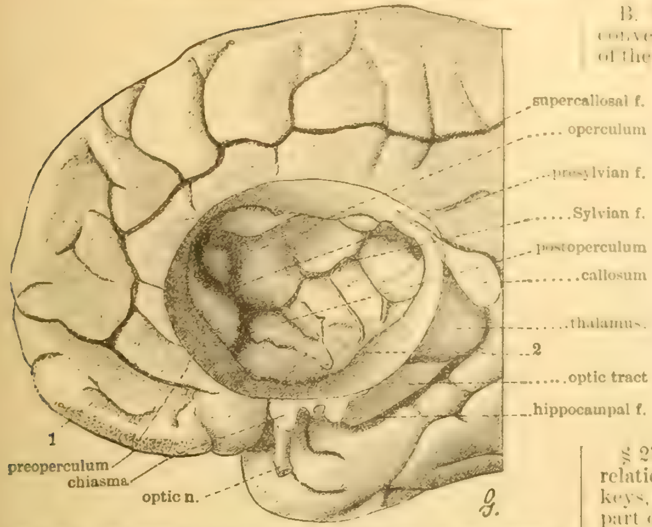

FIG. 4784.—The Mesal Aspect of the Right Operculums of a Child at Term. 1823 : < 1.

Preparation.—The hemicerebrum had been hardened in alcohol while resting on the meson, and hence is a little thinner and wider than natural, but thereby better suited to the desired object. A probe was pushed through from the lateral aspect at the triangular place of divergence of the Sylvian, basisylvian, and presylvian fissures; from the hole so made upon the mesal aspect, cuts were carried in various directions, cautiously, until most of the thalamus, caudatum, lenticula, and insula were removed, thus exposing the ental or mesal surfaces of the operculum, postoperculum and preoperculum, with the intervening Sylvian and presylvian fissures.

Defects.—The inclusion of the occipital region would have rendered the figure somewhat more intelligible. The suboperculum and subsylvian fissure are not exposed ; the cut surface at the ventral side should be traversed by a line starting from just cephalad of the chiasma to represent that part of the basisylvian fissure.

the Cape of Good Hope, composed by the two countries. In general the same may be said of the postoperculum, sub- and preoperculum.

§ 268. Points illustrated by Fig. 4784.—A. The extent to which the several operculums lap over the insula, constituting so many supergyres.

B. The fissuration of the ental surface of the operculums.

C. The distinctness of the supercallosal fissure, and the absence of a fronto-marginal between it and the dorsal margin of the hemicerebrum.

D. The presence of the amygdaline fissure, partly concealed by the optic nerve.

§ 269. Points illustrated by Fig. 4785.—A. The existence of two zones of the lenticula, an ectal, the putamen, and a second, ental of the first, as seen from Fig. 4732 ; there is still a third, but it does not extend sufficiently far dorsad to appear in this or Fig. 4731.

B. The constitution of the insula as an elevation of the lateral region of the hemicerebrum, its cortex and medulla being continuous with the rest and with the overlapping operculums.

C. The peculiar form and location of the claustrum, a thin, subcircular disk of cinerea, between the putamen and the insular cortex, of which it is probably a dismemberment.

§ 270. Prop. CXLIV. Supergyres and subgyres occur by exception in other parts of the cerebrum, especially the occipital (see Figs. 4776 and 4777), and normally in many monkeys, the *poma*, § 272, Fig. 4788.

§ 271. Points illustrated upon Figs. 4786 and 4787.—A. The presence of a postcuneal fissure along the caudal margin of the cuneus ; its dorsal end is free, but ventrad it has a very shallow connection with the calcarine.

B. The concealment, in the undissected brain, of the convexities of the paroccipital fissure and gyre and part of the occipital fissure by an extensive supergyre, analogous to, though probably not homologous with, the poma (occipital operculum) of monkey brains (Fig. 4788).

C. The conversion of the paroccipital fissure and gyre into a subfissure and subgyre.

D. The apparent continuity of the exoccipital with the occipital in the undissected brain.

E. In general, the desirability of checking all conclusions based upon the obvious features of the cerebrum, by an examination of the concealed conditions.

§ 272. Prop. CXLV. The so-called "external occipital," or "external perpendicular," fissure of monkeys is a superfissure, factitious, variable, and heterogeneous, resulting from the lapping of a supergyre, the *poma* ("occipital operculum"), upon the parts cephalad of it ; it may therefore be called the *pomatic* fissure.

§ 273. Points illustrated upon Fig. 4788.—A. The relation of the poma ("occipital operculum") of monkeys, as a typical supergyre, to the paroccipital and part of the supertemporal, which are here subgyres.

B. The relation of the pomatic ("external occipital") fissure of monkeys, a typical superfissure, to the paroccipital and occipital fissures, which are here wholly or partly subfissures.

C. The, so to speak, factitious nature of the pomatic fissure, since it results, not from the opposition of two adjoining and approximately equal gyres, but from the lapping of one over the crests of those adjoining ; as may be seen by comparing the two sides, it really comprises three distinct parts, viz., a lateral, between the

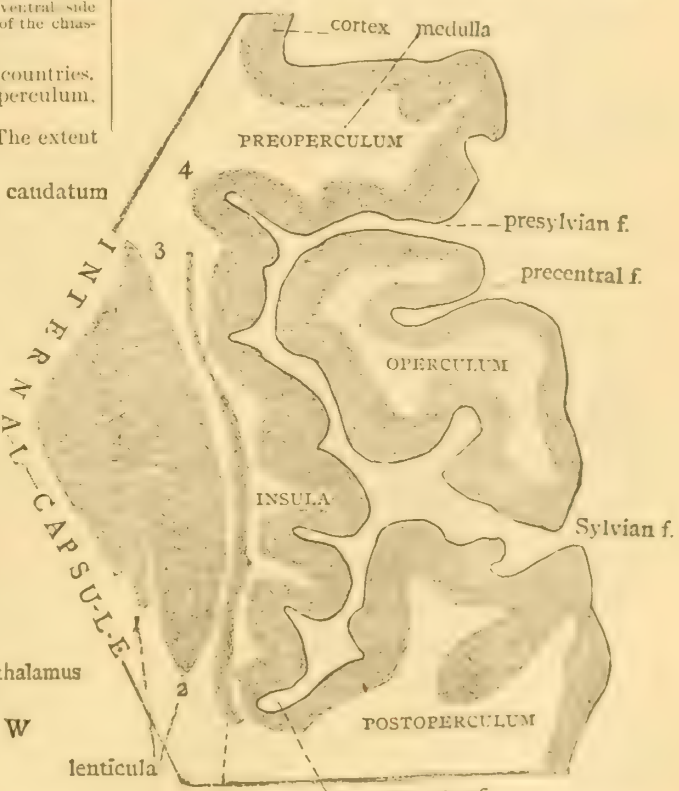

FIG. 4785.—Longisection of the Right Insula and Adjacent Parts. [illegible] Enlargement of the corresponding region of Fig. [illegible]. 1, 2, [illegible] the latter and larger the putamen ; 3, the stratum of alba between [illegible] claustrum, sometimes (most undesirably) called "external capsule" ; 4, [illegible] of circuminsular fissure. *Internal capsule* should be [illegible].

pomatic margin and the ental surface of the temporal gyre; an intermediate, connecting with the cephalic slope of the paroccipital fissure; a space, formed by the

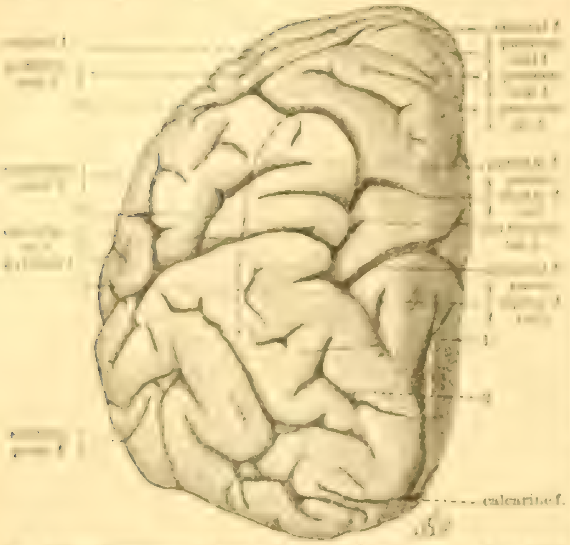

Fig. 4786.—Dorsocaudal Aspect of the Left Hemicerebrum of an Adult [illegible]

For the preparation, see Fig. 4786.

pomatic margin and the paroccipital gyre. Finally, since the dorsal termination of the occipital fissure is covered by the poma, there results an apparent continuity of the pomatic and occipital fissures.

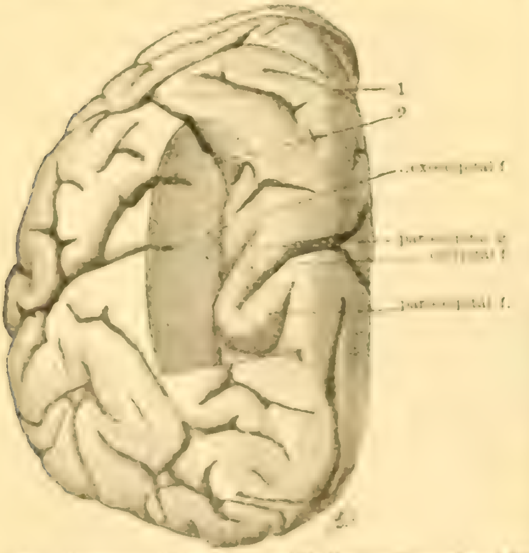

Fig. 4787.—Dorsocaudal Aspect of the Left Hemicerebrum of an Adult [illegible]

[illegible]

D. The continuity (depth not determined) of the paroccipital fissure with the occipital.

E. The junction of the Sylvian and supertemporal fissures.

F. The distinctness of the "angular gyres."

G. The existence of peculiarities and complexities which in the judgment of the writer render monkey brains less serviceable than those of human fœtuses for the elucidation of several problems.

§ 274. Prop. CXLVI. Under the various titles "external perpendicular," "external occipital," "temporo-occipital," "ape fissure," "exoccipital," etc., have been included several different human fissures or combinations of fissures, viz.: (A) The dorsal extreme of an unusually deep occipital fissure, Marshall, "The Brain of a Bushwoman," *Philosophical Transactions*, cliv., p. 5[illegible], Figs. 1, 2, 3; (B) a fissure on the lateral aspect, caudad of the supertemporal, and having a general dorsoventral direction: the vordere occipital of Wernicke ("Das Urwindungssystem des menschlichen Gehirns," *Arch. für Psychiatrie*, 1876, Pl. v., Figs. 19 and 22), called *exoccipital* in the present article in order to

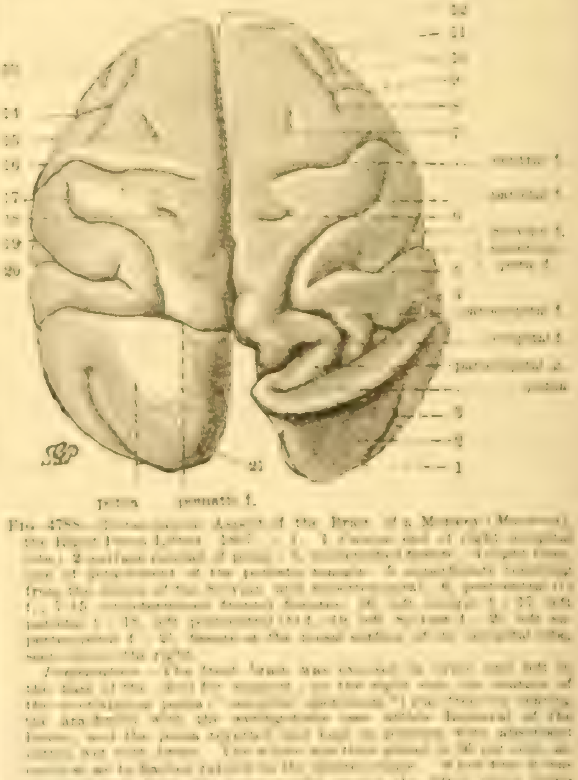

Fig. 4788.—Dorsocaudal Aspect of the Brain of a Monkey (Macacus), [illegible]

Preparation.—[illegible]

avoid using the more natural synonym, *preoccipital*, already applied elsewhere by Meynert; (C), the combination of A and B,* on account of a supergyre which covers the dorsal end of the true occipital fissure (A) and permits the adjacent end of B to apparently become continuous with it, as in Figs. 4786 and 4787.

§ 275. Prop. CXLVII. No one of the fissures or fissural combinations mentioned in § 274 is identical with the pomatic fissure of most monkeys; but the exoccipital may exist in the true apes and in *Ateles* (Huxley, *Zool. Proc.*, 1864, Pl. xxix.). It is doubtful whether the term "ape fissure" is a desirable one to retain.†

§ 276. Prop. CXLVIII. The depth of fissures should be determined either (*a*) by sounding, as practised by Jensen (*Archiv für Psychiatrie*, 1874, p. 596) or by the careful removal of interfissural blocks capable of being replaced and secured by pins, as represented, *e.g.*, in Figs. 4776 and 4787.

---

* [illegible]

† [illegible]

§ 277. Prop. CXLIX. The fissures of idiots, of insane persons, and of criminals are usually peculiar; whether these peculiarities have the significance sometimes ascribed to them, and especially whether murderers' brains present characteristic features, are questions of exceeding interest and importance. The writer does not feel ready, as yet, to discuss them, but refers with confidence to the admirable paper of Dr. Charles K. Mills, *Jour. of Nerv. and Mental Disease*, 1886, September and October.*

§ 278. Prop. CL. It seems at least probable that the well-marked human races present fissural peculiarities; careful figures and descriptions of such are not yet numerous enough to serve as a basis for useful generalization. The paper of Dr. Mills above cited refers to mulatto brains, and contains figures and a preliminary description of a Chinese brain, a most rare and interesting specimen. The brain of a Bushwoman has been described and figured by Marshall (see § 274), and that of a Hottentot is discussed by Wyman, *Boston Soc. Nat. Hist. Proceedings*, ix., 353.

§ 279. Prop. CLI. Abundant fissuration is of course one of the factors in cortical extension, but not the only or perhaps the principal one. Whatever may be the average derived from a considerable number of cerebrums, more or less fissured, there occur exceptions, such as the two brains shown in Figs. 4778 and 4779. The mechanic's cerebrum is fissured to an unusual degree and the insula completely hidden; the philosopher had a larger brain, but its lateral aspect presents an equally unusual absence of fissural complexity and the insula is exposed.

§ 280. Prop. CLII. For the determination of the correlation between mental characteristics and cerebral peculiarities it is desirable that the brains of well-known persons of marked idiosyncrasies should be carefully preserved and thoroughly studied. Among the individuals best adapted to subserve this object are college professors, who have usually somewhat sharply defined capacities and attainments, and are the subjects of prolonged and discriminating observation and discussion among their trustees, colleagues, and students; no professor's brain should be lost to neurological science.

§ 281. Prop. CLIII. Considerable interest attaches naturally to the comparisons of brains as to *weight*, absolute and relative, and as to other points, between individuals, the sexes, races, ages, and different species. Any present statement of the case must be largely negative and qualified, hence neither compact nor altogether satisfactory. Many of the following figures and generalizations are taken from the excellent account of the subject in *Quain*, ii., 382–384.

§ 282. Prop. CLIV. In comparing brains, and especially cerebrums, the following data are desirable but seldom all attainable. 1. Absolute weight, after removal of the dura. 2. Relative weight, *i.e.*, in comparison with that of the entire body. 3. Weight of the cerebrum, including the thalami. 4. Form (very difficult to determine upon the fresh brain). 5. Degree of fissuration. 6. Depth of fissures. 7. Arrangement of fissures. 8. Age. 9. Sex. 10. Cause of death. 11. Degree of emaciation. 12. Mental state (insanity, etc.). 13. Thickness of cerebrocortex. 14. Firmness of the cortex. 15. Chemical and histological integrity.

§ 283. Prop. CLV. The *average weight* of the adult human brain, according to Quain (ii., 382), is 1,247 grams (44 oz. avoir.) for the female and 1,400 (49.4) for the male. The more recent conclusions of Bischoff and Mendel make both these a trifle lower. In a series of 278 male brains, the *maximum weight* was 1,842 grams (65 oz.) and the *minimum* 964 (34 oz.). Among 191 female brains the corresponding figures were 1,587 (56) and 879 (31). Certain female brains are heavier than certain male; for example, Gambetta's weighed only 1,180 (41.62), while that of an insane woman fifty-seven years old (No. 2268 of the Cornell University Museum), has an *alcoholic* weight of 1,285, and (assuming this to represent 80 per cent. of the original) may have weighed 1,606 when fresh. It is to be noted, however, in this connection (1) that there are some reasons for regarding unusual weight as a not infrequent concomitant of mental disturbance; and (2) that there are not, as yet, recorded the brain-weights of any women known to have been intellectually superior. The comparison between the two sexes is not, therefore, altogether satisfactory.

§ 284. Prop. CLVI. In *absolute weight* the human brain is exceeded by those of whales and porpoises (2,265–3,171 grams, 5–7 pounds) and of elephants (4,530 and upward, 10 pounds or more). The lowest of these figures is higher than the greatest weight (1,983.80, 70 oz., or 4 pounds 6 oz.) claimed for a *non-hydrocephalic* human brain, viz., that of a negro described by Dr. C. Tompkins, *Virginia Med. Monthly*, Jan., 1882, pp. 291–293.*

§ 285. Prop. CLVII. But in no animal other than those mentioned above (§ 284) is the brain as heavy as the smallest human, viz., that of a Bushwoman, 871 grams (30.75 oz.).† In a bull it was 337 grams, in a lion, 198, and in an adult gorilla only 425 (15 oz.) (Owen, iii., 144). The largest ape brain is then only half as large as the smallest normal human.

§ 286. Prop. CLVIII. The *relative weights* of the body and brain vary greatly according to the condition of the former at death. Most of the cases tabulated were of persons dying after more or less prolonged disease, and the figures are as follows: for 81 males, 1 to 36.50; for 82 females, 1 to 36.46; according to Bischoff, 1 to 35.20. Quain concludes that in healthy individuals dying suddenly from disease or accident, the ratio is probably about as 1 to 45. In comparing man with animals in this respect this last ratio should commonly be adopted.

§ 287. Prop. CLIX. Owen estimates the adult male Gorilla at 200 lbs., or 90,720 grams, and the brain would be as 1 to 213; in a bull it was as 1 to 2,000, and in a lion as 1 to 555. On the other hand, in a sparrow the ratio was as 1 to 25; and in a marmoset (*Midas*) 1 to 20, (Owen, iii., 142); and in *Jacchus vulgaris* (No. 664, Cornell University Museum), as 1 to 19. But it is to be noted that in these small monkeys, as in birds, the cerebrum is *not fissured*. Perhaps the least misleading mode of stating the case is to say that the human brain is relatively heavier than that of any animal larger than a cat, in which the cerebrum is fissured.

§ 288. Prop. CLX. With many intellectually eminent men the brain-weight has been decidedly above the average (1,400 grams, 49.4 oz.); *e.g.:* Broca, 1,484 (52.34); Louis Agassiz, 1,495 (52.73); Schiller, 1,580 (62.96); Cuvier, 1,861 (65.64, commonly given as 64.50); Turgenieff, 2,120 (74.74). Yet the weight has been below the average with several persons of undoubted mental power, *e.g.*, Gambetta, 1,180 (41.62); Dante, 1,320 (46.56); Liebig, 1,352 (47.69). Finally, with several unintellectual individuals the brain-weight has been high, *e.g.*, a bricklayer who could neither read nor write, 1,899.45 (67 oz.), re-quoted by Dr. Morrison (*British Medical Journal*, October 26, 1878). Of people mentioned in § 284, [illegible] (70 oz.) Morselli [illegible] p. [illegible] that the brain weighing less than 900 grams (32 oz.) were more or less idiotic, but this perhaps applies to the white males only. Taking all exceptions into account, it is probable that the average of any 100 brains of intelligent persons would always be found heavier than that of an equal number of the illiterate; but since correct form is an element of intensive as well as of extensive value, it is very desirable that, as well observed by Topinard, there should be careful examination of the differences of the weight of the brain among [illegible] belonging to the two distinct classes of (1) those who are engaged in intellectual pursuits, and (2) those whose vocations demand great muscular activity.

---

* To some persons the idea that there is a "criminal type" of brain is very attractive; that this is not yet accepted by all neurologists may be seen from the following conclusions of Schwekendiek ("Untersuchungen an zehn Gehirnen von Verbrechern," etc., 1882), substantially as stated in the *American Journal of Neurology and Psychiatry*, i., 569–573: "These brains are irregularly developed, but we cannot yet assert that they present a reversion to animal brains or that there is a criminal type; with regard to Benedikt's chief claim that fissural confluence is characteristic of the criminal brain, just the reverse was found to be the case."

* The brain of a Chippewa Indian squaw, 85 years old, [illegible] Army Medical Museum, Anatomical Section, No. 1031, [illegible] fresh 73.5 ounces (2,083.72 grams) but it was *hydrocephalic* [illegible] rator, Surgeon J. S. Billings, U. S. A., [illegible] tricular liquid was probably included in the weight.

† It should be noted, however, that the weight of the [illegible] brain as here given was *estimated* by Marshall (*Philosophical Transactions*, cliv., 506) in the following way: The weight [illegible] alcohol was 21.77 oz. (617 grams). He assumed [illegible] twenty-fourths (between a third and a fourth) of the [illegible] weight, which would then have been as stated above. [illegible] tions lead him to regard the average loss of weight as only [illegible] *fifth*; upon this basis the original weight of the [illegible] only 771 grams (27.19 oz.), not quite double that of the Gorilla. [illegible] and repeated observations are needed to determine the [illegible] of weight of an adult human brain thoroughly hardened in alcohol.

§ 289. Prop. CLXI. According to J. Reid, as quoted by Quain (II., 284), the weight of the cerebrum (including the thalami and [illegible]) is to that of the cerebellum (with the pons and oblongata) as rather more than 8 to 1, which Owen states (III., 145) to be a higher ratio than in any other mammal.

§ 290. Prop. CLXII. Whatever value be ascribed to brain-weight, accuracy in its determination and statement should be rigidly observed. Especially essential is it that the scales and weights be verified, and that the weighing be done in the presence of two or more, each of whom should make an independent observation and memorandum. There are considerable discrepancies in the various accounts of the brain-weights of noted persons, *e.g.*, of Gambetta, 1,160 and 1,180 grams; of Turgenieff, 2,012 and 2,120; of Cuvier, 1,800 and 1,861. Sometimes there may be typographical errors, but more often the differences are due to the processes of reduction and re-reduction between the metric and other systems, or to the dismissal of fractions of the ounce; for example, the brain-weight of Cuvier is given commonly as 64 oz., sometimes as 64.5, neither perhaps exactly indicating the number of grams. Again, the retention of the falx or any other part of the dura will add considerably to the weight, while the removal of the pia, commonly retained, will diminish it. Finally, the brain tissue absorbs water quite rapidly if placed in it, and dries if left uncovered. All these conditions must be borne in mind and mentioned when the weight is stated, permitting each to make his own allowance therefor. Some other points in this connection are given in the article Removal of the Brain.*

§ 291. Prop. CLXIII. *Cortical extent.*—So far as may be judged, the surest criterion of potential cerebral power is the extent of the cortical surface. From the nature of the case this is very difficult to determine, and has, in fact, been determined for only four individuals. The Wagners, father and son, measured the cortical superficies, both exposed (intersulcal) and concealed (intrasulcal), with an ordinary woman, a workman, a mathematician, Gauss, and a clinical teacher, Fuchs. The results were, in the order named, 1,907.40 sq. ctm. ([illegible] sq. in.); 1,882.20 (291); 2,086.20 (323); 2,120.40 (328). Between the workman and the mathematician the difference was [illegible] sq. ctm., or [illegible] sq. in., very nearly the size of one printed page, which is about 250 sq. ctm. This difference is regarded by Quain as less significant than it appears to the writer.

§ 292. The history of encephalic anatomy is given by Vicq d'Azyr (1786) and Burdach (1822). Since the latter date the number of new parts discovered is small, the advances being rather in accuracy of description and delineation, and in the interpretation of the relations of parts to one another, and to the general mammalian and vertebrate types; see the treatises of Schwalbe and Henle, and the writings of Meynert, Spitzka, and others. From the nature of the case, greater progress has been made and is making in respect to the elucidation of histological relations, for which see the next article.

§ 293. The following list includes the principal treatises upon the gross anatomy of the brain, mostly recent, and likewise a few special papers. Other papers are named in the text. For the current literature of Neurology consult the following journals: [illegible] *Anzeiger*; *Zoologischer Anzeiger*; *Index Medicus*; *Neurologisches Centralblatt*; *Brain*; *L'Encéphale*; *Jahresbericht für Anatomie*, etc.

BRAIN: HISTOLOGY.

BRAIN: HISTOLOGY.—Physiologically considered the brain is composed of two forms of nerve tissue; the ganglionic and the conducting. The former is the active agent in the reception and registration of impressions, and in the evolution of motor impulses. The latter plays the more passive rôle of a conduit of these impressions and impulses. The essential and characteristic feature of the brain mechanism is the union of these two, and their consequent more or less direct connection with the various organs of the body. The chief task of modern brain histology has become the tracing out of the conducting tracts from the periphery through the white substance to certain ganglia. For example, a tract which is found to unite the retina to the external geniculate body is thus demonstrated to be a visual tract, while the external geniculate body is shown to be a visual centre. The thinking neuro-anatomist sees with his mental eye the opaque interior of the brain transparently resolved into an intricate yet well-defined set of projecting and associating mechanisms, connecting the functional mosaic of the cortical surface with the outer world, and binding it into that complex unity of functions which constitutes the mind. The analysis of brain-structure consequently exhibits a dovetailing of features visible to the naked eye, with those features that are visible only under high magnifying powers. The methods employed reflect this fact: they combine the macroscopic with the microscopic.

---

* In addition to the books and papers cited in § 288, the following may be consulted regarding brain-weights: [illegible] "Brain-weights of Man and Woman," [illegible] 1887 [illegible] Popular Science Monthly [illegible] Topinard's summary of Broca's conclusions [illegible] 1882 [illegible] "Brain-weight and size in relation to [illegible]" [illegible] January 18, 1888, [illegible].

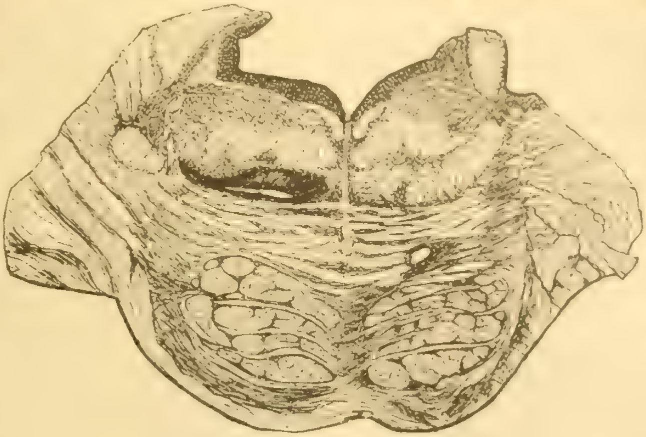

FIG. 4789.

Examination of the Fresh Brain.—The encephalon in the recent state is a more firm and resilient organ than is usually supposed, and, properly supported in a vessel imitating the shape of the cranial cavity, may be divided into a series of segments, transversely, sagittally vertical, or horizontal, which on close scrutiny exhibit delicate color shades, fine striations, and subtile transitions from white to gray matter, which become obliterated as decomposition advances, and much altered by the methods of preservation and hardening to be detailed. From the ganglionic depôts exposed by such sections small portions may be removed for teasing, for section in the freezing microtome, or for hardening.

Defibrillation of the Hardened Brain.—To the naked eye the fresh brain presents a large variety of details, but these relate rather to the topographical features of that organ than to physiological connections. The white substance, now known to embody numerous separate channels, each of which is endowed with a special functional rôle, appears a homogeneous mass without any specialization except in the crude form of commissures, of emerging nerve-roots, or of morphologically isolated strands such as the fornix. But on tearing asunder a brain hardened in alcohol, indications of specialized nerve-tracts are observed; strands are seen traversing the white interior of the convolutions, some passing like the rays of a fan from the basilar ganglia to the cortex (*corona radiata*), others skirting the latter like festoons (*fibræ propriæ*), and others connected with the commissures. Many facts elicited through this crude method by Goll, Rolando, Reil, and Burdach have been confirmed by more reliable methods. But defibrillation is as apt to lead to the registration of fortuitous as of true connections, and as a method of original research has been abandoned. Attempts made by Meynert and the younger Stilling—the latter beautifully modifying the older method by subsequent maceration of the hardened brain in acetic acid—have found no followers. As a means of demonstrating nerve-tracts established by other methods it is of value. Thus, by cutting a preliminary trench which is to guide the fracture, along the sulcus of Rolando, then boldly across the middle of the temporal lobe, along the outer third of the pes, the outer quarter of the pons, through the sulcus separating the olive from the pyramid, ending by a diagonal sweep in a plane running centro-laterad and dorsad, and making the fracture along the line thus indicated, the tract conducting voluntary motor impulses from the paracentral and Rolandic regions to the extremities may be demonstrated, even to its decussation.

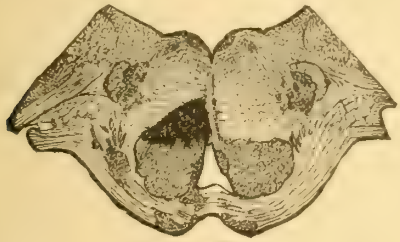

FIG. 4790.

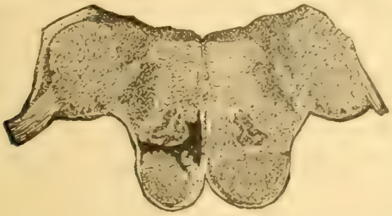

FIG. 4791.

Microscopic Sections through the Hardened Brain.—The brain, after having been hardened by the use of bichromate of potash, Müller's fluid, alcohol, or successively in several of these, is either in whole or in part embedded in a microtome cylinder, with the various media mentioned in another part of this work, and cut into successive thin sections, which may be mounted with or without preliminary staining. Such sections reveal at once the topographical relations of white and gray matter, and the precise extent and minute characters of nerve elements. Placed under a high microscopic power, they often exhibit the precise manner in which the conducting fibrils terminate in the latter. Much depends on the direction in which these sections are made. Those best calculated to familiarize the mind with the bewildering internal labyrinth of the brain are transections made vertical to the brain axis, according to Stilling and Meynert. The human brain as it lies *in situ* has a curved axis. It is, as man stands, nearly horizontal in front of the pons, oblique in and caudad of the pons, and becomes vertical in

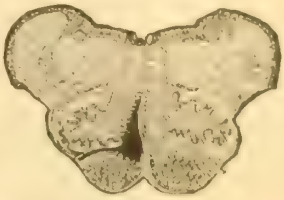

FIG. 4792.

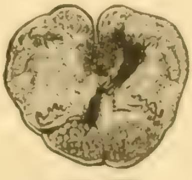

FIG. 4793.

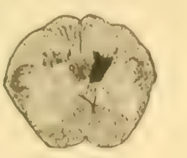

FIG. 4794.

FIGS. 4789-4794.—Secondary Descending Degeneration of the Voluntary Tract, following Hæmorrhagic Lesion in the Pons. Fig. 4789, the site of lesion; 3, cyst representing site of hæmorrhage. Figs. 4790-4794, semi-schematic representation of the [illegible]: 2, at the level of the facial nucleus; [illegible] at level of hypoglossal root; 5, at the [illegible] voluntary tract; 6, just below that level, [illegible] columns of Goll and Burdach.

the caudal part of the oblongata. In order to correct this, the axis is straightened in hardening, an easy operation, requiring the removal of the membranes and the utilizing of the natural softness of the parts. By studying a successive series of such sections the gradual metamorphosis of the cord into the oblongata, the opening of the central canal into the fourth ventricle, its subsequent reduction and closure as the aqueduct, the emerging of the pes from the pons, the relations of most cranial nerve-roots to their nuclei, the topographical relations of the great cerebro-spinal fibre systems, and the apparent origins of many of them, can be advantageously studied. Original investigators employ sections taken in other planes, varying with the special object requiring demonstration. Such sections from the paracentral lobule show the connection of the giant pyramids with medullated [illegible] cortical fibres of the pyramid tract. Sections parallel with the optic tract reveal its relations to the external geniculate and thalamic ganglia. The course of a nerve-tract revealed by other methods may be beautifully demonstrated by the following modification: The brain axis is pared down to within a few lines' depth of the tract in question. The opposite aspect of the brain axis is also pared down, until the segment including the required tract is sufficiently supple to lie flat in the true direction of the latter. The segment is then hardened and cut. By this means the course of the tegmental brachia, from their origin in the ciliary nuclei, through their decussation to their apparent termination in the red nuclei of the tegmentum, can be demonstrated in the actual outlines of an open scissors, to which Stilling happily compared them.

Fig. [illegible].—[illegible] the Oblongata from same Case. Level of [illegible]. D, D, [illegible]

The Developmental Method.—In the lowest forms of nervous systems there is no differentiation of gray and white matter, the nerve fibrils being naked or devoid of the myelin sheath, which in compact accumulations gives to the white substance its opacity and color. What is true of the Invertebrata is also true of the embryonic human brain. Tiedemann found that in the fœtus the white substance of the adult is represented by a translucent grayish-red tissue. Meynert observed that the development of the white color in this tissue is not general and simultaneous, but appears to follow this law, that the tracts of highest function obtain their white color latest. Flechsig elaborated this observation, and showed that each great tract obtains its white color at a definite period of fœtal or infantile life. The pyramid tract attains the color indicating maturity so late, as compared with the surrounding tracts, that it can be discriminated in its entire course by the contrast of its grayish gelatinous look with the white, opaque surrounding field. It is a significant fact that the tracts devoted to sensory transmission precede those devoted to motor conduction; that those transmitting reflex action are developed before those connected with volition; while the latest to mature are the associating fibres which underlie the highest manifestations of the intellect. It is consistent with this that in the reptilian brain these parts only show the medullary white which exhibits it in the early human embryo; while even in the higher [illegible] mammals the differentiation of medullated tracts in the external capsule, the substantia innominata, the subcortical, and subthalamic regions has not advanced

beyond the point reached in the human brain before birth.

The Study of Secondary Degenerations.—Since the days of Türck and Bouchard it has become recognized that a lesion destroying a nerve-tract in any part of its course induces a change in the entire course of that tract in the direction of its functional transmission. Thus if a motor tract be destroyed in the brain or in the upper part of the spinal cord, there would ensue a descending degeneration; while if a sensory tract were injured in like manner, an ascending (centripetal) degeneration would follow. Secondary degeneration is in a way an inverted analogue of the developmental appearances above described. The immature nerve-tract is discriminated from its surroundings by its grayish color, due to the fact that *it has not yet acquired* myelin. The secondarily degenerated nerve-tract is similarly demarcated from its healthy surroundings by a grayish color, due to *the loss of myelin.* Nearly every observation made by the developmental method has been confirmed by the study of secondary degenerations, and in many cases amplified by it.

In addition to its change in color, due to the disappearance of myelin, the degenerated tract exhibits a marked shrinkage. On making microscopic sections through a brain or cord affected with this lesion the area of the degenerated tract can therefore be recognized, not alone by the color change but by an actual change in outline. In carminized sections the degenerated field is deeply stained, in contrast with the surrounding normal white substance (Figs. 4789–4794); in sections prepared according to the Weigert hæmatoxylin method, it is bleached as contrasted with the latter.

It is not alone the gross outline of the tract that is revealed by such sections. Often the minute relations of its fibres to nerve elements may be discovered through their associated atrophy. In like manner, whenever there is a deviation in the course of its component bundles, wherever these send detachments to other tracts, or run into and comprise constituent elements of ganglia, the fact is revealed by the stain of degeneration in carminized (Figs. 4795–4797), or the bleached appearance, indicating absence of myelin, in Weigert preparations. Just as the geologist determines the course of a coal stratum by the sinking of a few shafts at long distances, so the neuropathologist, on discovering a degenerated patch in the posterior part of the lateral column in the cord, a similar one in the sagittal fibres of the opposite half of the pons, and a lesion in the internal capsule, knows that he has exposed segments of a continuous nerve-tract destroyed by that lesion. He is thus able to demonstrate its cause.

The Study of Natural and Artificial Atrophies of Nerve Centres and Tracts.—The congenital absence of peripheral organs is accompanied by a defective development of the tracts and centres connected with such organs. Thus in persons born without eyes, or microphthalmic, the optic nerve, chiasm, and tracts, the external geniculate body, the anterior pair of the quadrigemina, the pulvinar, and the optic radiations of the corona are atrophied. Observations

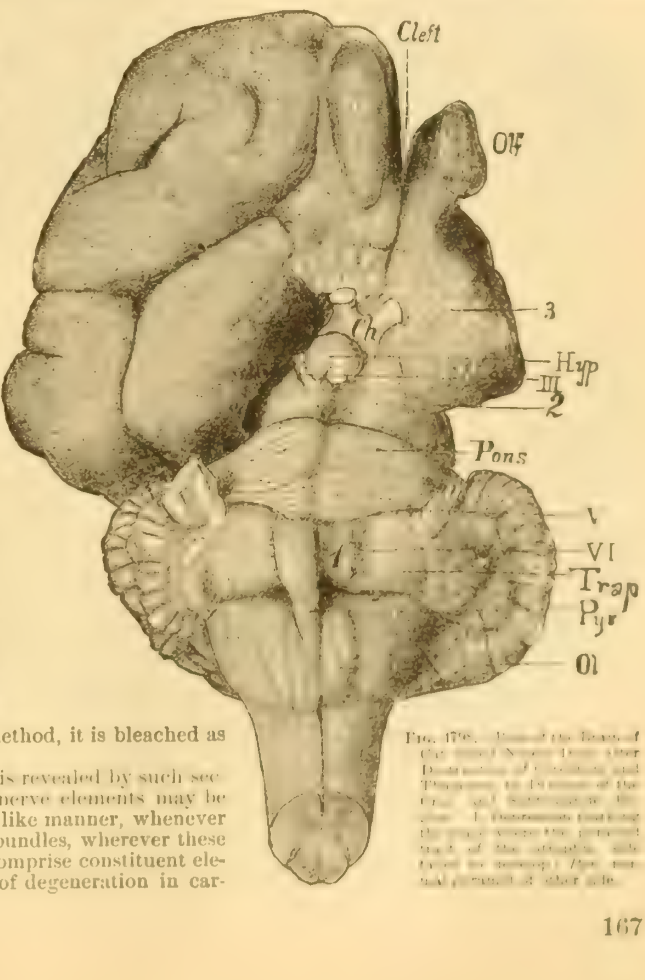

FIG. 4798.—[illegible]

thus made rank with those made by studying secondary degenerations. They have been amplified by the artificial induction of atrophies in the brains of new-born animals. Gudden and his pupils have shown that the course of a nerve-tract, or the connection of a centre with its projected periphery, may be elucidated by the elimination of the latter. If the cochlea be destroyed the auditory tract atrophies. If one extrinsic muscle of the eye be removed, its nidal centre wastes; if the facial nerve be divided, the facial cell-nest diminishes. Further observations in the same direction are made by studying the influence of nerve centres on nerve tracts. If the motor area of the cortex in a new-born animal be destroyed, the entire pyramidal tract is found absent. If the cerebrum be removed, all centrifugal tracts connected with the cerebrum disappear, and if, in addition to the cerebrum, the thalamus be destroyed, the resulting distortion of the brain axis, through the unilateral absence of tegmental and pedal fibre systems is a startling (Figs. 4798–4800) and convincing proof of their dependence on the destroyed ganglia.

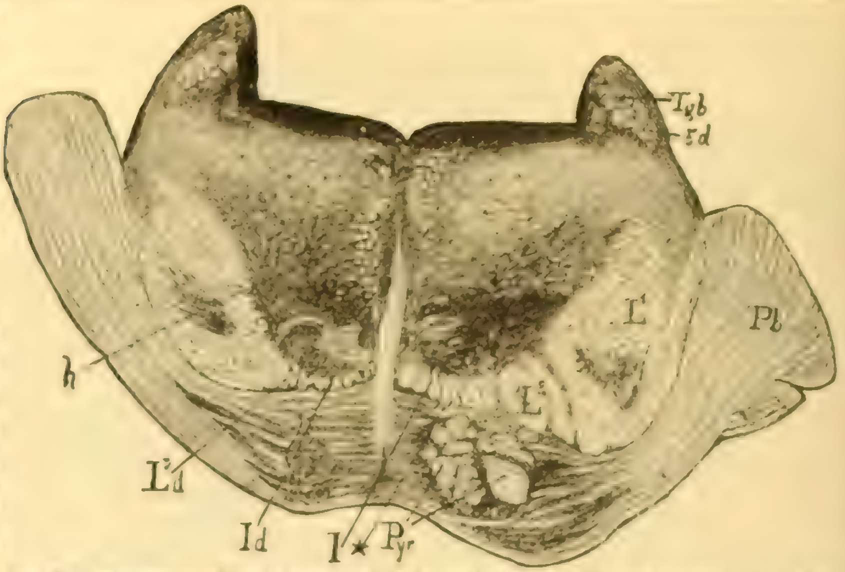

FIG. 4798.—Transection of Pons in Same Case. On normal side Pyr, the healthy pyramid tract; L², the healthy middle segment of lemniscus; I, the healthy intermediary tract. On the atrophied side the pyramid is absent. L²d, the [illegible] middle part of lemniscus; Id, the rudimentary intermediary tract.

6. *The Comparative Method.*—It is noted that animals having peculiarities in the development of peripheral organs have peculiar features of brain structure thereto related. Thus the blind rat of Palestine has rudimentary optic lobes, the microphthalmic mole rudimentary oculo-motor nidi, the elephant with his wonderful proboscis an enormous facial nidus (Fig. 4801). The cetacea, whose hind limbs are wanting, have no column of Goll and no nucleus of that column (Figs. 4802 and 4803). Since prehensile voluntary usage of the extremities is denied them, they have no pyramid tract (Fig. 4804). But in harmony with their exquisite sense of hearing their enormous auditory nerve is accompanied by a powerful trapezium, an enormous acustic division of the lemniscus (Fig. 4804), and overgrown post-optic lobes (Fig. 4805). Such cases constitute natural atrophy, or hypertrophy, experiments as it were, and while not in themselves of exact demonstrative value, furnish valuable and interesting suggestive evidence of the correctness of the results obtained by the other methods detailed. It is seldom that a

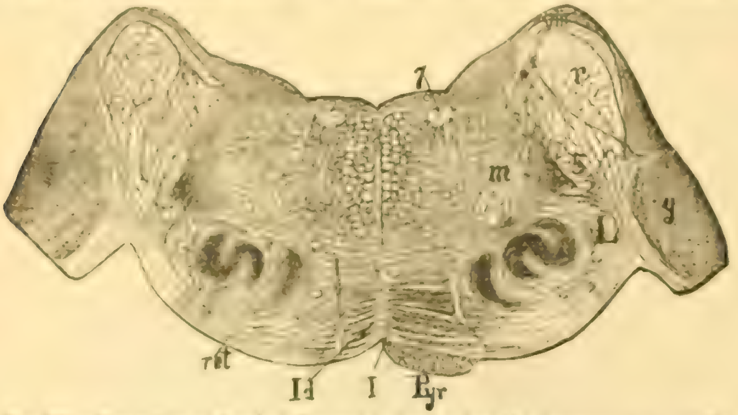

FIG. 4799.—Transection at Level of Trapezium, showing how the Asymmetry is gradually Diminished as it [illegible] Caudad. The lettering has the same signification as in Fig. 4798.

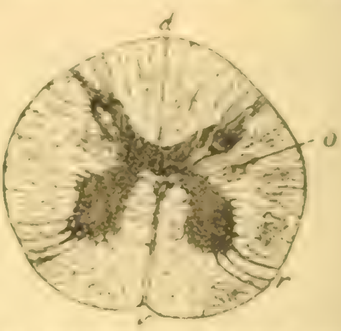

FIG. 4802.—Transection of Cord at Upper Cervical Level of a Porpoise. d, Posterior [illegible]; the [illegible] [illegible] is absent, as there is no [illegible] of [illegible].

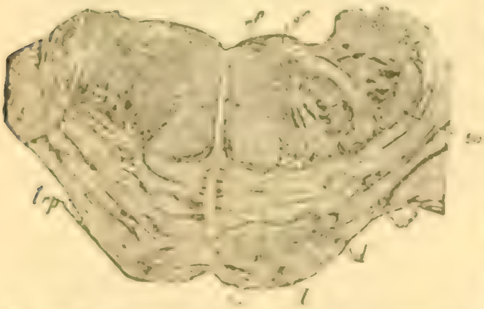

FIG. 4801.—Transection of Pons of Elephant. Natural Size. nf, Facial nidus [illegible].

valuable result is obtained by the exclusive pursuit of a single method. To determine the significance of a given ganglion its minute structure must first be studied by methods strictly histological. Its relation to neighboring nerve-tracts, if not determinable by direct observation, may be demonstrated by studying the secondary tract degeneration ensuing after its disease in man, or the atrophy following its elimination in lower animals. The latter, in its turn, involves a correct homologization by comparative anatomy.

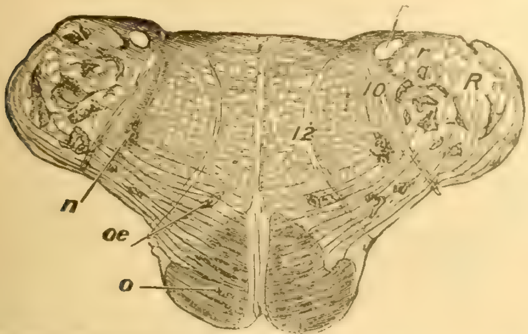

FIG. 4804.—Transection through Oblongata of Dolphin more Cephalad than Fig. 4803. *o*, Olivary nucleus, nearly in contact with its fellow, owing to absence of pyramids.

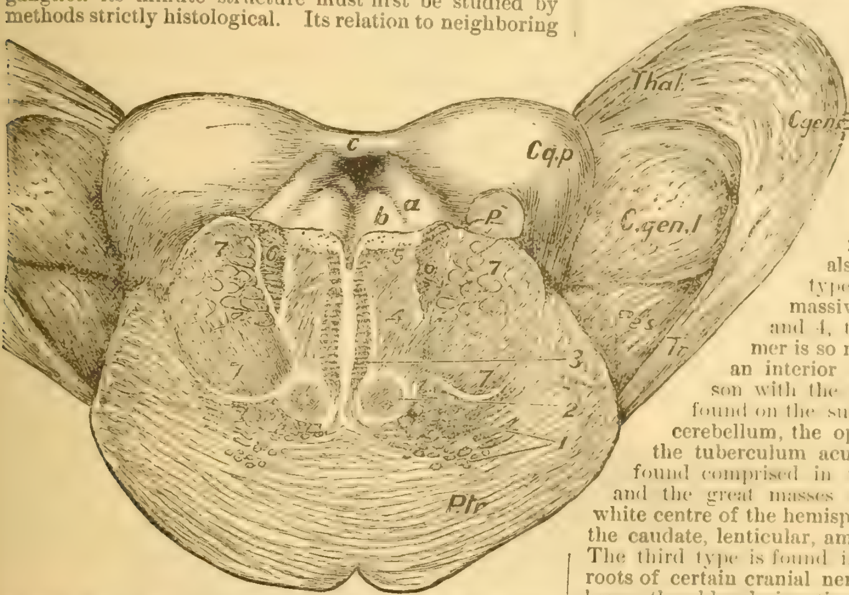

FIG. 4805.—Caudal Face of Dolphin's Isthmus. *Cq.p*, Postoptic lobes; *C.gen.I*, inner geniculate body; 7, hypertrophied (auditory) division of lemniscus.

To the eye the chief difference found in the component elements entering into brain structure is one of color. *White* (alba) and colored tissues, the latter conventionally designated as *gray substance* (cinerea), are seen to alternate in a definite way. It must not be supposed that the distinction between the two is a sharp one. While the white substance is exclusively conducting substance, the gray is not exclusively ganglionic, for the former encroaches on the latter. In some situations, as in the so-called vesicular columns of Clarke, the admixture of white or myelinic nerve fibres is so great that the ganglionic substance is rather white than gray. Even in the cerebral cortex and the anterior horns of the spinal gray the admixture of myelinic fibres is considerable. The physiological transition of conducting to "receiving" or "evolving" substance must therefore be located within the confines of the ganglionic substance, and not at its contact line with the white. The reaction of gray matter is slightly acid, as is shown by injecting the flavopurpurate of sodium in the veins of a living animal. The dark red solution, is changed to a golden yellow hue by the slightest excess of acid, and all the gray substances of the brain and cord, in an animal thus injected, are found of that color. Its natural color is due to four factors: 1, translucency; 2, degree of capillary injection; 3, amount and color of pigment in the nerve elements; 4, admixture of white substance. In thin slices it is transparent and almost colorless. When injected with arterial blood it presents a rosy hue (cortex, red nucleus of the tegmentum), when pigmented, various shades of yellow, *café au lait* (nucleus of Luys), dark gray (ala cinerea), deep bluish gray (locus cæruleus), or black (substantia nigra). An admixture of medullated nerve fibres causes it to present white streaks (the lines of Vicq d'Azyr and of Baillarger), or give it as a whole the appearance of white matter (columns of Clarke).

The specific gravity of the cortical gray is 1.0206–1.0239, of the great ganglia 1.0334–1.0346, of the cerebellum and mesencephalon 1.0479–1.0584, and of the white substances 1.0273–1.0289.

It is to the peculiar mutual relation of white and gray substance that the various cerebral provinces owe their optically characteristic features. Three well-marked types of ganglionic structure are generally recognized; a fourth, less well studied, is also to be distinguished. These types are, 1, the cortical; 2, the massive ganglionic; 3, the nidal; and 4, the intrafascicular. The former is so named because its situation on an interior white centre invites comparison with the rind (cortex) of a fruit. It is found on the surface of the cerebrum, of the cerebellum, the optic and olfactory lobes, and the tuberculum acusticum. The second type is found comprised in the diencephalon (thalamus) and the great masses which are embedded in the white centre of the hemisphere like so many nuggets—the caudate, lenticular, amygdalar, and claustral nuclei. The third type is found in direct connection with the roots of certain cranial nerves and comprises cell nests, hence the older designation of nuclear, and the one here proposed, nidal type. The fourth is found either as a diffuse admixture in the course of nerve strands, or in compact accumulations to which these strands occupy definite relations. They are regarded as terminal, as interrupting or as condensing stations for the latter. The club- and flame-shaped nuclei of the columns of Goll and Burdach, the concentric hollow spheroids of the red nu-

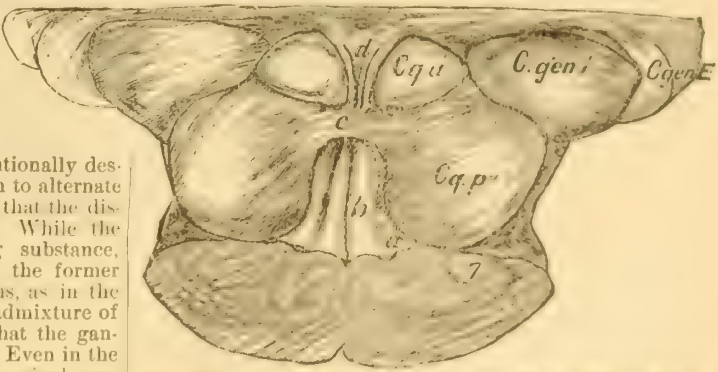

FIG. 4806.—Dorsal View of the same Segment. *Cq.a*, optic lobes; other designations as in Fig. 4805.

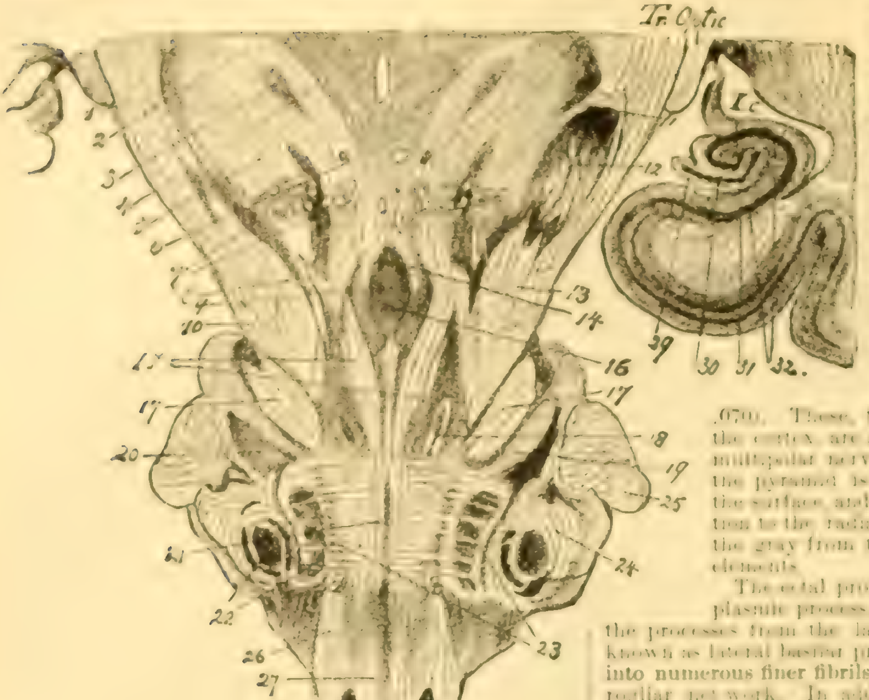

FIG. 4807.—Transverse Section through Isthmus of Dog, showing the [illegible]

cleus of the tegmentum, the stratiform nuclei of the pons, the dentated volutes of the olive, cerebellum, and trapezium, the laminæ of the external geniculate body, and the basket-work intercalations of the reticular and lemniscus fields belong to this type. It is to these various dispositions of gray matter, and the related interdigitating with white tracts that sections of the crus and oblongata owe their beautiful and characteristic marbling (Figs. 4807 and 4808).

The cerebral cortex covers the distal face of the gyri and the walls of the septum lucidum, presenting various degrees of [illegible] sixth of an inch. It is thinner at the bases than at the apices of the gyri. In the fresh brain it is translucent, and exhibits a stratiform arrangement; the gray, [illegible] which is darker in the old than in the young, [illegible] than in the white [illegible], being interrupted by pale opaque zones. These are found on minute examination to consist of a predominating proportion of myelinic nerve fibres. There is a bluish-white zone, fading more or less into the adjacent gray, over the greater part of the cerebral surface (Baillarger's stria), and a distinctly defined set in the occipital lobe (stria of Gennari or Vicq d'Azyr). It is in the area characterized by the four-layer, comprising the entire frontal lobe, the Rolandic region, the apex of the temporal and those parts of the parietal lobe which abut on the Rolandic region, that the typical four* strata are distinguished under the microscope. Passing from the pia surface to the white substance they are as follows: (1) ependymal layer, barren of nerve elements but rich in medullated nerve fibres, which chiefly run parallel to the surface of the gyrus. Its thickness is 0.2-0.275 mm. (2) Comprising more than half the thickness of the cortex, a layer of pyramidal elements, very numerous, small at the confines of the barren layer (.004-.010), larger as they lie deeper (.020-.070). These, the characteristic elements of the cortex, are a modification of the ordinary multipolar nerve element. The long axis of the pyramid is almost uniformly vertical to the surface, and consequently parallel in direction to the radial nerve fibres which penetrate the gray from the white, as if to reach these elements.

The distal prolongation is a branched protoplasmic process, known as the apex process, the processes from the lateral angles of the base are known as lateral basilar processes. Both these break up into numerous finer fibrils, which contribute to the neuroglia network. In addition the larger cells have a process which, as a rule, proceeding from the axis of the basilar part of the cell, remains unbranched, becomes covered with myelin, and traversing the intervening gray reaches the white substance. Such cells have therefore the same relation to fibres of the white substance which the multipolar nerve cells of the anterior horn of the spinal gray have to the anterior roots of the spinal nerves. (3) The layer of pyramids is followed by the layer of granules. These are small nerve elements (.007-.010 mm.), angular in shape, with very fine processes and

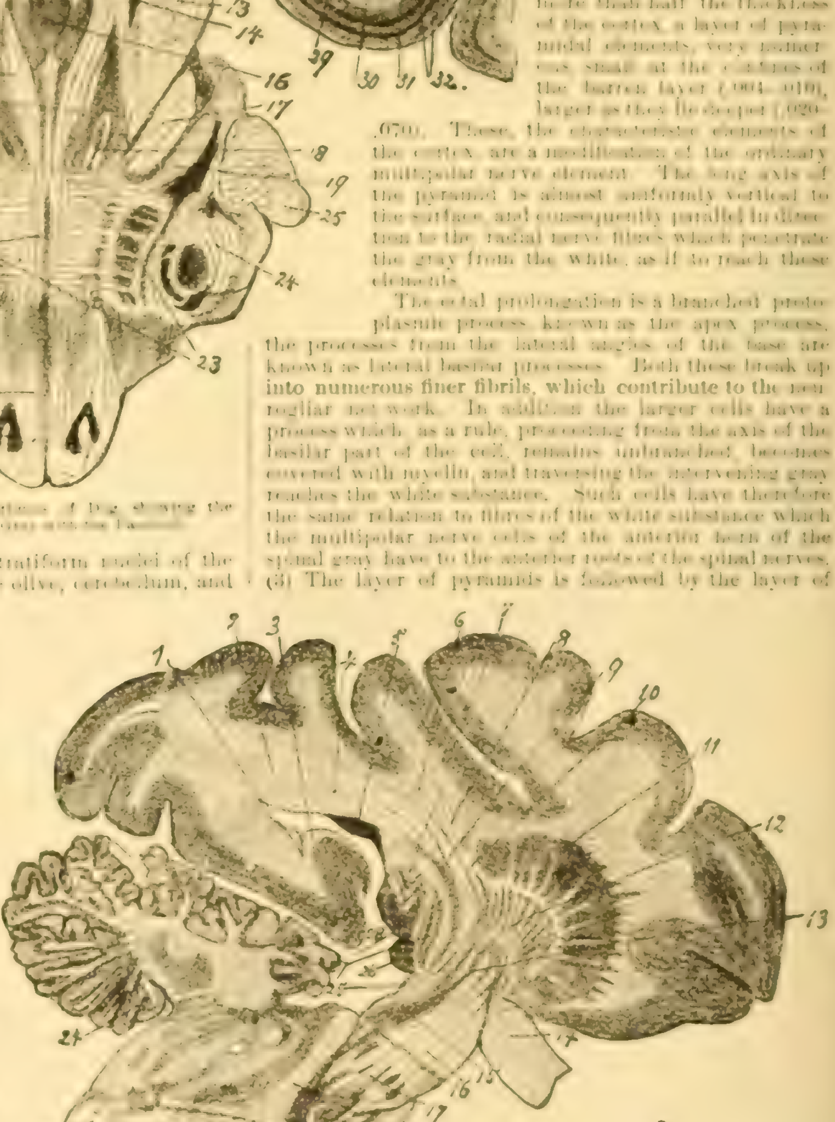

FIG. 4808.—Section in Sagittal Direction, the Plane Extending from Dorsomesal to Ventrolateral, of a [illegible]

lying closely crowded. Inasmuch as the medullated fibres which leave the white substance to reach the layer of pyramids traverse the layer of granules in groups, it follows that the granules do not everywhere appear as a continuous stratum, but seem in section to be broken up into irregular parallel columns. The pyramids do not cease abruptly at the ectal boundary of the layer of granules, but encroach upon it, usually lying among the medullated fibres just mentioned. The pyramids thus intruding, while not as numerous as in the layer named after them, are very large, and in one particular region of the cortex attain the largest dimensions found in the human nervous system. They are the giant pyramids of Betz. The largest are found in nests or rows in the cortex of the paracentral lobule (.050 mm. wide, .125 mm. long). They are slightly smaller toward the middle of the pre- and postcentral gyri, still further diminishing toward the Sylvian region. In distribution they correspond to the cortical motor fields, and it is a suggestive fact that the largest are found in the focus of the leg centre, the next in size in the focus of the arm centre, and the smallest in the facial and hypoglossal centres, thus corresponding to the relative size of the innervated muscular masses. The layer nearest the white substance is marked by the intrusion of many nerve fibres running near the boundary between the gray and white substance. At the floor and sides of the fissures their course is parallel to the cortical surface.

---

* [illegible] "small" and "large" [illegible]

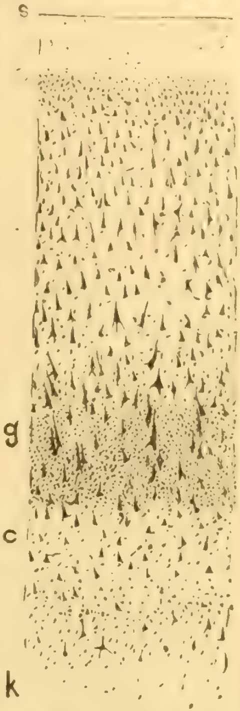

FIG. 4809. Vertical Section through Cortex of Middle Frontal Gyrus, at its Apex. Elements only represented. *s–e*, Ependymal or barren layer; *e–g*, layer of pyramids; *g–c*, layer of granules with interspersed larger pyramids; *c–k*, ill-defined cells, transition to spindle shape; *k*, white substance.

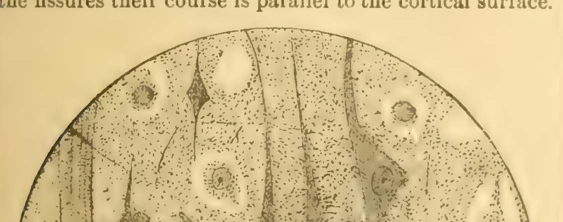

FIG. 4810.—Large Pyramids from Cortex of Imbecile, showing a Basilar Process proceeding from the Middle of the Base of One, and from the Lateral Angle of another of these Elements.

But at the apices or free part of the gyri these *tangential* fibres verge toward the surface. From this results a peculiar disposition of the nerve elements of this stratum. They are fusiform, connected with the fibres named, at one end of their attenuated bodies (.003–.010 wide, .020–.035 long). Hence they lie parallel to the fibres near and among which they are scattered, and are parallel to the cortical surface at the base and sides of the sulci, but vertical to it at the apices. Meynert regards these fusiform or spindle cells as "association cells," and from their alleged preponderance in the claustrum, which he considers to be the differentiated and isolated deepest layer of the cortex of the insula, denominates them as comprising the "claustrum formation."

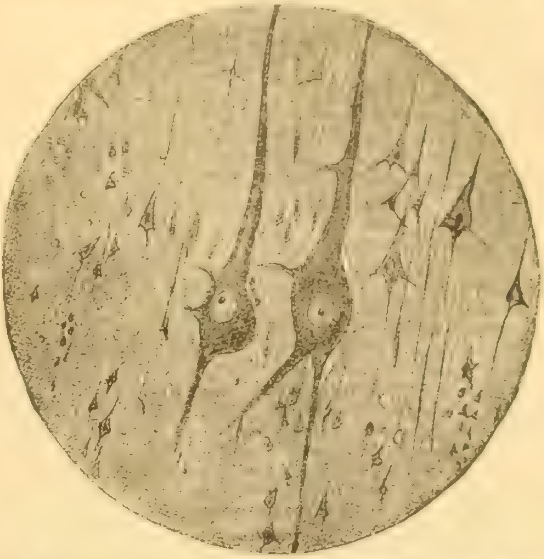

FIG. 4811.—Two Giant Pyramids from Paracentral Lobule of Man. × 100.

From the above type of cortical structure there are several local variations. The most important are found in the occipital lobe and the cornu ammonis. Briefly, the occipital type may be described as presenting the following points of correspondence or contrast with the fronto-parietal type: (1) The barren layer is present in both; (2) the layer of pyramids is present, but thinner in the occipital lobe; (3) the layer of granules is hypertrophied and subdivided into three strata by two intercalated zones, barren in elements (a few of large dimen

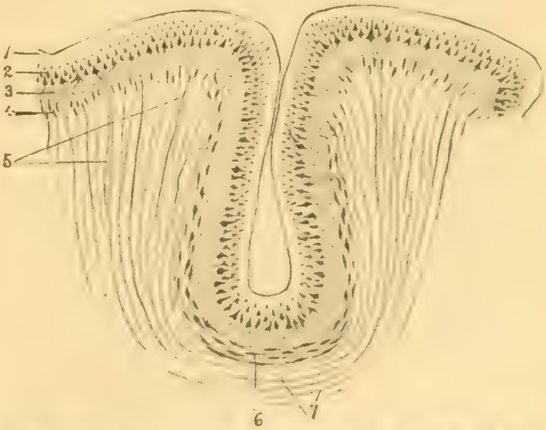

FIG. 4812.—Diagram of a Section Vertical to the Surface of Two Adjoining Gyri. F, base of intervening fissure; 1, barren layer; 2, layer of pyramids; 3, granule layer; 4, 6, layer of spindles, vertical to surface at 4, parallel to surface at 6; 5, projection fibres of white substance, directly connected with large pyramids or [illegible] in the cortical [illegible] maze; 7, tangential (association) fibres.

[illegible] are found such known as "axillary" [illegible] fibrils in medullary nerve fibres. It is these white striae which, to the naked eye, appear to form a single sharply marked streak, particularly distinct at the calcarine fissure, the white lines of Vicq d'Azyr;* as the layer of spindles is present as before. Thus by the subdivision of the one granular layer of the frontal cortex into three granular and two intergranular layers, the occipital cortex presents eight strata: 1, the barren layer; 2, a narrow stratum of pyramids; 3, the ectal granular layer; 4, the ectal intergranular layer; 5, the intermediate granular layer; 6, the ental intergranular layer; 7, the ental granular layer; 8, the stratum of spindles.

In the cornu ammonis the pyramids are very numerous, closely crowded, and much elongated. To understand the significance of this peculiar [illegible] cortical structure, let the student imagine the cortex enfolded on its pyramidal layer, and that layer rolled in such a way that a transection elsewhere would show an S-shaped curve. The position of this S (subiculum) must be so understood as if two of opposite sides faced each other, thus: S Ƨ (Fig. 891, 52). The upper half of the S faces the ventricle with its convex head forming the prominence of the hippocampus; it is here covered by white substance, the alveus. The ventral end of the S, falling out in the ventricle with a free cortical surface, shows a remarkable hypertrophy of the white fibres in the barren layer, which intrude like a thin sheet between the upper convexity of the S and a remarkable band which bears the relation of a "[illegible]" to the cornu—the fascia dentata.

The fascia dentata is an amorphous [illegible] aggregate of the cornu ammonis, and just as the latter is the temporal extremity of a ring-shaped convolution surrounding the callosum, so the fascia dentata is the temporal development of a (human) rudimentary gyrus, running parallel with the gyrus fornicatus, constituting the longitudinal grayish striae (medial nerves of Lancisi) interposed between the edge of the gyrus fornicatus and the callosum. Its cells are small, closely crowded in two or three rows. Their protoplasmic processes run peripheral. The nerve fibres from the cornu ammonis and fascia dentata are collected to a sharp-edged ridge, gradually rising higher as new additions are made to its substance, which is the fimbria. Its main direct source of fibre supply is the alveus; its continued prolongation is the fornix.

By many the olfactory bulb is regarded as a part of the cerebral cortex. In reality it is merely analogous in texture, and represents an independent brain segment (see Centres of Special Sense).

The cortex of embryos between the third and fifth months, when hardened, already shows that peculiar fracture line characteristic of the adult cortex, the cleavage being as if in fine parallel fibrils vertical to the surface. This indicates some disposition, because of the ultimate arrangement of cell rows, entering nerve fibres and blood vessels. The first distinct elements are observed in the second layer at about the sixth month. The granules of the third layer appear at the seventh month. Generally speaking, the development of the gray and the cortical elements [illegible]. In the embryonic human brain only the cortical layer is represented; then the white fibres develop and gradually obtain that preponderating mass characteristic of the mature brain, in their order of functional dignity, the [illegible] projecta being the latest to mature.

The ganglia embedded in the interior white matter of each hemisphere are the caudatum, lenticularis, amygdala, and claustrum. Of these but one, the caudatum, has a free surface at the floor of the lateral ventricle; the others are embedded in the white matter of the cerebral interior, or fuse with the cortex. Their shape and connection is intimately allied with the growth and shape of the cortical mantle, to which they are often regarded as bearing the relation of subordinate, subcortical, centres.

The lenticularis resembles an irregular, triangular pyramid, lying on its side. Its base is parallel and near to the cortical expanse of the insula and of about the same extent. The three sides of this pyramid are an upper, sloping caudad, an anterior, sloping [illegible], a lower, sloping [illegible]. All these sides attenuate toward the mesal plane, so that they unite in an apex which is directed toward the [illegible] (Fig. 898, 11 and 17).

If the pyramid just described be regarded as an axis of rotation for the caudatum, the relations of the latter are readily understood. Except at the base of the brain and a number of anastomoses in the anterior division of the internal capsule, the caudatum is a free ring circling around the lenticularis. As it is nearest to the frontal portion, becomes attenuated caudad, and the attenuated part is reflected on itself to run along the roof of the inferior horn, whereas the remainder lies at the floor of the anterior horn and body of the lateral ventricle; the cephalic part is called the head, the caudal part the tail.

The claustrum is a thin expanse interpolated between the cortex of the insula and the base of the lenticularis. It also corresponds in extent nearly with the extent of the insula. The streak of white matter separating it from the lenticularis is known as the external capsule; the one separating it from the insular cortex is unnamed.

The nucleus amygdalae is an irregular lump of gray matter situated in the apex of the temporal lobe, between it and the apex of the inferior ventricular horn. It lies ventrad of the lenticularis.

As distinct as all these gray masses appear in sections taken in certain planes, there is a common ground on which they meet, with which they fuse, through which they are indirectly united, and by which their embryonic derivation from a common origin is proven. This is the gray matter of the anterior perforated space. In front this fuses with the lenticularis, which in part rests on it; it penetrates between the latter and the amygdala and unites with a broad spur from the claustrum. With the caudatum it does not directly unite, but as the mesal [illegible] of the caput caudati fuses with the lenticularis they are indirectly continuous.

The caudatum presents a ventricular and a capsular surface. The ventricular is lined by an ependyma so dense that it may be separated and demonstrated as a coarse membrane. The capsular face is irregular, numerous strands of capsule fibres entering it obliquely, so that on transection they appear as white spots, on sagittal sections as streaks. They extend to about half-way through the ganglion, and there split up into finer and finer bundles which become lost to the naked eye. Two kinds of elements are found in its reddish gray matter. A larger, intermediate to a star shape and the pyramid type (20–30 μ); they have numerous protoplasmic and an axis cylinder process. The smaller variety (15–20 μ) have only the former. In addition a large number of nuclear bodies surrounded by apparently granular protoplasm contained in vesicular spaces, whose nature is disputed, as well as glia cells, are found in this ganglion.

The lenticularis is composed of three* concentric segments, the dividing line being laminae of medullary fibres which run parallel to its ectal face. The subdivisions are known as [illegible]; the most ectal is specially designated the putamen. It is of a deeper reddish gray color than the two mesal divisions, which together are termed globus pallidus. The aforenamed streaks are joined by lesser streaks emerging from within the putamen, or traversing the [illegible] of the globus pallidus; from this a very characteristic striated appearance results. The minute structure of the lenticularis corresponds to that of the caudatum, the proportion of large cells being greater. The amygdala is regarded as a hypertrophied layer of the temporal cortex, which has become nearly isolated from its cortical connection by intruding white matter. Except that streaks of white matter run irregularly into and through it, it has the structure of cortical substance. The same applies to the claustrum, which is commonly regarded as the isolated spindle-cell stratum of the insular cortex, although neither embryological nor comparative anatomical observation support that view.

---

* These are sometimes much [illegible] in Vicq d'Azyr [illegible]

* Four and even five layers have been observed by the author, the supernumerary ones lying within the globus pallidus.

White Substance of the Hemispheres.—The entire space intervening between the cortex cerebri, the cavity of the lateral ventricles, and the great ganglia at the base, is filled out by white substance; the greater part of the cerebral mass being thus composed of a mass of myelinic nerve fibres. These connect the ganglionic elements of the cortex with other parts of the nervous system. Some pass from the cortex about the calcarine fissure and apex of the occipital lobe to the external geniculate body and a special region of the thalamus, both of these being in turn connected with the optic tracts. Another set passes into the olfactory tracts. Still another unites the cerebral hemisphere to the cerebellum. Some traverse the entire length of the cerebro-spinal axis, placing every segment of the spinal gray in relation with a definite part of the cortical area. Others remain intracerebral in every part of their course, uniting one area of the cortex with another, crossing the median line—like the corpus callosum—to associate the two hemispheres, or finally establishing a functional bond of union between the cortex and the great ganglia.

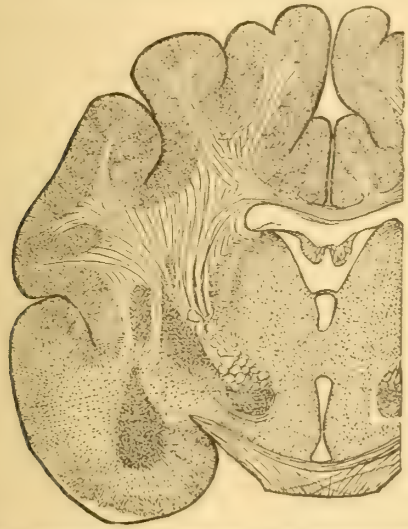

FIG. 4813.—Cross-section of a Cat's Brain. The gray substance, cortical and ganglionic, represented by dots, the white by lines, indicating the main directions of the fibres.

In the fresh brain this white substance may be compared to an irregularly shaped kernel, of which the cortex is the shell. Where the cortex is raised in folds, the white substance enters it like a ridge. The union between the two is intimate; fibres enter the lower strata of the cortex to connect with the axis cylinder processes of the larger pyramidal bodies, others appear to run nearly to the surface, and some are inseparable from the plexus of intracortical nerve fibrils. It is because of the preponderating development in man of those tracts which place the lower centres under the cortical dominion, and above all of those which serve to establish association of different cortical districts, that relatively to the gray substance the white kernel of the hemispheres appears proportionately larger than in other animals (Figs. 4813, 4814, and 4815).

As a whole the fibres of the white substance tend to converge, like the sticks in the handle of a fan, toward the base of the cerebrum, where the crus carries off a large proportion of them, notably those which traversed the *internal capsule*. The latter is a detachment of the corona radiata, caught as it were between the basal ganglia. A flatwise section of the cerebrum shows it to be bent, very much as a leg is bent on the thigh, with the knee mesad. The anterior or caudo-lenticular division is confined between the parallel ectal border of the caudatum and the cephalo-mesal border of the lenticularis. The genu receives the apex of the lenticularis in its hollow, while the posterior or thalamo-lenticular division lies between the ectal border of the thalamus and the caudo-mesal border of the lenticularis. In front it merges with the white interior of the frontal, behind with that of the occipital, above with that of the Rolandic opercular and parietal organs, from all of which the fibres of the corona radiata pass into it. Some traverse it and enter the crus, others enter the great ganglia on its border, contributions being received to make up for their desertion by fibres which leave the great ganglia to join its columns.* We must therefore distinguish

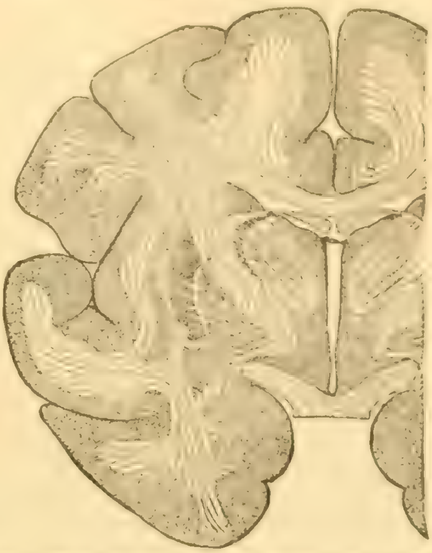

FIG. 4814.—Ditto of Baboon. The white substance is more voluminous, the demarcation of the lenticular and other nuclei by intruding fibres is more distinct.

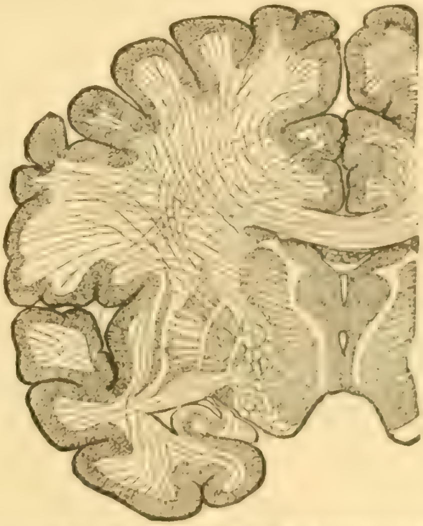

FIG. 4815.—Ditto of Man. The commissural and associating fibres appear to make up the great bulk of the white substance.

---

* V. Marchi claims that [illegible] in the capsule itself.

the following cardinal fibre systems in the white matter of the hemispheres: 1. Projecting systems which unite the cortex to lower centres. These are classified according to their length: (a) The longest direct motor tracts (pyramids to the body), which pass to the spinal gray; (b) those which pass to the pons—these two sets must traverse the capsule and crus, constituting their most important ingredients; (c) tracts uniting the cortex to the caudate, lenticular, subthalamic, thalamic, geniculate, and other nuclei—they traverse the capsule in large part, but do not enter the crus proper; (d) tracts which connect the great ganglia with each other (disputed in some).

In addition to these tracts there is one structure made up of medullated fibres whose relations are unsettled. This consists of a narrow white streak intercalated between the thalamus and caudatum at the ventricular floor. In color it resembles translucent whalebone, owing to a vein which passes along and under it. It is the *stria cornea*. It follows the inflection ventral of the tail of the caudatum, and there its fibres radiate into the nucleus amygdalæ. The terminus of its cephalic end is unknown, but it is certain that it does not, as older authors claimed, join the fornix, notwithstanding that—in the most cephalic course of its fibres.

Aside from the projecting fibres which form the corona radiata and converge from the interior of the cortical expanse to the central ganglia and capsule, the interior white of the hemisphere contains fibre tracts which unite various provinces of the cortex with each other. Two classes of the latter may be distinguished: the one arches from gyrus to gyrus, narrowly skirting the cortex at the base of the sulci (fibræ propriæ); the others unite distant cortical areas with each other. Such are a *fronto-occipital associating bundle*, forming the *tapetum ventrally*, uniting the cortex of the frontal with that of the occipital lobe (fasciculus longitudinalis superior). A similar bundle unites the apex of the temporal with the occipital lobe (*fasciculus longitudinalis inferior*). Other bundles have been described; their existence is not established. The labyrinth of projecting and associating fibres derived from and proper to each hemisphere is further complicated by the commissural systems, which unite the opposite cerebral hemispheres in such a way that their white matter constitutes an anatomical continuity. These are the callosum and the precommissura.

The *callosum* is composed of transverse fibres which penetrate the white interior of each hemisphere; intermingling with the fibres of the superior longitudinal associating fasciculus they are ultimately lost in the labyrinth of subcortical and projecting tracts. That they unite symmetrical brain provinces (i.e., the right occipital to the left occipital, the right frontal to the left frontal, and the right Rolandic to the left Rolandic cortices) is the prevailing opinion, and harmonizes with pathological observations.

The *precommissura* is composed of white substance. Its fibres are transverse and commissural. They are of two classes. The anterior and smaller division unites the two olfactory lobes; the posterior and larger is a commissure of the temporal lobes. In its course to the temporal lobe this division forms a beautifully distinct fasciculus which perforates the lenticula. The olfactory division passes into the ventral part of the olfactory tract and detaches a small portion to the orbital face of the frontal lobe.

The *fornix* is the equivalent of the corona radiata for that part of the cortex which undergoes metamorphoses into the fornix, callosum, and fascia dentata. It should be regarded as distinct from its fellow of the opposite side, for the so-called lyra is properly commissural. Each fornix, then, is the projecting bundle of the gyrus hippocampi, from which it collects the medullated nerve fibres through the fimbria. Having arched over under the callosum, each crus of the fornix, passing caudal of the precommissura, circles ventral of the porta (Monro), and plunges into the central gray of the third ventricle, forming a visible prominence thereby. It then runs caudo-ventrad, insinuating itself between the bundle of Vicq d'Azyr and the lateral ganglion of the mammillary body. Dorsad of the medial ganglion of the mammillary body one division of the fornix decussates; the other's termination is unknown.

Through the fornix, as well as more directly by the attachment of the posterior part of the capsule on the thalamus, the transition from the hemispheres to the diencephalon is established. The chief ganglion of this segment is the *thalamus*. The cells of this nucleus are scattered irregularly through the gray portions; larger forms of the multipolar variety, and presenting axis-cylinder processes, predominate. In all other essential respects it corresponds to the caudatum. It differs from it in being subdivided into a number of distinct nuclei. Of these three are universally recognized. The largest are the ental and ectal; they are separated from each other by a white layer (lamina medullaris interna) which runs parallel to the wall of the third ventricle for its greater length; posteriorly it runs mesal, overlapped by the ectal nucleus. Numerous offshoots run from it through the ectal nucleus, parallel to its dorsal surface (Fig. 4816, 5). In the anterior half of the thalamus the inner medullary lamina subdivides into two branches, thus permitting the intrusion of a third or anterior (cephalic) nucleus between the two main nuclei. This constitutes a distinct elevation on the dorsal face of the thalamus and on a small scale repeats the shape of the dorsal aspect of the caudatum, its rounded head being cephalic, its attenuated part caudal. The pulvinar is in reality but a hypertrophied extension of the ectal thalamic nucleus. Both are covered by a *stratum zonale*, a layer of medullated fibres spread out over the dorsal and posterior, in fact the entire free face of the thalamus, and in large part nothing more nor less than an expansion of the optic tract. At the contact plane of the ectal thalamic nucleus and the white matter of the hemisphere a peculiar appearance results from the interdigitation of thalamic and cerebral fibres, and their inclusion of thalamic gray substance in a rather regular pattern; this is the lattice work stratum of the thalamus (*stratum reticulatum*). A compact layer on its mesal aspect, more distinct in lower animals than man, is called the ental medullary lamina.

As the optic tract courses up and behind the slope of the pulvinar it is intimately connected with a ganglion which is by some regarded as an accessory ganglion proper to the optic nerve, but according to most modern researches is a derivation of the thalamus. This is the *external geniculate body* (*pregeniculum*). It is characterized by the regular alternation of deeply gray and white lamina. The former are thicker, the latter thinner and apparently continuous with the optic tract fibres. The nerve cells in the gray substance are large (30-50 μ), multipolar, and pigmented.

A white streak of medullated fibres, nearly corresponding to the attachment of the tela choroidea (tænia thalami), separates the free surface of the thalamus with its characteristic zonal stratum, from the gray matter lining the third ventricle. The latter is not properly a ganglion of the thalamus, but separately designated "*central gray of the third ventricle*." It extends from the porta (Monro) along the side of the ventricle, lines its floor (lamina terminalis, tuber cinereum, posterior perforated region), and by its fusion forms the so-called commissura mollis (medi-commissura).

The eminence on either side of the postcommissura known as the habena includes the *ganglion habenulæ*, which is composed of small angular nerve cells and numerous granules. It apparently constitutes a terminal point for three sets of fibres: 1, Those from Meynert's bundle; 2, the tænia thalami; 3, the habena proper.

Each of the two symmetrical eminences known as the *corpora mammillaria* incorporates three ganglia.* One of these, the lateral, is applied against the two medial ganglia, so as to represent a crescent on cross-section. Its cells are large. The so-called peduncle of the mammillary body, which in man is difficult of identification, is connected with it. The other two ganglia are situated cephalo-dorsad and ventro-caudad with relation to each other. The former (*Gudden's ganglion*) is connected with the tegmental bundle, also named after him, and which can be traced mesad of Meynert's bundle to a group of cells situated ventrad of the posterior longitudinal fasciculus of the tegmentum and caudad of the great tegmental decussation. The ventro-caudal ganglion is in like manner connected with the *bundle of Vicq d'Azyr*, a fibre-tract formerly confounded with the fornix, now known to be distinct from it, and which runs cephalodorsad to terminate in the anterior tubercle of the thalamus. It is the spreading out on the surface of these two medial ganglia, by the somewhat interwoven fibres of Gudden's and Vicq d'Azyr's bundles, that forms the rounded medullary capsule, uniting them in the spurious unity of the corpora mammillaria.

---

* Not recognized in man.

The *hypophysis* (pituitary body) is composed of two divisions, distinct in structure, as they are in embryonic origin. The part directly continuous with the infundibulum contains a cavity originally derived from the third ventricle, its walls have a nervous structure, containing small nerve cells, nerve fibres, and neuroglia. It is invaginated, as it were, into the larger or epithelial division, which contains epithelial tubes, dovetailing with large blood-vessels from the pia. They contain a special pigment, and appear to secrete a colloid material which is often present in large masses.

The *epiphysis* (pineal gland) is not regarded as an important neural ingredient of the brain. Indeed, its nervous nature has been disputed. It unquestionably includes some nerve-fibres and a few scattered nerve cells. The chief interest attaching to its study lies in its phylogenetic relations. It is generally believed to be a rudimentary relic, representing a cyclopean eye: the primitive eye of some extinct ancestral vertebrate. In some living lizards (Hatteria) the epiphysis has a structure closely resembling that of a molluscan eye, even embodying a crystalline lens and a pigmented and unpigmented (retinal) epithelial stratum. In mammals a neural and a glandular portion are distinguished. The latter includes the so-called brain-sand (acervulus), which is a product of the epithelial secretions.

The posterior perforated space (area intercruralis) is the surface development of the *interpeduncular ganglion*, a gray mass of much reduced dimensions in man, but very large in the rodentia. It is shaped on cross-section like an inverted letter T, the vertical branch merging dorsad with the median raphe. Its cells resemble those of the ganglion habenulæ, but are less angular. Meynert's bundle connects it with the ganglion habenulæ.

In addition to the ganglia of the thalamus and of the eminences visible on the ventral and dorsal faces of the diencephalon, large and important intercalar nuclei are exposed on transection of this segment. The more important of these are the body of Luys, the ganglion of Soemmering, and the red nucleus of the tegmentum. The *ganglion of Soemmering* (*substantia nigra*) is the most readily identifiable. It is exposed on cross sections through the level of the corpora quadrigemina and crura cerebri. In its greatest extent it represents a crescentic interpolation between the pes pedunculi and the tegmentum. Mesad it nearly touches its fellow of the opposite side, being separated by the rudimentary interpeduncular ganglion. Its ventral face sends numerous ramifying prolongations among the fasciculi of the pes (Fig. 4816, 13). The cells are large, multipolar, their bodies approaching the fusiform or angular in outline. In man, and man alone,* they are characterized by a pigment, which varies from a deep brown to an absolute black in color. This gives to the entire ganglion its black color so sharply contrasting with the surrounding tissues. It is not pigmented in the new born, of a pale brown in young persons, and increases in blackness with age.

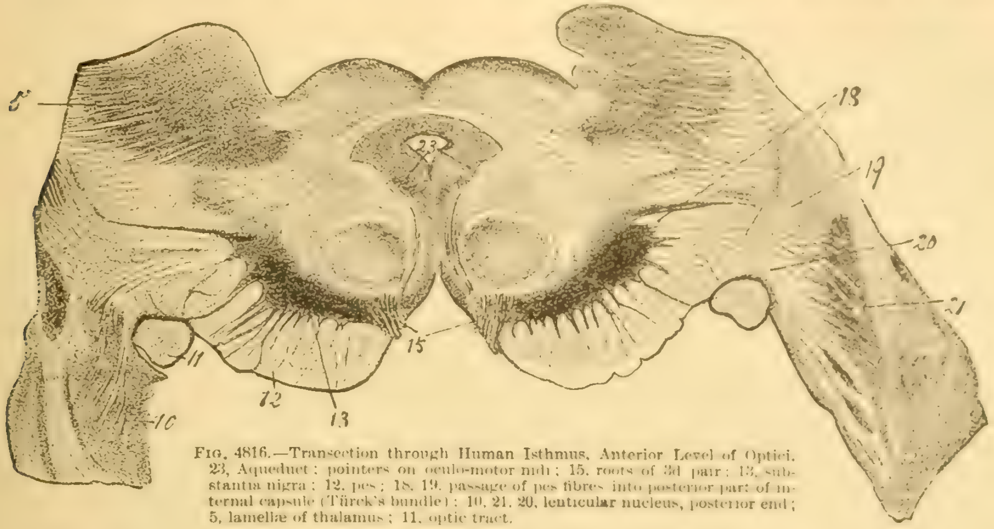

FIG. 4816.—Transection through Human Isthmus, Anterior Level of Optici. 23, Aqueduct: pointers on oculo-motor nidi; 15, roots of 3d pair; 13, substantia nigra; 12, pes; 18, 19, passage of pes fibres into posterior part of internal capsule (Türck's bundle); 10, 21, 20, lenticular nucleus, posterior end; 5, lamellæ of thalamus; 11, optic tract.

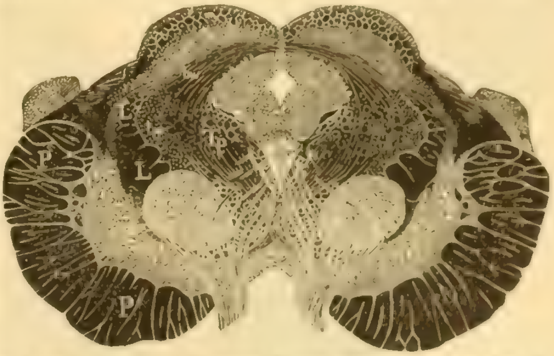

FIG. 4817.—Transection of Human Isthmus through Optici and Pes. P, Pes; L, lemniscus; T, red nucleus; Tp, fibres passing to "fountain decussations"; bw, deep white of optici.

The *nucleus tegmenti* or *red nucleus*, so termed from its reddish tinge in the fresh brain, which it owes to its richness in neuroglia as well as to its great vascularity, is found in those section levels where the ganglion of Soemmering has its greatest extent (Fig. 4817, T). In transections its outline is irregularly round, in sagittal sections an elongated oval. The nerve elements are an-polar, with numerous poles; many of the processes show a noticeable tendency to apply themselves to the walls of neighboring capillaries. The ganglion is surrounded by a capsule of medullated fibres, partly belonging to the reticular field, partly to the [illegible] [illegible]. The fibres of the latter traverse it in coarse bundles running latero-cephalo-dorsad, thus imperfectly walling the nucleus from neighboring fields.

---

* Adult anthropoids [illegible]

The body of Luys is a fusiform ganglion, of a dark and yellow color in the fresh brain, which forms the cephalic continuation of the lateral part of the ganglion of Soemmering. On transection it appears lenticular, whose greater convexity is dorsad; its greatest width is just caudad of the level of the corpora mammillaria (10–12 mm. in the former, 3–5 in the dorsal, and 3–4 in the cephalo-caudal direction). It represents the boundary between the pre- and tegmentum, just as the ganglion of Soemmering does in mesencephal levels. It is made up of fine medullated fibres, crossed in great profusion and confusion with numerous delicate-walled blood-vessels, and sparse multipolar nerve elements of moderate size, angular or spindle-shaped, without any demonstrable axis-cylinder processes; while the protoplasmic processes show a remarkable resistance to staining reagents.

The tissues interpolated between the ventral face of the thalamus, the body of Luys, and the red nucleus consist of a fine, felt-like mass of fibres, whose relations are so obscure that even their boundary is not well determined (zona incerta). In the aggregate this area is known as the regio subthalamica.

The corpora quadrigemina comprise two pairs of ganglia, which are very distinct in structure. The anterior pair presents a true cortical type, which is beautifully evident in the optic lobes of lower reptiles (Fig. 818) and birds. In man the outermost layer is an expansion of the optic tract; then follows a superficial gray layer with numerous small cells,* a deep white layer, also derived from the optic tract, and deepest of all a second gray layer, containing few but large multipolar elements. The underlying tissues do not appertain to the ganglion of the anterior pair, but are a part of the central tubular gray matter and the [illegible] tracts.*

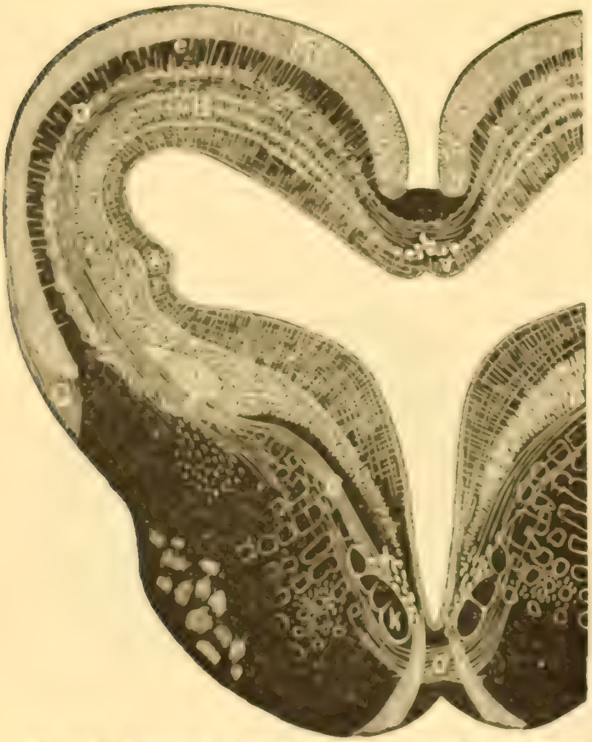

FIG. 818.—Transection of Optic Lobe of Turtle. [illegible]

The posterior pair (posterior pair) are more homogeneous in texture: a fine fibrillar groundwork, with numerous small multipolar elements. The cylindrical ganglia represented by this pair are distinct, and held in a loop of fibres (stratum zonale†), partly derived from the laqueus, partly from the post-brachium. In the median line there is an interchange of such fibres whose exact relations, whether commissural or decussational, are unknown. A similar uncertainty exists with regard to the transverse nerve fibres of which the valvula Vieussenii is composed, and which constitute a caudal continuity with the former.

The cerebellum is convoluted on a plan entirely different from that of the cerebrum. Each primary fold is folded by secondary, and these in turn by tertiary folds, so that on a sagittal section a cypress-leaf appearance is noted (Fig. 1808, "arbor vitæ cerebelli"). The white substance follows all these branchings and subbranchings, forming a core of the minute leafs which are termed folia. The gray substance presents two marked layers: an outer of a pale gray color—the molecular—an inner of a rusty brown tint—the granular layer. At the contact line of the latter with the white substance a slight intrusion of granules is noted. The closely crowded granules of the layer named after them (0.007) are of two kinds: the one studded by numerous fine fibrils, the [illegible] cells of Denissenko, are neuroglia cells; the others, with from two to four-branched processes (brush cells), are decidedly of a nervous character. At the junction with the molecular layer the neuroglia cells are flat, and form a sort of internal limiting membrane, from which radial supporting fibres run through the molecular layer connecting with the external limiting membrane, which is a delicate connective investment interposed between the true pia and the cortical layer of the cerebellar folia. At the boundary of the two cerebellar layers, but more within the molecular than the granular, are found the characteristic nervous elements of the cerebellum—the flask-shaped elements of Purkinje. These are composed of a round body elongated distad like a flask (0.065 long, 0.03 wide, 0.025 thick), with a large distinct nucleus (0.016) and nucleolus. They contain little or no pigment. Their peculiar features are the processes. The central process penetrates the granular layer. Its nature is disputed; some claim it to be the axis-cylinder process, others assert it to be lost in the net-work of fibrils in the granular layer. The distal process branches dichotomously, each cell covering an enormous field of the molecular layer with its ramifications. The branching, remarkably enough, occurs in one plane, so that only such sections as run vertical to the ridge of the cerebellar folium expose them. They are also in definite relation with the cortical superficies, so that the cells are more numerous at the apices of the folia than at the bases of the sulci. At the outer part of the molecular layer the processes become lost to observation; some claim that they become reflected and run back to the granular layer to contribute to its net-work; others assert that they spread out parallel to the surface to form a subpial plexus.

The medullated fibres of the white core of each folium penetrate the granular layer, lose their myelin, and a fine nervous net-work appears to proceed from them, with which are mingled the fibrillar processes of the nerve cells of the molecular layers.

In the interior white of the cerebellum are contained several gray masses. The largest and best studied are the dentated nuclei of each hemisphere. They are also known as ciliary bodies. Like the similarly constructed dentated nuclei of the olive, they are not dentated in lower animals—even in monkeys they are comparatively simple (Fig. 4808, 24). In man each *nucleus dentatus* is located in the mesal part of the corresponding cerebellar hemisphere, in the direct prolongation of the prepedunculus which enters it, and very close to the roof of the fourth ventricle. It is composed of a folded lamina of gray matter, convoluted like the similar nucleus of the olive, and open cephalo-mesad, where its *hilum* admits fibres from various sources, chiefly from the prepedunculus. It measures 20–22 mm. in the sagittal, 10–12 mm. in the lateral, and 11–13 mm. in the dorso-ventral direction. Its basis substance is a fine neuroglia containing numerous multipolar nerve elements (25–35 μ), which in the adult contain a yellowish pigment. The intervening substance is traversed by numerous nerve fibrils, but not as direct in course as those of the olive in the oblongata. Within the inferior vermis cerebelli there is a flat expanse of gray matter on each side, directly over the roof of the fourth ventricle, the *nucleus fastigii*. The nuclei of opposite sides approach each other so nearly as almost to fuse. The nucleus dentatus and nucleus fastigii lie nearly in a horizontal plane,* leaving an interval between them of about 15 mm. In this interval several lesser gray masses are seen. The one nearest the nucleus dentatus is elongated cephalo-caudad, the *nucleus emboliformis*;† that nearest the nucleus fastigii is exposed on section in several smaller round or oval masses, all in reality connected and constituting the *nucleus globosus*. The former is to be regarded as an accessory detachment of the nucleus dentatus, with which it corresponds in structure; the latter bears a similar relation to the nucleus fastigii, and like it has larger multipolar cells (60 μ) than the other nuclei named. The space between the cerebellar cortex and the ganglia named is filled out by the white centre of the cerebellum, which incorporates subcortical, radiating, commissural fibres and fibres emerging in the peduncles. There is every analogy between the fibre tracts of the cerebellar interior and those of the cerebrum. Thus there is a transverse commissure uniting the cerebellar hemispheres, sagittal fibres passing from end to end of the vermis, arched fibræ propriæ uniting the various folia and the hemispheres with the vermis, fibres uniting the cortex with the interior ganglia, fibres uniting the cortex with the peduncles, and finally, such uniting the dentated and other nuclei with the peduncles and auditory nerves.

---

* [illegible]

* This deepest portion is commonly termed [illegible] as the "stratum [illegible]."

† The term stratum zonale is applied to all enveloping fibres, where they form a continuous layer on the outer face of any ganglion.

The part of the brain which, situated axially, serves to unite the forebrain, the cerebellum, and spinal cord, aptly termed *isthmus* by the older writers, includes the best studied as well as the most intricate constituents of the central nervous mechanism. Roughly speaking, it comprises the following: (1) The central tubular gray matter with the included cell nests from which the cranial nerves from the third to the twelfth pairs inclusive originate. (2) Nerve tracts uniting these cell nests in presumable automatic co-ordination. (3) The great nerve tracts which connect (*a*) the spinal gray with the cerebral hemispheres, (*b*) the spinal gray with the thalamus, (*c*) the spinal gray with the cerebellum, (*d*) the spinal gray with special ganglia of the oblongata, (*e*) the ganglia of the oblongata with the cerebral hemispheres, (*f*) the cell nests from which the cranial nerves originate with the cerebral hemispheres, (*g*) the cerebellum with the cerebrum. (4) The special ganglia of the oblongata and pons.

The *central tubular gray* is so termed because it retains more perfectly than any other part of the gray matter the primitive relations to the medullary canal of the embryo (see Embryology). In many places a direct transition from the epithelia of the central canal to nerve cells can be seen, and in certain lower vertebrates this is particularly distinct (Fig. 4819). The endyma, or lining epithelium of the ventricles, is composed of a finely reticulated basis substance, continuous with the substantia gelatinosa centralis of the cord. On its surface it is faced by cylindrical epithelia, ciliated at their free ends and rooted in the underlying supporting substance by fine radial fibres. Where the endymal expanse is reflected to cover the various choroid plexuses the epithelium becomes more pavement-like.

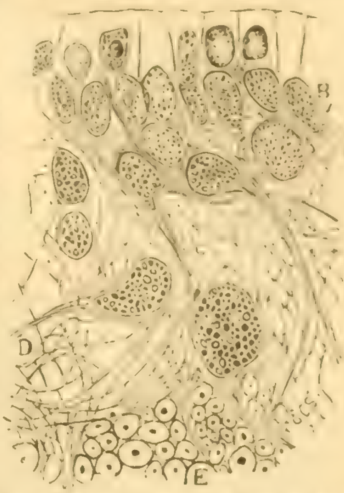

Fig. 4819.—Section near Floor of Fourth Ventricle of Menobranchus. At E transversely divided nerve tubes, at D net-work of nerve fibrils, at B transition from intermediate to epithelia and large nuclear nerve element centres.

Aside from the defined nests of nerve elements, which from their relations to the cranial nerve roots are known as the cranial nerve nidi, the central tubular gray includes scattered multipolar elements of various dimensions, and presenting every transition between the typical nerve element and the neuroglia corpuscle.

Although other ganglia are embryologically derived from the central tubular gray, and retain, even in adult man, structural connections with it, the term is conventionally limited to the gray matter surrounding the central canal of the cord and oblongata, the cornua directly connected with it, the gray matter at the floor of the fourth ventricle, the included and insulated cranial nerve nidi, and the gray matter of the aqueduct, that lining the third ventricle, inclusive of the lamina terminalis. There is a perfect continuity between the spinal gray and that of the oblongata. As far as the oblongata remains closed, the disposition of the cornua resembles that of the cord. The anterior horn, the posterior horn, with its gelatinous head, and the processi reticulares are easily recognized. The changes which gradually take place as the open part of the oblongata, where the central canal opens out into the fourth ventricle, is approached are best exposed by contrasting a transection of the upper cervical cord with one made through the closed or caudal part of the oblongata. We find the following differences:

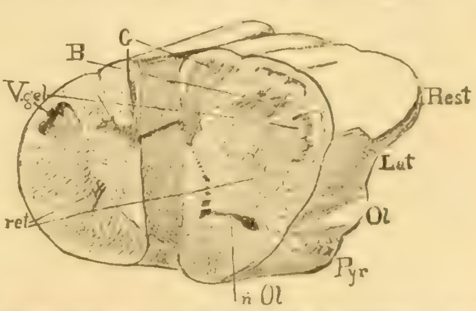

Fig. 4820.—Human Oblongata, Caudal Face to Spectator. The right half is cut more cephalad than the left to enforce the contrast. C, the nuclei of the columns of Goll; B, those of Burdach. V gel, tubes of ascending root of fifth pair; ret, reticular field; n.Ol, beginning of olivary nucleus; Pyr, pyramid; Ol, olive; Lat, lateral field; Rest, restiform column.

The contour of the cord is roundish, that of the oblongata is marked by prominences. This is due to the individualization of certain nerve tracts which emancipate themselves from the homogeneous fusion in which the spinal columns appear. They form plastic columnar protrusions on the outer face of the oblongata. Such are the pyramid and restiform columns. Other features are due to the initiation of the oblongata nuclei by ganglionic masses shown in the cord; such are the nuclei of the columns of Goll and of Burdach, and of the olive. Beginning at the ventral fissure and passing to the dorsal we encounter the following: (a) The decussation (ventral fissure); (b) the convex contour of the pyramid; (c) the sulcus between the pyramid and olive, in which the hypoglossal nerve roots emerge; (d) the bold protrusion of the olive; (e) the depressed lateral field; (f) the funiculus of Rolando; (g) the restiform column; (h) the column of Burdach; (i) the column of Goll; (j) the dorsal fissure which takes the place of the postero-[illegible] in the cord.

---

* With reference to the cerebellum; in reality this plane is inclined, *i.e.*, cephalo-ventrad, downward and forward.

† The accessory part of the nucleus dentatus of Meynert.

As we pass from the level of the decussation of the pyramids cephalad, these demarcations become more distinct (Fig. 4820), and the following transitory conditions can be readily followed in the sections. The nucleus of the column of Goll (Fig. 4820, G) becomes more voluminous, inflating the slender column (funiculus gracilis) of the cord into the clava of the oblongata; the column of Burdach (B, same figure) also increases, and an accessory nucleus is seen in the periphery of the column; the caudal [illegible] of the posterior horn becomes larger and consolidated as the nidus of the ascending root of the trigeminus nerve (V asc.); the reticular field increases, particularly in its gray mesh-work, and in place of the dwindling and disappearing anterior horn, [illegible] and complicated by the crossed bundle of the pyramid tract, the internal accessory division of the olivary nucleus is seen (O). As we pass farther cephalad this latter becomes more and more prominent, inflating a special [illegible] which forces out between the pyramid and the lateral field like a bean out of its pod, the olive (O). At the same time there is a gradual shifting of fibres from the lateral field to a more dorsal position. These are the fibres from the direct cerebellar tract (myelo-cerebellar tract), joined by other fibres from deeper parts of the oblongata; they attain conspicuous prominence as the restiform column (Fig. 4820, Rest.; Fig. 4820, R). Thus the individualized tracts and protrusions growing out of local hypertrophies of gray matter give to the outline of the upper part of the oblongata a sort of butterfly-shape (Fig. 4821), owing to the deep sculpturing of its surface.

The floor of the fourth ventricle, when exposed by the removal of the cerebellum and the [illegible] membranous velum covering its posterior division, is shaped like a lozenge. The anterior end is prolonged into the aqueduct, the posterior into the central canal. It exhibits regional elevations, depressions, and color differences which are in relation with the deep anatomy of the oblongata and tegmentum. Its floor is divided into symmetrical lateral halves by a shallow sulcus ventriculi, which dips cephalad into the aqueduct, caudad into the central canal. Each lateral half is subdivided into an anterior larger and posterior smaller triangle by white striae connected with the acoustic tract. These striae are composed of medullated nerve fibres and at the sulcus appear to sink into its depth. Occasional aberrant striae [illegible] the surface of the anterior triangle. At their lateral end the surface appearance would lead the observer to regard the striae as continuous with the cochlear division of the acoustic nerve, from which they are imperfectly separated by a thin grayish ridge, the [illegible] (which corresponds to the tuberculum acusticum of lower mammals).

In the posterior triangle the middle area is occupied by an elongated triangular field, whose apex is directed to the striae, and which is of a pronounced grayish color, the ala cinerea. As its base reaches the point where the sulcus ventriculi sinks into the central canal it follows that a triangle of inverted position—that is, with its point directed caudad—is included between the sulcus, the ala cinerea, and the [illegible] end of the striae. This is the ala alba medialis. The field to the outside of the ala cinerea is the ala alba lateralis. There are thus two white triangular alae with their apices directed caudad, separated by one gray triangle with its apex directed cephalad. The gray triangle covers the nidi of origin of the vagus and glossopharyngeal nerves. The inner white triangle less accurately corresponds to the nidus of the hypoglossal. In its most cephalic part—in the angle open latero-caudad, formed by the striae and sulcus—it often shows a slight elevation, marking the site of a nidus of unknown significance.

The anterior triangular quarter-field is marked by a depression located slightly cephalad of the middle of its lateral side, which is often seen to be of a bluish color, due to a subependymal vein. A slight groove runs caudad from this fovea and but for the intervention of the striae would reach the depression containing the apex of the ala cinerea. Cephalad of the fovea, and continuing some distance along the aqueduct, is the dark bluish locus cœruleus, which owes its color to the refraction of the pigmented cells of the substantia ferruginea by the milky-white ependyma. In the angle formed by the stria and sulcus ventriculi open cephalo-laterad, is the eminentia facialis, so called because the knee of the facial nerve root, in rising to the ventricular floor, is compelled to circle dorsad and mesad of the abducens nidus at this point.

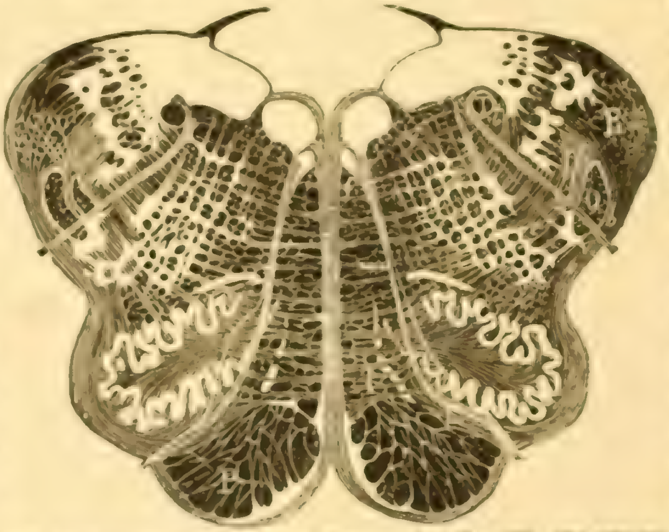

Fig. 4821.—Anterior Part of Segment Represented in Fig. 4820. The gray substance [illegible] by [illegible]. P, pyramid; O, olivary nucleus; R, restiform [illegible]; Q, ascending root of fifth pair; L, L, [illegible].

In a crude way, then, the ventricular features enumerated correspond to the deep structures of the oblongata and tegmentum, the floor of the fourth ventricle representing a rhomboidal landscape of the cranial nerve nidus field in a figure formed by the anterior and posterior cerebellar peduncles:

Ala cinerea.	Nuc. of vagus and glossopharyngeal nerves.
Ala alba medialis. [illegible]	Hypoglossal nerve. [illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

Intermediate to the ala cinerea (in lower animals overlapping on it) and the clava which form the lateral boundary of the ala alba lateralis, there is a peculiar half-nervous, half lymph-absorbing organ, which is richly vascular, containing abundant fibrillar connective tissue. Its nerve cells, whose connections are as yet unknown, are of the granular variety. Aside from this tissue, the floor of the fourth ventricle is lined by endyma. The epithelia of the latter are cylindrical over the alæ, near the aqueduct, and in the sulcus centralis, elsewhere they are flatter, and devoid of cilia. Their basilar processes are connected with the neurogliar net-work.

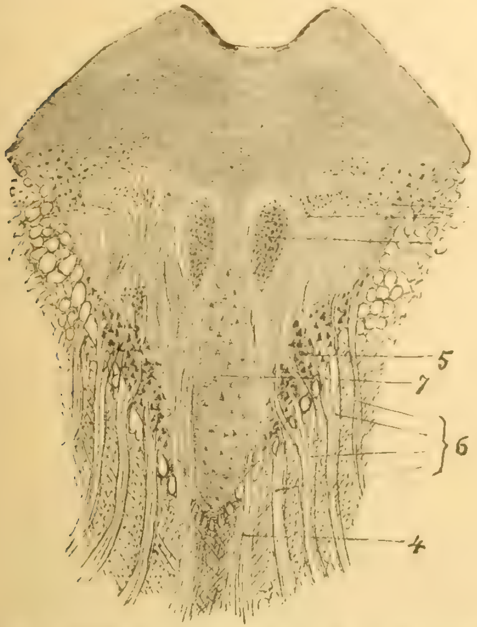

Fig. 4822.—Transection through Central Tubular Gray, Ventrad of Aqueduct in Cephalic Level of Optici (Man). 3, Cephalic nidus, vertical branch; 1, disappearing horizontal branch; 2, root fibres of third looped around the former (pupillary fibres?); 5, main ventral nidus; 7, sagittal (internal rectus?) nidus; 4, 6, roots of third pair traversing the beginning posterior longitudinal fasciculus.

The Cranial Nerve Nidi.—The origins of the cranial nerves, from the third to the twelfth, and excluding the eighth, show a great analogy to those of the spinal nerves. This resemblance extends to the shape and character of their cell-like elements. Thus those of a purely motor function (third, fourth, sixth, seventh, eleventh, twelfth, and the nidus of the motor root of the fifth) contain well-marked multipolar elements, identical in every respect with those found in the anterior or so-called motor horn of the spinal gray, so that in a structural as well as in morphological respects the analogy between the motor cranial nerves and the motor roots of the spinal nerves is a complete one. Distinct axis-cylinder processes can be traced from these cells into the respective roots. As a general rule it may be stated that the larger the muscular mass to which a given nerve is in relation, the larger is its nidus, and the larger also are the included multipolar elements. Thus those of the motor root of the trigeminus and of the facial nerve are larger than those of the hypoglossal, and this in turn is larger than the nidi of the nerves suppying the muscles of the eyeball. At the same time those cell nests related to muscles with intricate functions and subtile co-ordinations appear to have more numerous processes and a more slender and graceful outline than those of coarser function. The elements of the motor trigeminus nidus are more plump in contour than those of the hypoglossal.

The nidi of sensory cranial nerves are in like manner repetitions in structure of the posterior horn of the spinal gray. The caput gelatinosum of the cord is uninterruptedly continuous with the nidus of the ascending division of the sensory root of the trigeminus.

The substantia gelatinosa, which composes the nidi of origin of the ascending as well as the pontile portion of the sensory root of the trigeminus, presents itself as a deeply stained, apparently homogeneous blastema, containing numerous closely crowded nuclei in carminized sections. Closer observation shows that each of these nuclei has its proper protoplasm, and that the apparent continuity of the blastema is a false appearance due to the close crowding. There is a fine fibrillar net-work and a narrow-meshed glia, with numerous equally closely crowded glia cells.

In addition to these two distinct and well studied types, there is a third, of unknown functional relations. It is surmised to be associated with vegetative life, glandular or vasomotor action. The elements of this type are round, oval, or fusiform, they have one or no axis-cylinder process, and very slender, often undemonstrable protoplasmic processes. In some locations, as in the substantia ferruginea and the vagus nucleus, they become strongly pigmented with age. The fusiform ones approach the elements of the columns of Clarke in outline, those of the aqueduct nidus of the trigeminus resemble the elements of the spinal (intervertebral) ganglia, and this resemblance extends to the presence around the elements of a capsule of connective and endothelial character. There is this one textural difference between the basis substance of the cranial and of the spinal nerve nidi. That of the spinal gray is more elaborate, and differentiated into a ground net-work and cell net-work, while the former is composed of the former only, its elements supplemented by formless ground substance ensheathing the nerve elements proper.

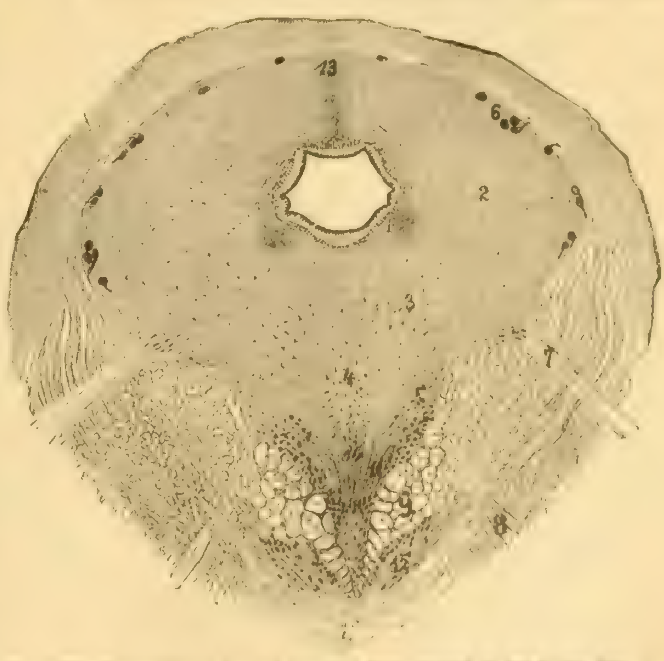

Fig. 4823.—Transection of Human Aqueduct Gray, Caudad of that of Fig. 4822. 1, Molecular masses in raphe; 2, diffuse central tubular gray; 3, [illegible] elements of same; 4, sagittal nidus; 10, fibres entering same; 6, [illegible] vesicular cells of mesencephalic trigeminus origin; 7, [illegible] rootlet probably destined for levator palpebræ; 8, rootlets from main nidus; 9, posterior longitudinal fasciculus; 12, decussatio fontanalis.

The Nidus of the Third Pair is situated in the central tubular gray of the aqueduct, at its ventral portion, and extends for the whole cephalo-caudal extent of the optici, encroaches on the level of the post-optici, and cephalad on the third ventricle, where it gradually becomes lost at the slope formed by the opening out of the aqueduct. Its nerve elements are found arranged in definite groups (Figs. 4823-4834). The most cephalic of these is composed of smaller elements, closely crowded, embedded in deeply staining molecular ground-tissue. In the level of the post-corpusculum the main nidus of each side resembles an inverted L, the vertical branch of which is close and parallel to the median line ⅂ Γ. In the cephalic part of the optici level the upper lateral extension becomes lost (Fig. 4825, 1 and 2). In this level the main nidus is composed of larger elements lying closely crowded against the ventro-lateral contour of the aqueduct gray (Fig. 4825, 5). Several small subgroups can be distinguished in it; one in the middle line may be designated the cephalic nucleus, demonstrable only by the atrophy method (Fig. 4834), as the caudo-lateral group. The rootlets of the third pair can be traced into all these groups except the last. They originate in and among them, either passing directly, or, after sweeping around them (Figs. 4822, 3, 5) and breaking through the posterior

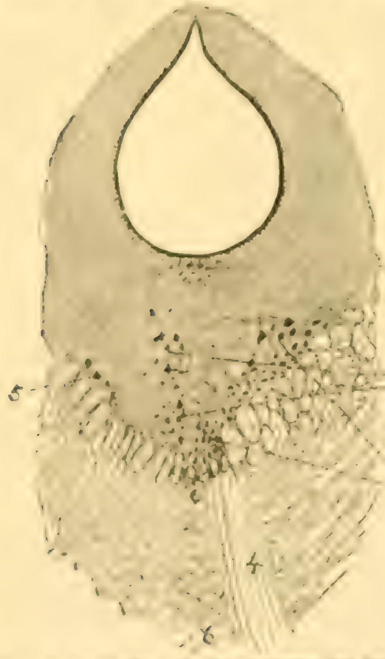

Fig. 4824.—Aqueduct Gray of a Cat, showing the Emergence of the [illegible] Third [illegible]. 1, [illegible]; 2, [illegible]; 3, [illegible]; 4, [illegible]; 5, [illegible]; 6, [illegible].

longitudinal fasciculus, separate like the strands of a horse's tail, by the interference of the red nucleus of the tegmentum, to become bunched together again in and between the mesal end of the ganglion of Soemmering and (interpeduncular region), to emerge compactly on the mesal aspect of the pes (Fig. 4817). It is demonstrated by the atrophy method as well as by direct observation, that in animals with conjugated lateral eye movements, such as man, the dog, and cat, the origin of each third nerve is not limited to the side of its exit. A part is decussated, and the decussated origin is related to the innervation of the internal rectus. Physiological and pathological considerations render it probable that the cephalic small-celled L-shaped nidus is related to pupillary motion. With regard to the caudo-lateral group, which is not connected with the third pair, it is assumed that emerging fibres join the posterior longitudinal fasciculus, to course along the floor of the fourth ventricle, eventually leaving it (Fig. 4825) between Plf and 7 g, to join the root of the seventh pair. In this way the paralysis of the facial nerve supplying muscles under the (orbicularis palpebrarum), instead of the third pair, is explained. The nerve fibres supplying that muscle are derived from the oculo-motor nidus, they only reach that muscle by another path.

The Nidus of the Fourth Pair is situated in the level of the cephalic half* of the post-optici. Its elements are larger, sharply angular, so as to appear star-shaped in many cases. The root fibres have a peculiar course; they accumulate in the latero-dorsal angle of the aqueduct gray (Fig. 4826, IVr), run caudad, gradually rising dorsad, and suddenly turn mesad to undergo a complete decussation with the root of the opposite side in the valvula (Fig. 4826, IVx). The root consequently traverses successively the molecular gray of the aqueduct, the cephalic part of the substantia ferruginea, and the valvula.

The Root of the Fifth Pair.—This enormous nerve has a corresponding extensive origin, including nuclei of the mesencephalon, pons, oblongata, and cord. They are most conveniently considered in topographical order.

A. Nidi and Roots Cephalad of the Exit Level of the Nerve.—The dorsal contour of the aqueduct gray in the

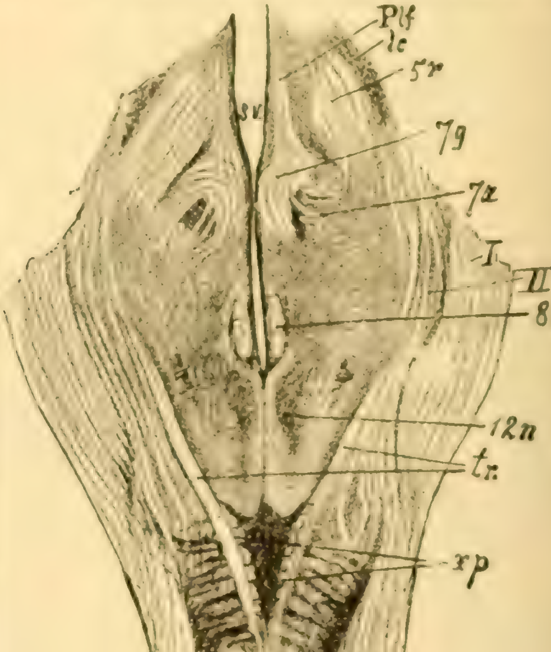

Fig. 4825.—[illegible] Section nearly Parallel to Floor of Fourth Ventricle. Plf, Posterior fasciculus of tegmentum; Sv, [illegible]; [illegible]

level of both optici and post-optici is found on transection (Figs. 4816, 4817, and 4823). Along this entire contour large elements (60 μ), spheroid or ovoid in shape, either single or in groups of two to five, are found. They are surrounded by a capsule (with nuclei), resembling the elements of the Gasserian ganglion in this and other respects. Their powerful axis-cylinder processes, soon become myelinic, and running caudad, accumulate in distinct fasciculi at the lateral angle of the aqueduct gray, where they constitute a sort of lateral appendix and extension to the posterior fasciculus. This is the descending ramus of the trigeminus roots.* The cells above described extend to the level of the velum, where they become intermingled with the elements of the *substantia ferruginea.* This latter has been regarded by some (Meynert) as a nidus of the descending root. A clear connection cannot be demonstrated, and is questioned by other writers (Forel). The elements of the substantia ferruginea are pigmented in adult man alone. While many gradations in shape between the vesicular elements of the descending trigeminus root and the former are visible, the majority are more fusiform, and lack the powerful axis-cylinder process so characteristic of the latter. They occupy the lateral angle of the central tubular gray in, and caudad of the level of, the velum (Fig. 4826, Loc.) and correspond in extent to the locus cœruleus which indicates their location in the fresh brain. The elements are 60–70 μ long and 25–35 μ wide.

---

* It is said by [illegible]

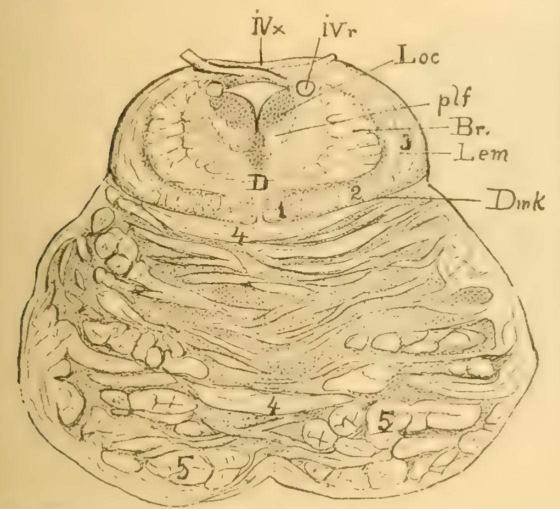

FIG. 4826.—Transection of Human Pons in Level of Valvula. IVx, Decussation of fourth pair; IVr, root of same; Loc, substantia ferruginea; plf, posterior fasciculus of tegmentum; Br, prepedunculus (*Bindearm* of Germans); Lem, lemniscus layer; 1, pedo-tegmental division; 2, main division (cortex lemniscus); 3, lateral (auditory) division passing to post-optici; Dmk, demarcation line between tegmentum and pons proper; 4, transverse; 5, sagittal fibres of pons; D, Wernekink's commissure (decussation of prepeduncle).

The Raphe Root of the Trigeminus.—In all levels of the pons ventrad of the level of the velum to the exit-level of the formed root, fibres are seen sweeping transversely from the raphe to the sensory root of the nerve (Fig. 4789, 2). A section parallel to the ventricular floor shows the real direction of these fibres from the raphe to be latero-caudad. Thin in cross-section, they occupy an enormous extent flatwise (Fig. 4825, 5r).

Nidi and Roots of the Trigeminus Caudad of the Exit-Level.—The caput gelatinosum of the posterior horn of the spinal cord in the level of the two (perhaps three) upper cervical pairs exhibits on its ectal face an accumulation of nerve fibres, which increase cephalad, until in the oblongata they constitute a distinct bundle, crescentic in cross-section (Fig. 4821, Q) which continues its cephalic course through the oblongata and pons, accompanied by more or less regularly disposed gelatinous nerve substance on its mesal border. In the caudal half of the pons it undergoes a sudden inflection ventrad, and joins the great or sensory root of the trigeminus. The gelatinous substance, whose accumulation in the caudal half of the oblongata causes the prominence known as the funiculus of Rolando, is to be regarded as the nidus of this root.

Nidi of the Trigeminus in Its Exit-Level.—In speaking of the exit-level this term must not be taken too literally. The direct roots of the fifth pair, or those of the exit-level, while rectilinear in course, emerge from the pons cephalic of their nidal origin. There are two such roots, a sensory and a motor. Their nidi are closely together in the lateral part of the tegmental division of the pons. The motor nucleus is mesad of the sensory. The former is composed of large multipolar cells, the latter of small granules closely crowded in deeply staining molecular groundwork. The latter is divided into numerous small sub-nidi, and may be regarded as an ideal though interrupted continuation of the caput gelatinosum.

The nidal relations and root origins of the trigeminus may be tabulated as follows:

Roots.	Nidal or other origin.	Destiny.
A. Descending or mesencephalic root.	A. Vesicular nidus of large vesicular elements.	A. To motor root (Forel), to sensory root (Meynert).
B. Undetermined.	B. Substantia ferruginea (?).	B. Undetermined.
C. Raphe root.	C. Decussation in raphe, probable cerebral origin of the sensory fibres.	C. To sensory root.
D. Sensory or pontin root of exit level.	D. Sensory nidus of exit level.	D. To sensory root.
E. Motor root of exit level.	E. Motor nidus.	E. To motor root.
F. Ascending or myelencephalic root.	F. Caput gelatinosum of cord and oblongata.	F. To sensory root.

The nidus of the abducens nerve is a round mass of spongy gray matter 1–2 mm. wide, containing multipolar nerve cells, somewhat larger at the ventro-lateral part than in the mesal part of the nidus (25–45 μ). It is near the floor of the fourth ventricle, in the angle formed by the acustic striæ and the ventricular sulcus, and is embedded as a stone would be in a sling in the curve made by the knee of the facial nerve root. It is this knee conjointly with the abducens nidus that causes the ventricular elevation known as the eminentia facialis. From the abducens nidus the rootlets proceed directly ventrad parallel to the raphe, spreading slightly as they traverse the trapezium, pursuing a less regular course through the pons, to emerge at its posterior border in a line continuous with the exit-line of the hypoglossal roots.

The Nidus Facialis is a single large group of multipolar nerve elements (45–60 μ) situated in the ventro-lateral part of the caudal division of the tegmental segment of the pons. It lies mesad of the auditory and emerging facial nerve roots, dorsad of the nucleus of the trapezium, and a little over four millimetres from the ventricular floor. Scattered forerunners of this nidus are found in sections at the pons-oblongata transition. The elements of this nidus are arranged in numerous sub-groups which are definitely arranged, uniformly in each individual examined by the writer. The rootlets emerge from among these sub-nuclei and converge toward the ventricular floor to there form a compact bundle. This has a remarkable course. It curves over the abducens nidus from behind (caudad), and overlies it like a horseshoe hung over a ball; not as a straight, but as a bent horseshoe, bent so that its cephalic (efferent) branch is pointed more laterad than its caudal branch, which is the one that emerged from the nidus. The curve is at the same time convex mesad. This part is known as the *genu facialis*, and together with the underlying nidus of the abducens causes an eminence on the ventricular floor previously described (eminentia facialis). After having encircled the nidus abducentis the facial root passes ventrad, and at the same time slightly ectad and caudad, passing its own nidus on its ectal face and emerges in the recessus facialis (Fig. 4827, rf. and 7). The remarkable course of this nerve root—leaving the ventrally situated nucleus to reach the ventricular floor, returning again to pass its origin on its way to the exit—is explained by the fact that at the ventricular floor it receives an accession from the posterior fasciculus.

The Nidi of the Ninth, Tenth, and Eleventh Pairs are usually considered in their topography. This mode of treating them is justified by the uncertainty which prevails regarding their peripheral innervation and complex interconnections.

---

* Forel and Henle assert that it joins the motor root, all older writers that it joins the sensory root, and a few believe that it gives fibres to both.

At the ventricular floor the ala cinerea includes a gray mass which contains distinct groups of nerve elements. As the fourth ventricle merges into the central canal this gray mass extends caudad on the lateral aspect of the latter. The two groups in it are a dorso-lateral one with smaller cells embedded in a fine fibrillar network and a meso-ventral one of fusiform and roundish larger elements 35–45 μ long and 15–20 μ wide, which often become pigmented in the aged, in epileptics, and in premature * cerebral involution. Both of these groups are demonstrated to be connected with the tenth or vagus nerve. Its cardiac and visceral innervations are referred to this the subendymal nidus vagi.

More deeply embedded in the oblongata, included in its reticular field, and intermediate to the olive and emerging vagus and accessory rootlets, is a mass of multipolar elements of the same size as those of the facial nidus, which lie in the direct caudal continuation of the nidus facialis. The fibres which emerge from this cell nest take a course similar to that of the horseshoe-shaped facial nerve root. They run dorsad till they reach the solitary bundle (Fig. 4825). Then they curve around and run caudo-laterad to emerge at the lateral field of the oblongata. Those of these rootlets which emerge in more caudal levels do not penetrate the crescentic transection area of the ascending trigeminus root and become accessory nerve rootlets. Those which emerge in more cephalic levels do so encroach and constitute a part of the vagus nerve. Whichever of these nerves they join, the cell nest from which they arise merits the designation nidus laryngeus.† In addition to its origin from the oblongata, which, as physiology has shown, represents its laryngeal distribution, the accessory nerve has an origin from the cord; the cells of the spinal accessory nucleus are multipolar, large (30–40 μ), and though but few are found in each transsection, they form a long continuous column, extending from just below the middle olivary altitude to the seventh and perhaps the eighth cervical nerve origin. In the oblongata the nidus accessorii is dorso-lateral of the nidus hypoglossi. In the upper cervical level it lies in the centre of the anterior horn, and more caudad approaches and finally reaches the most lateral and dorsal part of the anterior horn. Where there is a lateral horn it is situated in it, or at its base. The roots pursue a uniform course, running to the periphery in a sharp curve, whose convexity is ventro-lateral. In the cord they closely hug the contour of the posterior horn. Near their exit they often break up into a sort of delta.

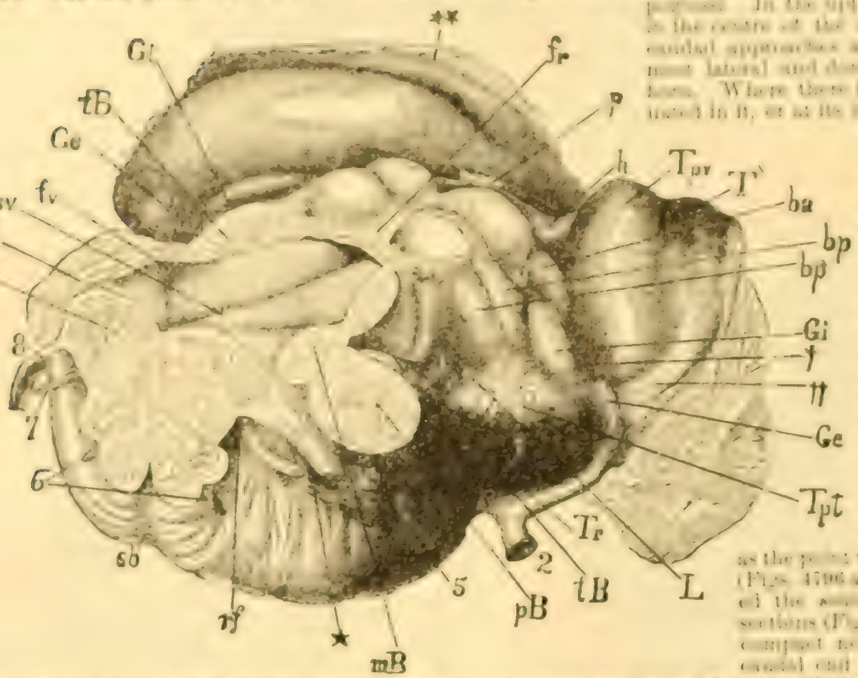

FIG. 4827.—Human Brain. [illegible] the Cerebellum Removed by a Section. [illegible] L, lemniscus; rf, [illegible]

In the levels of the oblongata cephalad of the decussation of the pyramids a round bundle is noted near the median line, skirting the central canal gray matter. This is identified in every section-level cephalad of this as far as the point where the ninth pair arise (Figs. 4796 and 4797 t), and designated the solitary bundle. In [illegible] sections (Fig. 4827, tt) it appears as a compact nerve strand, which at its caudal end approximates its fellow, suggesting a direct or decussated origin from among the fibres of the decussation of the cortex lemniscus. It is accompanied in its course by a partial sheath of gray matter. While it appears to receive accessions of fibres from the inner arciform bundles, through the intervention of this gray matter it gives off a regular series of rootlets to the vagus, and above all to the glossopharyngeal nerves. These rootlets join those which were described as derived from the nidus laryngeus in those levels where the latter is found.

The known origins of the ninth, tenth, and eleventh pairs may be summarized as follows:

The ninth pair originates directly from the solitary bundle.*

The tenth pair originates (a) from the subendymal nidus vagi in the ala cinerea (visceral nidus), (b) from the solitary bundle (sensory origin), (c) from the nidus laryngeus (motor origin).

The eleventh pair originates (a) from the nidus laryngeus of the oblongata, (b) from the nidus accessorii of the cord.

The *Nidus Hypoglossi* extends from the level of the decussation of the pyramids to very near the level of the striæ acusticæ. It bears an inverse relation to the ala lateralis, with which its outline is sometimes confounded; where the ala is widest, which is at the intersection with the striæ, the hypoglossal nidus is least demonstrable. It gradually becomes more compact caudad and with the closure of the central canal comes to lie just ventrad of the latter. In this position commissural fibres can be demonstrated to exist, uniting the two of opposite sides. In the middle of its cephalo-caudal extent it shows a beautiful grouping of cells, whose axis-cylinder processes form undulating strands segmenting it into numerous subsidiary groups, to eventually accumulate at its meso-caudal aspect, there to form the emerging root which traverses the reticular field, forming the boundary between its mesal and lateral divisions, and leaves the oblongata in the furrow between olive and pyramid (Fig. 4821). Some rootlets enter the hilum of the olivary nucleus and break through its ventral folds, others sweep gracefully between the medial accessory and main nuclei of the olive. Not all efferent fibres of the nidus take this course. A distinct bundle leaves the latero-ventral cell-groups and can be traced far ventrolaterad among the reticular meshes. At the meso-ventral edge, close to the raphe, a small nidus (Fig. 4821) is noted, whose cells are either very small, or, where larger, fusiform or spherical, and appear bipolar. Their significance is unknown. The white layer of the ala overlying the nidus contains numerous fibres, which unite the cephalic and caudal parts of the nidus with each other.

---

* Insanity and senile dementia. [illegible]

† [illegible]

* It is conceivable that the glossopharyngeal nerve has a similar origin.

The description of the central apparatus of olfaction, vision, and hearing completes the enumeration of the deep origins of the cranial nerves.

The Olfactory Nerves.—The central olfactory apparatus, or olfactory lobe, comprises the olfactory tuber, tract, and bulb. The tuber is a triangular field, in front of the anterior perforated space, which is covered by a thin cortical layer. Cephalad it becomes attenuated, and continued as the tract. The tract is in section three-cornered, the dorsal corner corresponding to the edge held when in situ by the sulcus rectus of the orbital face of the frontal lobe. At its anterior end it is enlarged, and covered, as it were, by a hood of gray and white substance, the so-called bulb. (1) The bulb is covered on its free surface by an intricate plexus of white fibres, directly derived from the peripheral olfactory nerves (*fila olfactoria*). (2) The individual bundles of this layer become lost in peculiar bodies known as *glomeruli olfactorii*. These are round masses held together by connective tissue derived from the pia, partly filled by glia cells, and containing delicate nerve cells with very numerous fine, and some coarser, nerve fibres, the interstices being filled by an apparently structureless (?) basis substance. Each glomerulus is surrounded by a blood-vessel, branched like a bird's claw. (3) Inside of the glomeruli is a layer of nerve cells, resembling the smaller variety of pyramids, and embedded in gelatinous nerve tissue. (4) This is followed by a layer of granules, and (5) a medullary layer. It is from the medullary layer that the white substance of the olfactory tract is mainly derived. Here a discrimination must be made. In the embryo, as is permanently the case with many lower animals, the bulb is hollow, its cavity communicating with the anterior horn of the lateral ventricle. The axis of the olfactory bulb in man contains a slight amount of molecular gray matter, which represents the endyma of the obliterated olfactory ventricle. The white matter surrounding this (the fourth layer of our enumeration) is analogous to the white matter of the cerebral hemispheres, and connected with it by a direct superior root. It also sends a notable detachment of fibres to the anterior commissure, one division of which is a true olfactory commissure. A slender branch of this bundle leaves it before the commissure is reached, and enters the thalamus. In their course through the tract three categories of fibres may be distinguished: (1) Those which pass from the cortex of the bulb to the cortex of the tract; (2) those which pass uninterruptedly through the tract from the bulb to higher destinations; (3) those which pass in the same direction as the latter from the cortex of the tract. At its lateral and mesal edges the cortex of the tract becomes so rudimentary that the white preponderating appears as two striæ, the lateral and medial olfactory striæ. The former of these goes to the gyrus uncinatus, the latter to the cephalic end of the gyrus cinguli.

Each *optic nerve* in man contains 438,000 individual nerve fibres, which, as there are 3,360,000 cones in the retina, allows a distribution of one nerve fibre to each 6 to 8 cones, assuming an equal (?) distribution. In proportion as the binocular field of vision becomes identical, a condition most nearly approached in man, the decussation of these fibres in the chiasm becomes more incomplete. Thus, in the dog, the uncrossed bundle is one third as great as the crossed, but in man two-thirds as great. We are also able to identify the bundle of fibres which are connected with central vision. In the optic disk within the eye this area occupies a temporal sector, immediately caudad of the eyeball a marginal sickle, and behind the entry of the *arteria centralis retinæ* a vertical oval area ectad of the axis, but separate from the periphery. In the level of the optic foramen it is again peripheral, occupying a sector in the ventro lateral quadrant. The course of the optic nerve fibres toward the chiasm becomes complicated, and it is in the optic tract that we alone can identify the different strands uniting the retinæ to the visual centres. In considering these we must exclude a fortuitous ingredient, the *commissura inferior*,* a cylindrical tract which passes through both optic tracts across and in the dorsal part of the chiasm. It apparently connects the postgeniculata and has no actual relations to the optic nerves, tracts, or centres.

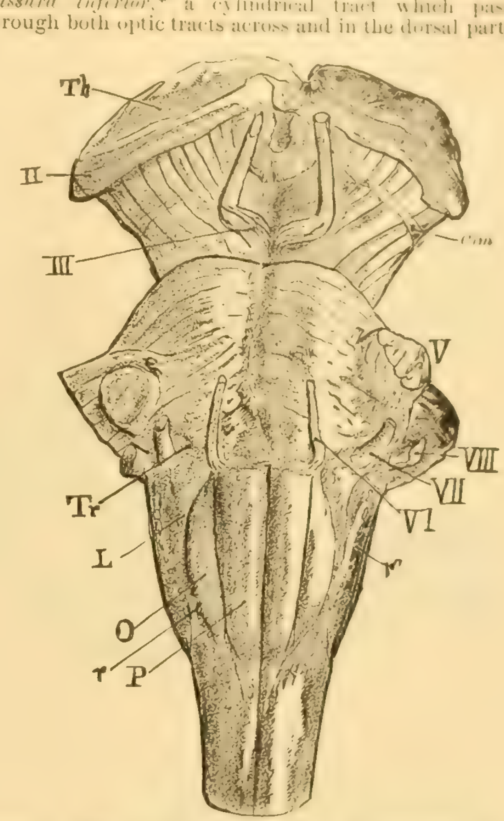

FIG. 4828.—Basal View of Sea-lion's Isthmus. II, Optic tract; III, V, VI, VII, VIII, cranial nerve roots; *Th*, cut surface of thalamus; *Cim*, cimbia (tractus peduncularis transversus of v. Gudden); *Tr*, trapezium, almost concealed; *O*, olive; *P*, pyramid.

The true optic tract passes in three divisions respectively, into the pulvinar, pregeniculata, and optici. Atrophy experiments demonstrate that from all these ganglia a powerful tract, the optic radiations of *Gratiolet*, run into the occipital cortex, distributed nearly in accordance with the distribution of the white line of Vicq d'Azyr (?). The intracoronal optic tract runs on the ectal face of the postcornu, detaching fasciculi to all the occipital gyri. In the posterior part of the internal capsule, near their entry into the pregeniculata and pulvinar, the fibres are so arranged that those representing the medial infracortical centres lie caudo-laterad, and those representing the lateral infracortical centres (pulvinar) lie meso-frontal. It is established that Gratiolet's bundle is not exclusively constructed at least in a trophic sense. When the eye is extirpated the atrophy of the optic nerve, the crossed optic tract, and contralateral optic lobe is greater than where the occipital area of the cortex is destroyed; while where the latter is destroyed the atrophy of the postgeniculate and pulvinar is greater than after enucleation of the eyeball (v. Monakow).

---

* Not to be confounded with the [illegible] in the central tubular gray, one of which [illegible] of the chiasm.

The anterior members of the corpora quadrigemina (pre- and postgeminum) have been erroneously regarded as homologous ingredients of the optic system. The prægeminum is derived from the deep white matter (third layer) of the optic, and by small part from the zonal layer. These fibres pass into the deeper strata of the respective lateral of the prægeminum. They are central projecting fibres. In addition, the prægeminum incorporates fibres from the optic tract, so that it is a conduit for centripetal fibres from the retina to the optic, and from the optic to the occipital lobe. The postgeminum is connected with the post-optic and post-geniculata.

The atrophy method has demonstrated the relation to the visual apparatus of the cingulum (transverse peduncular tract), discovered by Gall and Spurzheim, rediscovered, and its real nature determined by v. Gudden. It courses round the crus from the anterior margin of the optic, to lose itself, passing the mesial fasciculi of the pes, constituting a visible prominence in some cases (Figs. 4777, 4778, and 4779). Destruction of the retina or of the occipital lobe causes atrophy in it, and the atrophy is total and crossed in animals with complete decussation of the chiasm, partial and bilateral with those having semi-decussation of the optic nerves.

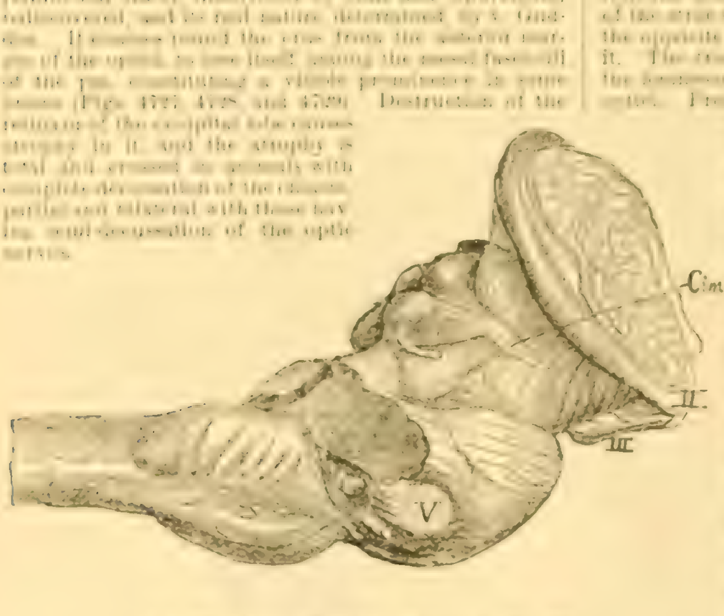

FIG. 4829.—Lateral View of same Isthmus as Fig. 4828.

The acoustic nerve is composed of two divisions, distinct at their termination in the cochlea and vestibule, and distinct at their origin from the oblongata. They differ in texture. The cochlear division has finer fibres, and the myelin sheath has no rings of Ranvier. The vestibular part has coarse fibres with thick myelin sheaths, showing the usual characters of peripheral nerves. In addition it contains small islands of gray substance. The cochlear division at its oblongata entry lies caudad and dorsad of the other. It courses round the convex face of the restiform column and enters into direct connection with a nidus of nerve elements, filling out the triangular space between the cochlear entry dorsad, the vestibular entry ventrad, and the restiform column mesad. It is also connected (probably indirectly and after interruption in the nidus mentioned) with the tuberculum acusticum. This body is represented in the human brain by a thin gray lamina, apparently interposed between the lateral part of the striæ, swelling to its largest dimensions in the lateral angle of the fourth ventricle, and becoming gradually lost in the cochlear root. In lower mammals it is much more voluminous, and shows an exquisite cortical texture, there being (1) an outer barren layer; (2) a layer of small cells; (3) a layer of large cells; (4) a deep medullary layer. Its relative atrophy in man is in harmony with the fact that all the primary centres of special sense (bulbus olfactorius, superficial strata of the optic, tuberculum acusticum) have become reduced, owing to the higher development of the secondary centres in the cerebrum and subcortical ganglia. The ganglion cochleare is regarded as the homologue of a spinal ganglion for the cochlear nerve, which has become included in the oblongata, for in some lower vertebrates it is represented by an extramedullary ganglion.

The origin of the vestibular division is disputed. That it is connected with the vermis cerebelli is the only well-ascertained fact. The fibres having this origin can be distinctly traced traversing the restiform column, or running mesad of it in the cerebellar interior. Its oblongata entry is between the ventral face of the restiform column and the latero-dorsal aspect of the ascending trigeminus root.

The auditory tract has been traced, mainly by the atrophy method, from the entry of the cochlear division of the acoustic nerve in the tuberculum acusticum and acoustic field to the convolutions of the temporal lobe. Arched fibres from the tuberculum acusticum, to the reticular field of the pons-oblongata transition, and those of the striæ of the ventricular floor cross the raphe, find the opposite nucleus of the trapezium, and connect with it. The tract thence passes into the lateral division of the lemniscus layer. This enters the ganglia of the postoptic. From the latter the arm of the postoptic lobe, almost indistinguishably fused with a tract from the internal geniculate body, passes through the posterior part of the internal capsule to the cortex of the two upper temporal gyri at their posterior portion. Notwithstanding the fact has been questioned by the followers of Flechsig, the striæ acusticæ are to be regarded as connected with the auditory nerve roots. The only well-ascertained fact as to their course is that they dip into the raphe (Fig. 4825, St) and probably decussate therein.

Several gray masses are found in the interior of the oblongata and pons without possessing any direct relation to the cranial nerves. They are, at least in the majority, intercalary stations of the great fibre systems to be considered at the close of this article.

The first addition noted on tracing the spinal gray into the oblongata is the development from the posterior gray commissural part on either side of a long pedunculated and a broad sessile gray mass. The former extends into the column of Goll, and reaches its greatest volume in the clava. The latter extends into the column of Burdach.

In the level of the striæ acusticæ a distinct accumulation of small nerve elements, closely crowded, is found on either side of the sulcus ventriculi, the *nucleus funiculi teretis*. Its relations are unknown. Similar, more attenuated, and irregular masses are found in the external arciform fibres and scattered in the raphe. The former are known as nuclei arciformes. The nerve elements of the nuclei of Burdach, Goll, and the nuclei just named are so similar that one description will serve for all. They are small, angular, multipolar elements, often showing a transition to granules (15-25 µ long, 5-10 µ wide) from which an axis-cylinder process can be traced into the numerous nerve strands which break into these nuclei and divide them up into numerous subdivisions. The distal division of Burdach's nucleus is an exception. Here the elements are nearly twice as large (30-40 µ long, and 12-18 µ wide).

The nucleus of the column of Burdach is divided into two portions by the followers of the atrophy method. The lateral division this method shows to be intimately connected with the fibres of Burdach's column, while such a relation, if at all present, is very slight in the case of the mesial division. The cephalic connections are not so determined; by exclusion, relations to the restiform column, to the olive and the nucleus of Deiters have been negatived. It is very probable that the inner division of the cerebellar peduncle, as well as some fibres of the reticular field originate in it. It is certain that a part of the cortex lemniscus is derived from arched fibres originating in the nucleus of the column of Burdach, decussating across the raphe, and running a course similar to the arched fibres from the nucleus of the column of Goll.

The nucleus of the olive (Figs. 4796, 4797, and 4821) is a corrugated lamina of gray matter, whose extent nearly corresponds to the elevation seen on the base of the oblongata. It can be compared to a hollow oval sac, slit on its mesal aspect, and the edges of that slit everted. The eversions are known as the accessory olivary nuclei, the main mass, from the appearance presented by its corrugated folds in cross-section, is termed the dentated nucleus. The opening is the hilum. Numerous fibres run into the interior through this hilum, and others cut through the lamina to join the fibre arches of the reticular field and those passing toward the restiform column. As the hilum does not extend the whole length of the olivary ovoid, section through the cephalic and caudal ends of the latter show the dentated nucleus to be closed on all sides, while those passing through the middle two-thirds reveal the hilum. The inner accessory olive is continued as a caudal spur, bent like an obtuse L (on cross-section), caudad of the caudal extremity of the dentated main nucleus (Fig. 4797).

A section through the middle of the olive exposes the different divisions of the nucleus in their clearest relations (Fig. 4821). It is seen to consist of a main mass, and of two subsidiary detachments, all having the common structure of a gelatinous lamina containing numerous evenly distributed nerve cells, whose processes are few and can but rarely be traced beyond the border of the lamina in which they are situated. The olivary nucleus is in intimate relation with the arciform fibres in every altitude, some of these, the external arciform, merely course round its ventral face, others break into its nervous lamina, or cut through the accessory nuclei, and a large number accumulate in its interior after having entered at the hilum. We shall learn to recognize in this relation the rôle which the olive plays as a station of the restiform decussation. On the interior as well as the exterior of the olivary nucleus there are also longitudinal fibres. The hypoglossal nerve root passes through the olivary nucleus without entering into any connection with its nervous substance.

The *nucleus magno-cellularis*, discovered by Deiters and often designated by his name, is situated mesad of the restiform column at the entry level of the acustic nerve roots. From this fact and the clear and distinct entry of the fibres from the latter into its gray substance it was regarded as an acustic nidus. But nothing could better illustrate the fallacy of relying on the apparent connection of nuclei and tracts than this case. For it has been conclusively shown that destruction of the acustic nerve does not affect the cells of the magnocellular nucleus at all, while hemisection of the cervical cord leads to their total atrophy. It is probably a station for a spinal tract.*

Aside from the nidi and ganglia in the isthmus large nerve tracts run through it, for whose better understanding and classification the isthmus is assumed to be composed of a dorsal part, the *tegmentum*, and a ventral part, the *pes*. The boundary between them is furnished in the thalamic level by the ganglion of Luys; in the level of the optici by the ganglion of Soemmering; in the pons by the demarcation line, and in the oblongata becomes obliterated, but may be assumed to lie between the pyramid and the interolivary layer. The overwhelming majority of nerve fibres in the pes is derived from the cerebral hemispheres or their ganglia. The overwhelming majority of the fibres of the tegmentum is derived from the thalamus, optici, post-optici, and other ganglia scattered through it. The chief of these tracts are the lemniscus, the prepedunculus, the trapezium, the posterior longitudinal fasciculus of the tegmentum, and the restiform column with its appended inner division of the cerebellar peduncle.

From the level of the optici to the spinal cord the tegmentum is more or less perfectly divided into lateral halves by the *raphe*. This important structure varies in composition in various levels, being the medium through which various interchanges of fibres takes place. Occasionally it is entirely interrupted, as at the decussation of the prepedunculus (brachium conjunctivum, so-called commissure of Wernekinck, Fig. 4826, D) and the decussation of the pyramids, where it practically ends.* In the pons the raphe is limited to the tegmental segment. Proceeding caudad the following features are found in it: I. The *decussatio fontinalis*, so called because of the resemblance of the scattering strands to the jets of a fountain. It lies in the level of the optici, and is a decussation of tegmental fibres from the thalamus or the optici (?). II. The *fibræ rectæ*. These are fibres whose direction in the main is vertical (dorso-ventral). They are found from just caudad of the valvula level to the decussation next to be mentioned. It is with these fibres that the raphe root of the trigeminus is continuous. In the oblongata the fibræ rectæ are specially well developed. Some of them are derived from the external arciform fibres, some from the internal. Often the appearance is seen as if such fibres ran uninterruptedly from the pyramids, or pyramid tract, to the cranial nerve nidi at the floor of the fourth ventricle† (Fig. 4821). But it is also found that large numbers of arciform fibres entering the raphe on one side, after a longer or shorter course in it, leave it on the other; and most authors incline to regard the raphe as a continuous decussation, whose decussation angle is so fine as to simulate parallelism. Fusiform nerve elements are found in the raphe, particularly in those levels corresponding to the cranial nerve nidi, independently of those accumulations which have been considered in conjunction with the nuclei arciformes.

Among the most striking features of a cross-section of the oblongata are the arched fibres (*fibræ arciformes externæ* et *internæ*). Some of them are visible as distinct strands on the exterior, coursing round the caudal end of the olive, and often masking the prominence of the pyramids. In this situation the external arched fibres incorporate one or more flat lamellæ of gray substance, structurally like the olivary gray, known as the *nuclei of the arciform strands*. The internal arciform fibres in great part enter the olivary hilum, others enter the reticular field; some cross the raphe directly, others run in the raphe for a greater or lesser distance. It is among these fibres that we occasionally find small islands of gray substance, resembling in structure the nuclei of the arciform strands. It is largely due to the accumulation of arciform fibres on the dorso-lateral part of the oblongata that the restiform column owes its size. Their ultimate origin, which is probably derived from some spinal tract through the olivary nuclei, is as yet disputed. Less doubt exists as to another ingredient of the restiform column. The *direct cerebellar tract* originates in the lower dorsal cord, is situated, in cross-section, at the periphery of the lateral column on its posterior quarter or two-fifths (for its area increases cephalad). This area is crescentic and embraces the pyramid tract ectad. In its course through the dorsal cord it receives constant accessions of fibres from the vesicular columns of Clarke. These fibres spread out brush-like in transection levels and traverse the neck of the posterior horn and the pyramid tract to reach the direct cerebellar tract. The latter continues its course cephalad, and in the caudal part of the oblongata occupies the lateral field. Here its fibres change course, running sharply dorsad, they form a belt on the ectal face of the ascending trigeminus root to pass into and merge with the restiform column. With the latter they reach the cerebellar interior, and by means of the atrophy method are traced into the cortex of the dorsal vermis cerebelli. As the vesicular columns of Clarke sensitive centripetal fibres from the posterior spinal roots, the following may be laid down as a provisional course of this tract:

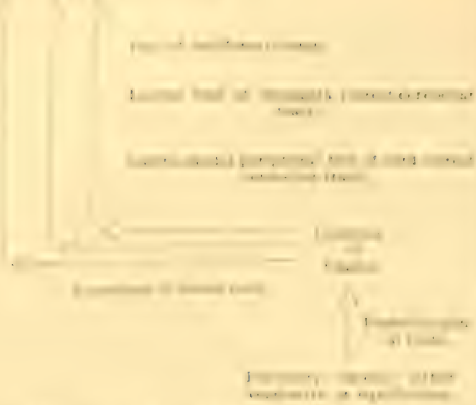
---

* V. Monakow states it to be connected with Burdach's column. Vejas denies this.

* To be faintly represented in the [illegible] cord.

† The connection has not been demonstrated. It is the substratum of Meynert's theory of motor projection.

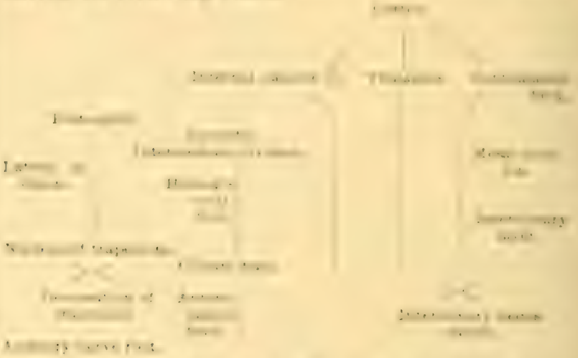
Course of [illegible]



The *inner division of the cerebellar peduncle* is an imperfectly demarcated strand on the mesal side of the restiform column (Fig. 4827, II) and topographically corresponds to the attenuated cephalic prolongation from the clava. It is connected caudad with the nucleus of the column of Burdach, and cephalad runs into the nucleus of the fastigium, partly crossed and partly uncrossed. In its course there is some gray substance, which is imperfectly continuous(?) with the accessory nucleus in the column of Burdach.

The *prepeduncle** (Fig. 4827, 1 B) originates in the hilum of the ciliary or dentated nucleus of the cerebellum, becomes a distinct surface strand of the tegmentum, and in cross-section lies mesal of the zonal fibres which connect the lateral lemniscus with the post-optici (Fig. 4826, Br). Just dorsad of this level its fibres pass to the raphe and there decussate, totally or partially (?), with those of the opposite side (Wernekink's commissure). After decussation they pass to, encapsulate, or enter the red nucleus of the tegmentum. An oblique, flatwise section would thus expose the contour of a scissors half open. The handles would be the two red nuclei, the bridge the decussation, the pointed cutting ends the prepeduncles, whose points would lie embedded in the dentated nuclei of the cerebellum. Indirectly this tract is supposed to be continued from the red nuclei to the ventral lamina of the thalamus by a special field of subthalamic fibres.

The term *lemniscus* (fillet) was originally applied to a triangular surface area on the lateral face of the mesencephalon and the fibres which, corresponding to it, could be traced deeply through the isthmus to the neighborhood of the olives. Considered as a whole, it is best studied in a transection at the level of the valvula (Fig. 4826). It here occupies an L-shaped field, the horizontal branches of those of opposite sides nearly meeting at the raphe (L, L). It is directly dorsad of the demarcation line of the pons and consequently constitutes the most ventral part of the tegmentum. Its horizontal division is confusedly spoken of as the "lemniscus stratum." The part which can be traced farthest cephalad is spoken of as the "upper," the part which connects with the stratum zonale and terminates in the ganglia of the post-optici as the "lower" division. The last designations are derivative from their topographical arrangement in transection. Nearest the raphe there is a crescentic bundle, embedded in diffuse gray matter, which is an aberrant bundle from the pes.† It should not be considered as a component of the lemniscus. Directly overlying the deep (dorsal) transverse pons fibres is the interolivary tract, so called because it is continuous with that division of the reticular field which in the oblongata lies dorsad of the pyramidal tract, and between the opposite olivary nuclei. Immediately laterad of this is Helweg's oval field* and most laterad a large field which, embodying the auditory tract, connects the trapezium with the post-optici. It is this part which includes the lateral ganglion of the lemniscus, a reticular mass of gray matter with small cells. The other bundles of the lemniscus are separated by molecular gray matter in less heavy accumulations. In a cephalad direction the lemniscus may be described as having the following course:



Its best known ingredient, the *interolivary lemniscus tract*, extends in its demonstrable course as follows: In the level of the optici (Fig. 4817, L L) it occupies a lamp-shaped area, laterad of the red nucleus, and curved over cephalad.‡ In the upper pons levels it is the mesal part of the true lemniscus layer, and, passing into the interolivary layer, decussates into the nuclei of the columns of Goll and Burdach (Figs. 4789-4797, D, DS, Da, Dam). It is through these nuclei indirectly continuous with the tract of the column of Goll and the tract which is represented in the comma-shaped area of the column of Burdach.

The *trapezium* consists of a transverse fibre mass situated in the ventral part of the tegmentum, nearly coinciding with the entry level of the cephalic acoustic root. On transection (Fig. 4800) it exhibits numerous fibres slightly wavy in their lateral, directly horizontal in their intermediate part, and separating at the raphe, where they undergo a sharp-angled decussation. In its lateral part the trapezium incorporates a folded cell mass better developed in lower animals than in man—the nucleus of the trapezium. It has been compared to the nucleus of the olive. Like it, it presents denticulations, a hilum, and accessory nuclei. Cephalad it extends into the lateral part of the lemniscus with an attenuated prolongation (Fig. 4807). The fibres of the trapezium bear a similar relation to it which certain arciform fibres bear to the olivary nucleus, that is, they enter its hilum, decapsulate and break into it. Owing to the defective development of the pons in lower mammals, the trapezium in them becomes exposed at the base of the brain (Fig. 4798), but much less so in those which approach man in the relative preponderance of the hemispheres (Fig. 4828). It is probably a part of the centripetal auditory tract.

The *posterior longitudinal fasciculus of the tegmentum* extends from the level of the optici into the deepest (most dorsal) part of the anterior column of the cord. It is everywhere, in this extensive course, closely applied against and ventrad of the central tubular gray, running beneath the oculomotor, the trochlearis, abducens, and hypoglossal nuclei. On cross-section the bundles of both sides resemble the horns of an ox (Fig. 4826, plf). They suffer a sudden reduction in the level of the abducens nucleus. Their incorporation of fibres running from the nidal centre of the orbicularis palpebrarum to the facial genu, and their probable inclusion of those fibres which unite the homolateral nidus of the external rectus of the eye with the nidal centre for the contralateral internal rectus, justifies the view that they are devoted to co-ordination of eyeball movements. They are, in accordance with this view, rudimentary in blind animals. The axis cylinders of the posterior fasciculi are of various dimensions, very large ones preponderating.

---

* Superior peduncle.

† See [illegible].

* The term is [illegible] transferred to the [illegible].

‡ In Fig. 4818 [illegible]

The ingredients of the *tegmentum* thus far enumerated, while the most characteristic and easiest studied, do not exhaust the anatomy of this part of the isthmus. There is a considerable space left in the oblongata, bounded mesad by the raphe, dorsad by the nidi and dorsal nuclei, ventrad by the olivary nuclei. It extends to the lateral field, the ascending trigeminus root and restiform column. In the pons its boundaries are the same, except ventrad, where the lemniscus takes the place of the olivary nuclei, and laterad, where the series of emerging auditory and trigeminus roots takes the place of the restiform column. In the level of the optici it is bounded mesad by the ventral apex of the central tubular gray and interpeduncular ganglion, dorsad by the deep gray of the optici; laterad imperfectly by the thalamus and internal capsule, with which it partly fuses (?), and ventrad by the substantia nigra. Up to this level it is termed the *reticular field of the tegmentum*, from the basket-work pattern exhibited by its interlacing fibres. This structure is heralded in the spinal cord by the *processi reticulares*, prolongations of the spinal gray, which ramify, anastomose, and thus produce a net-work, entrapping in its meshes fasciculi of white substance. Interrupted by the decussation of the pyramids, they reappear, but much more voluminously, in the oblongata. Three sets of fibres form its lattice-work: a sagittal, composed of fibres apparently extending from the thalamus and subthalamic fields into the posterior and lateral columns of the spinal cord. These fibres are cut across in transections, and therein appear as round or quadrangular areas of axis cylinders. The other two series run in the plane of the transection, comparable to equatorial and meridional lines. One set, the fibræ arciformes, runs in a gentle circular sweep from the region of the restiform column—in lower levels from the nuclei of the columns of Burdach and of Goll—to the raphe. The other crosses them at nearly right angles, incorporating and running parallel with the emerging roots of the ninth to twelfth cranial nerves. Wherever there is a space in this lattice-work it is filled out by gray substance, in some places merely molecular, in others embodying neuroglia and small nerve elements. From the level of the trigeminus exit to the decussation of the pyramids it incorporates multipolar nerve elements, among the largest in the nervous system, as individuals or as groups. In its aggregate this scattered gray matter, which repeats the lattice-work arrangement of the white bundles as much as a negative can imitate its matrix, would constitute a bulky accumulation of gray matter, the *reticular ganglion*.

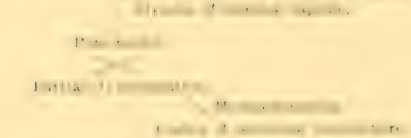
A minute study shows that the continuity of the sagittal fasciculi of the reticular field is more apparent than real. Fibres leave one bundle to join another, and may, for all we can demonstrate to the contrary, leave the latter again. Many connect with the elements of the reticular ganglion, which appears to be a depot, mediating the transition of sagittal to equatorial and meridional fibres, and *vice versa*. A number of imperfectly known nerve tracts are traced into the reticular field from the cord. The *antero-lateral spinal tract* is an as yet imperfectly studied bundle occupying a triangular area with a peripheral convex and two inner concave sides, in the anterior half of the lateral column of the cord. It may be crudely regarded as an ideal continuation ventrad of the area of the direct cerebellar tract, with which it has been confounded. Its mesal angle is prolonged toward the anterior horn. The English writers (Tooth, Sherrington, Gowers, Haddon) do not trace it far cephalad. Helweg asserts that it occupies a position in the lateral field of the oblongata ventrad of the direct cerebellar tract and ultimately merges into the halo olivaris, through which it becomes a part of the tegmentum (the oval tract of the tegmentum), which is the direct cephalic prolongation of the halo. Similarly certain nerve tracts from the diencephalon are traced into the reticular field from above. Those which become components of the lemniscus, prepedunculus, and posterior fasciculus have already been considered. In addition a distinct group of nerve bundles (*tegmental fasciculi*) can be traced in its lateral field from the thalami. The *posterior commissure*—which, according to some authors, constitutes a true commissure of the tegmentum, according to others a decussation of thalamus fibres—contributes fibres to its mesal division. Near the raphe, immediately subjacent to the posterior fasciculus, is a field of large axis cylinders derived from the *decussatio fontinalis*.

In the level of the red nucleus the tegmentum includes a remarkable bundle of fine fibres devoid of myelin, forming a homogeneous column. It passes dorso-ventrad, slightly caudad, uniting the ganglion habenulæ and ganglion interpedunculare (*Meynert's bundle, fasciculus habenulo-interpeduncularis*). Owing to the prominence of the red nucleus in man, it makes a slight curve to pass on its mesal side, and often traverses a groove in this aspect of the ganglion.

Throughout its entire extent there is an interchange of fibres across the raphe, between the opposite halves of the tegmentum. These decussations are most numerous from the level of the optici to the decussation of the prepedunculus.

The pedal part of the isthmus incorporates the pes pedunculi, pons proper, and pyramid. The composition of the former is practically identical with that of the internal capsule; exceptional features will be noted in their proper place. The term *pons* is used in a double sense; topographically the entire segment of the isthmus separated by a transection made cephalad of the anterior border of the pons elevation, and caudad of its caudal border is thus designated. On continuing these sections through its interior it is seen that everywhere there is a sharp line of demarcation between a dorsal and ventral portion (Figs. 4789, just below mark 5; 4799, just below end of mark Id; and 4826, Dmk). The dorsal division is uninterruptedly continuous cephalad with the lemniscus and thalamus, caudad with the reticular field of the oblongata, in short it is the united tegmentum. The ventral division is composed of a transverse mass of fibres, derived through the medipedunculus from the cerebellum (Figs. 4826, 4; 4789, 4; and 4799, Plo, traversed in a sagittal direction by the fibres of the pyramid (Fig. 4799) and pes pedunculi (Fig. 4826). This is the pons proper. To understand its constituents let the reader imagine a truncated cone, standing on its caudal as the smaller end, imagine further that it be split at its cephalic part, and that a belt had been welded around it to prevent that split from widening. The split and separating upper end would represent the pes of each side, the lower end the pyramids, and the belt the pons. On examining further we find that the transverse fibre mass is built up from two sources. If the section area of the pes be compared with that of the pyramids—for the two are directly continuous—it is found that only one-fifth of the former is represented in the latter. Consequently about four-fifths of those fibres which were derived from the internal capsula and concentrated in the pes become deflected from their course and lost in the pons. This they do partly by direct entry into the medipedunculus of the same side (Gratiolet, Türck, Flechsig), partially by decussating into the opposite side (directly ?) and partly by terminating in the proper ganglia of the pons. The latter are irregularly shaped gray masses, whose disposition may be best understood by conceiving the spaces left as the transverse bundles separate to permit the sagittal to traverse, filled out by gray matter. The tracts connecting the cerebral cortex and cerebral ganglia with the cerebellum all pass through the pons proper. (1) From the frontal cortex to the pons nuclei; this tract is situated in the medial part of the pes and encroaches on the periphery ventrad of the pyramid tract. (2) From the temporal cortex to those nerve elements of the pons ning in (between the pyramid and lemniscus); it is situated in the lateral third of the pes.

It is demonstrated that those fibres from the cerebral sphere which originate in the occipital, temporal and parietal regions are represented in the dorso-cephalic tegmental tract of the pons. Among these bundles the best known is that tract* which connects the occipital and temporal lobes with the cerebellum, through the pons nuclei (Flechsig) or directly (Majewski); it is situated in the lateral part of the pes and probably continues later in and parallel with Gudden's optic radiations. As regards all other connections between the cerebrum and cerebellum through the pons, the following plan may be regarded as representing their general character; the tract above mentioned serving as a paradigm.



The putamen of the lenticularis and the caudatum are connected with fibres which run in that part of the pes nearest the ganglion of Soemmering and immediately among its processes. It is as yet uncertain whether they connect with the ganglion or into the lemniscus.†

The voluntary motor tract originates in the pyramidal elements of the cortex cerebri. The bundle of fibres comprising it are an ingredient of the corona radiata and occupy in their origin, over one-third of the cortical area: the pre- and postcentral, the caudal ends of all the frontal gyri, the paracentral lobule, the superior parietal lobule, and even a few fibres from the cuneus. From a great part of this origin the fibres are scattering; the compact core of the voluntary motor tract would appear triangular in a horizontal section and corresponds in its axis to a line drawn from the junction of the paracentral lobule, the precuneus (superior parietal lobule) and the postcentral gyrus. The caudal angle extends into the precuneus, the ectal angle toward the sulcus of Rolando, the mesal (cephalic) angle to the paracentral lobule. After the fibres have become concentrated they compose a distinct ingredient of the corona (Rolandic loop) and enter the internal capsule, occupying a situation just caudad of the knee of the capsule, extending from the latter to a little caudad of the thalamo-lenticular or posterior middle division of the capsule. Pathological experience teaches that the genu part of this tract represents the voluntary innervations of the cranial nerve distribution. This part we will omit from consideration for the present. The trunk of these fibres is known as the *pyramidal tract*, from its ultimate condensation in the pyramids of the oblongata. It enters the pes pedunculi in such a way that the fibres, which in the corona were cephalic, become ventral, and caudal, lateral, in the pes. The bundles which are collected very much like the pieces of a fan at the handle. The semi-spiral twist they undergo is indicated in the fascicular sculpturing of the ventral face of the pes. In the pes it occupies one-fifth of the total area in and slightly ectal of the middle of its transsection. The pyramid tract then traverses the pons (Figs. 4789, 4790, 4791 Pyr, and 4826, 5), emerging as a compact ventral column in the oblongata; the pyramid proper. Which, arrived at the ventral fifth of the oblongata, decussates with its fellow of the opposite side, visibly to the naked eye, the alternate fasciculi interdigitating in the ventral fissure. The fibres for the arm decussate cephalad, those of the leg caudad.‡ Not all the fibres of the pyramid decussate; a minority remain in the original position on the same side of the ventral fissure. The former, or *crossed pyramidal tract*, enters the dorsal part of the opposite lateral column and extends uninterruptedly down to the lower lumbar levels of the cord. It undergoes abrupt diminutions in area, on the cervical as well as the lower dorsal (upper lumbar) levels of the cord, due to the entry of its fibres into the processus reticularis of the gray substance. Whether, as v. Monakow claims, they here contact with the multipolar small elements of the reticular processes, or traverse the latter uninterruptedly to enter the large multipolar elements of the anterior (ventral or motor) horn of the spinal gray, it is admitted that they are related to voluntary motility of the extremities. The fibres which remain on the side of the ventral fissure and remain constituents of the anterior column of the cord, constitute the *direct pyramidal tract*. They are not in immediate contact with the white commissure of the cord, but send fibres into it, so that they probably decussate through this commissure in their entire extent, which reaches to the upper third of the dorsal cord, repeating in detail what the crossed tract does in bulk.

Anatomical variations are said to exist in the course of the pyramid tract. v. Monakow found its crossed portion to be exceptionally [illegible] of the [illegible]. Flechsig claims that the crossed and direct portions may assume vicarious relations; the direct portion may preponderate over the crossed, nay, may absorb it entirely. This may be bilateral or unilateral. No confirmation has yet been offered for the latter view, but it is not improbable.

The pyramid tract is better developed in man than in any other animal. It is one of the latest to attain maturity in the new-born infant. It is defective in idiots, and absent in microcephali. It is present only in those animals who have free motor control of the extremities. It is undemonstrable in the cord in lowest animals. It is absent in the elephant and whale. These facts collectively, even if there were no pathological evidence pointing in the same direction, prove that it is the channel through which the motor area of the cerebral cortex is placed in communication with the muscles of the extremities of the opposite side, thus mediating intelligent motor activity of the latter.

The tract which originally constitutes a part of the Rolandic loop, and is located in the genu of the internal capsule, lies mesad of the pyramid tract in the pes.* It leaves the pes to break the demarcation line, entering the tegmentum.† Here it lies in the angle between tegmental lemniscus and demarcation line (Figs. 4805, 2 and 4826, 11). Caudad it becomes lost, either in the reticular formation or after rejoining the pyramid tract in the upper part of the oblongata. This the *[illegible] tract* is in all probability the channel through which the facial and hypoglossal nidi are placed under the dominion of the opposite cerebral hemisphere.

Further details regarding the cerebro-spinal fibre systems will be found in the article Spinal Cord.‡

BRAIN, MALFORMATIONS OF, WHICH ARE MORPHOLOGICALLY INSTRUCTIVE.—In Vol. I., pp. 654–656, and in Vol. III., pp. 735–738, encephalic malformations are considered mainly as affecting the viability of the individual. In the present article are given figures and brief descriptions of certain conditions which illustrate in some degree the normal structure and development of the organ as presented from a morphological point of view in the articles on its Development (Vol. I., pp. 633–642) and Gross Anatomy (this volume, pp. 107–164). Did space permit, the number of cases might well be increased almost indefinitely, for it is scarcely possible to imagine any encephalic malformation that may not suggest, illustrate, or apparently contravene some morphological idea. On this account it is to be the more regretted that so few such specimens are adequately preserved, examined, figured, described, and explained; indeed, no case is known to the writer in which the best possible use has been made of the opportunity; it is particularly desirable that, when malformation is suspected, the brain be thoroughly hardened by alinjection (injection of alcohol) of both the arteries and the cavities; see the article in this volume, Removal of the Brain. The accounts and explanations of the following cases are not altogether satisfactory to the writer, who believes it necessary to make careful comparisons of several exhibiting different degrees of the same general kind of malformation.

§ 1. Prop. I. In infantile hydrocephalus there may persist a relative extent of the cavities, and a tenuity of the parietes which normally characterize the earlier embryonic stages with man (Fig. 4693), and the adult conditions of certain low or generalized vertebrates (Amphibia, Fig. 4739, and Dipnoans), while yet the parts are large enough to be more easily studied than those embryonic or animal brains.

§ 2. Points illustrated by Fig. 4830. A. The fundamental morphological relation of each hemicerebrum as a lateral outgrowth, process, diverticulum, or "wing" of the mesal portion of the prosencephal.

B. The non-formation or obliteration of all the fissural corrugations and inequalities, excepting the Sylvian, which is a mere shallow depression extending obliquely dorso-caudad along the lateral aspect of each hemicerebrum.

C. The enormous size of the porta,* yet the maintenance of its complete circumscription.

D. The tenuity of most of the parietes; in the occipital region they are no thicker than a sheet of ordinary paper, and are really exaggerated by the two ink lines and intervening space.

E. The extraordinary distinctness of the mass named *caudatum*, of which another view is given in Fig. 4831.

F. The peculiar form and relations of the rounded mass intervening between the caudatum and the lateral wall, and which may represent the lenticula.

G. The non-appearance of the thalamus in the floor of the paracœle.

H. Upon the whole, the retention, substantially, of a condition of the cerebrum comparable with the normal state at a much earlier period of development; it is, as it were, an expansion of such a cerebrum as exists at twelve weeks; see Fig. 4708.

§ 3. Points illustrated upon Fig. 4831.—A. The great size of the porta in this hydrencephal; its ventral half is concealed by the caudatum, but the total length (dorso-ventral dimension) is 19 mm. (three-fourths of an inch), and its width 8–9 mm.

B. The complete circumscription of the porta, notwithstanding the delicacy of the parts and the pressure that may have caused its enlargement.

C. The great extension of the paraplexus and adjoining portions of the parietes; the parts marked 6 and 7 are membranous; the zone just caudad of 7 and forming part of the upper margin of the figure may be the fimbria, and the thicker zone just caudad of it may be the hippocamp.

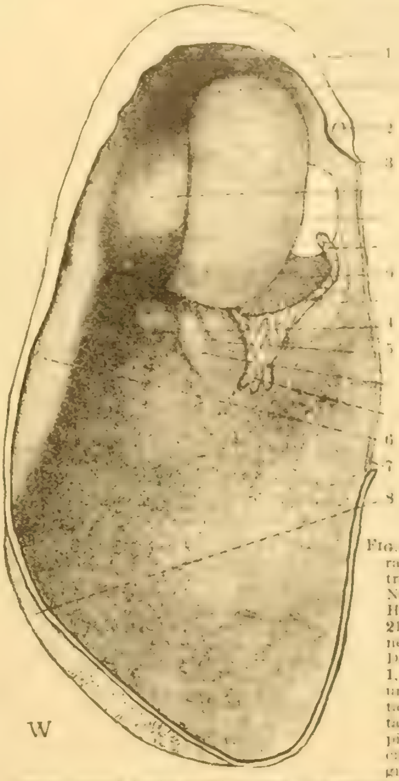

FIG. 4830.—The Left Paracœle (Lateral Ventricle) of a Human New-born (7 Months) Hydrocephalus. No. 2131, Museum of Cornell University. 1. Drawn by Mrs. W. [illegible] 1, One of several slight undulations of the cortical surface in the frontal region; 2, small pit, probably artificial; 3, cephalic margin of a break, apparently natural, in the mesal parietes; the ventral margin of this break is indicated by 7, and the corresponding caudal margin projects slightly mesad just caudad of the line; it may be supposed that this interruption of the mesal wall represents the location of the callosum that might have been formed; 4, 5, slight elevations as yet undetermined; 6, distinct though rounded ridge corresponding to the shallow Sylvian fissure, the only recognizable fissure; 7, see 3; 8, occipital end of the hemicerebrum, projecting slightly beyond the cut surface; 9, membranous portion of the parietes (perhaps an attenuated tenia) through which the thalamus shows.

Preparation.—The child was supposed by the physician and parents to be seven months advanced; it breathed a few times; the weight was 1,618 grams. The neck and scalp were swollen, but the head was not unusually large. Normal salt solution was injected into the umbilical vein and escaped, with blood, from the [illegible]. Then half a litre of ninety per cent. alcohol was injected, the [illegible]. The scalp, calva, and dura were removed, and the head suspended in brine while the brain was extracted; in spite of care there was some separation of the hemicerebrums at the meson. The contained fluid was allowed to escape, the brain placed in ninety per cent. alcohol, and the hemicerebrums inflated to their natural size. They were then covered with a thin layer of absorbent cotton to keep them [illegible]. The alcohol was changed twice at intervals of two days, and in [illegible] month the various sections were made under alcohol. The mass supposed to represent the caudatum was extremely dense. The [illegible] firm, and in parts more substantial than the [illegible]. The condition of the diencephal was not fully determined. The [illegible] seemed to be wholly occluded, which would account for the [illegible] of the cerebrum. The entire specimen needs further study and comparison with similar cases.

§ 4. Prop. II. In adult hydrencephals, although the parietes are thickened approximately as in the normal brain, the existence and connections of the cavities are more readily observed, and certain parts, ordinarily insignificant, become relatively more conspicuous

§ 5. Points illustrated upon Fig. 4832.—A. Several points illustrated upon Figs. 4734 and 4735 in the article Gross Anatomy of the Brain.

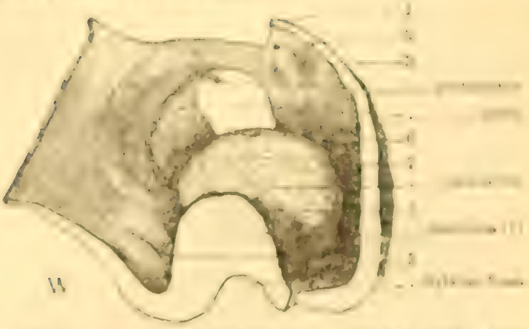

Fig. 4832.—Lateral Aspect of the Right [illegible] (Hydrocephalus). [illegible]

[illegible] [illegible] Fig. 4833, the paraplexus on this side was [illegible].

B. The relation of the paraplexus to the cella and medicornu.

C. The completeness of the paracoelian floor after the removal of the thalamus: the interval, rima, between the [illegible] and the lateral margin of the fornix (fimbria) is completely filled by the plexus and the membranes (pia and endyma) from which it is produced.

D. The greater width of the rima in the cella than near the end of the medicornu.

E. The extension of the postcalcarine fissure (stem of united occipital and calcarine) across the hippocampal gyre; it does not, however, reach the hippocampal fissure.

§ 6. Points illustrated by Fig. 4833.—A. The size, form, and direction of the porta from the mesal aspect.

B. The complete circumscription of the porta, caused by the reflection of the endyma upon the intruded plexus (Fig. 4745).

C. The greater length of that part of the paraplexus which hangs in the porta (portiplexus) than of that which hangs in the aula (auliplexus).

D. The constitution of the velum as a fold of pia, with blood-vessels intervening; one lamina of the fold belongs to the fornix, and the other to the thalamus, or rather to the diatela or primitive diacoelian roof (Fig. 4765).

E. The relation of the ventral end of the porta to the aulix ("sulcus of Monro").

F. The thinness of the fornicommissure (for [illegible]).

G. The length of the crista connecting the callosal rostrum with the fornix.

H. The extension of the [illegible] and of [illegible] the hemicerebrum. It is uncertain how far this existed normally, or was produced by the process of [illegible].

I. The continuity and apparent identity of the thin cephalic wall of the mesal cavities represented by the [illegible], the [illegible], and the [illegible]. Morphologically, however, these have distinct relations, as stated on p. 1[illegible], § 144.

§ 7. Page 111. Callosal [illegible].—In addition to about fifteen cases of absence or thinness of the callosum, there have now been reported at least twelve instances of its complete absence, together with the mesal part of the fornix. Commonly this deficiency was accompanied with mental and physical weakness amounting [illegible]; but Malinverni reported (*Giornale* [illegible] *Acad.* [illegible], 1874; *Gazette Médicale de Paris*, January 16, 1875; *Gazetta delle Cliniche*, 1874, No. 15; *London Medical Record*, 1874, No. 73) the case of a soldier forty years of age, who had been noted merely for irritability, taciturnity, and lack of [illegible]. The last instance to be recorded is that of Onufrowicz (*Arch. für Psychiatrie*, xviii., 1887) who refers to the literature of the subject very fully. To a certain extent these [illegible] brains represent on a larger scale the stages in mammalian development before the hemicerebrums are connected by the callosum and the fornicommissure. Likewise the permanent conditions of the brains of the monotremes, marsupials other than [illegible], where the callosum and fornix are absent or rudimentary; see the papers of H. F. Osborn (*Morphologisches Jahrbuch*, xii., 223-251, and 530-543).

§ 8. Points illustrated upon Fig. 4834.—A. The absence of the callosum and of the fornicommissure (mesal part of fornix).

B. The development of the fimbriodentum as far dorsad as a point corresponding apparently to the dorsal limit of the aula and porta (which is not distinctly indicated).

C. The roofing in of the aula and diacoele by a thin membranous [illegible] tela, the remnant of the primitive roof of the cavities.

D. The absence of the medicommissure and small size of the precommissure, in contrast with the same parts in the [illegible] cat (Fig. 4835).

E. The independence of the occipital fissure, and the apparent junction of the calcarine with the hippocampal.

F. The radial disposition of the mesal fissures; some

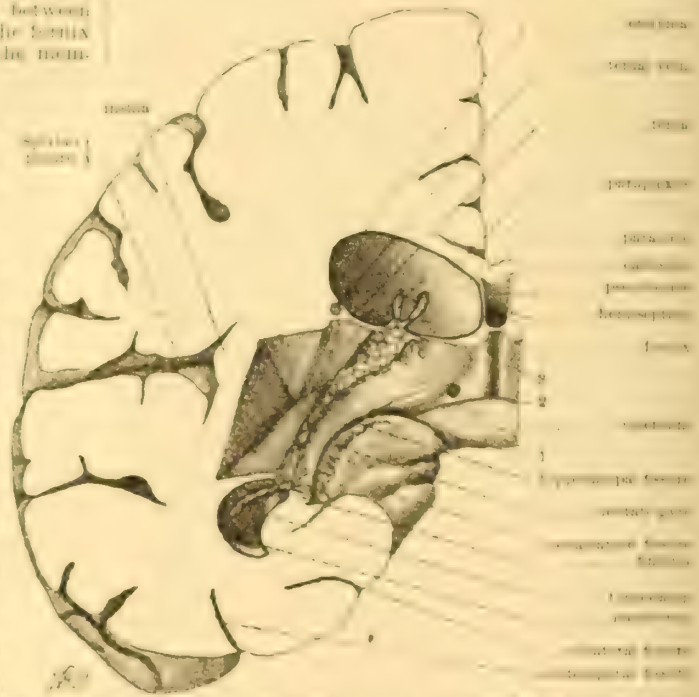

Fig. 4833.—Transection of the Right Hemicerebrum of an Adult Hydrocephalus. [illegible]

[illegible]

of them probably represent the transitory fissures mentioned in vol. i., p. 640, and shown in Fig. 4757, 2, 3, 4.

§ 9. Prop. IV. Among other mammals than man the abnormal absence of the callosum has been observed, so far as known to the writer, only in three cats examined in the anatomical laboratory of Cornell University; one of these cases is represented in Fig. 4835.

§ 10. Points illustrated by Fig. 4835.—A. The total absence of callosum and fornix (its mesal part) in a cat apparently nearly grown and not markedly peculiar.

B. The normal development of the fissures, excepting, of course, the callosal and—presumably—the dorsal end of the hippocampal; contrast the fissures in the incallosal human brain, Fig. 4834.

C. The retention of so much of what is commonly called *fornix* as pertains to the primitive condition of a mammalian brain, viz., the prosoterma (dorsad of the precommissure) with its retreating margin, to which, doubtless, was attached the original thin roof of the mesal aula and diacœle.

D. The unusual size of the precommissure and medicommissure, as if to compensate for the absence of the callosum. In a normal cat's brain (No. 342) where the hemicerebrum is 35 mm. long, the precommissure is 1.8 mm. in

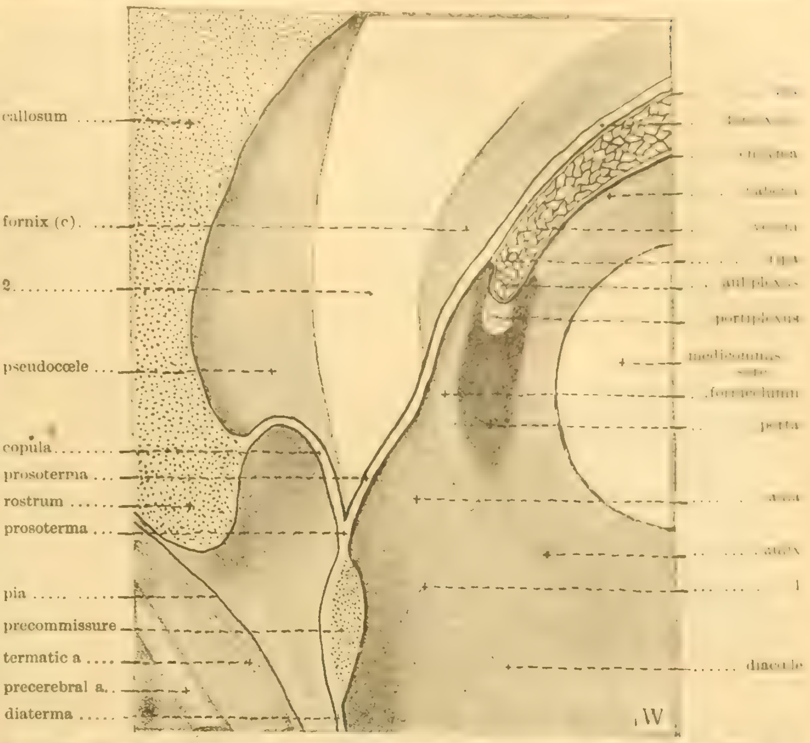

FIG. 4833.—The Right Porta and Adjacent Parts, seen obliquely from the Caudal Side. 385; [illegible] 1. Drawn by Mrs. Wilder. The lateral aspect of the left porta of the same brain is shown in Fig. 4742, under which the mode of preparation is described. 1, Dotted line from the ventral end of the porta to the ventral margin of the precommissure, and assumed to demarcate the diacœle from the aula. 2, part of the mesal surface of the hemiseptum, unusual and not fully understood. See § 6.

Defects. The area marked 2 is not a cut surface, as its plainness would indicate; it was shaded lightly in the drawing, but became blank in the engraving. The extent of the pseudocœle and the length of the copula are so unusual as to be anomalous; these peculiarities, however, do not materially affect the porta, which is the important feature of the figure. The dots indicating the fibrous constitution of the callosam and precommissure are too heavy and too closely placed.

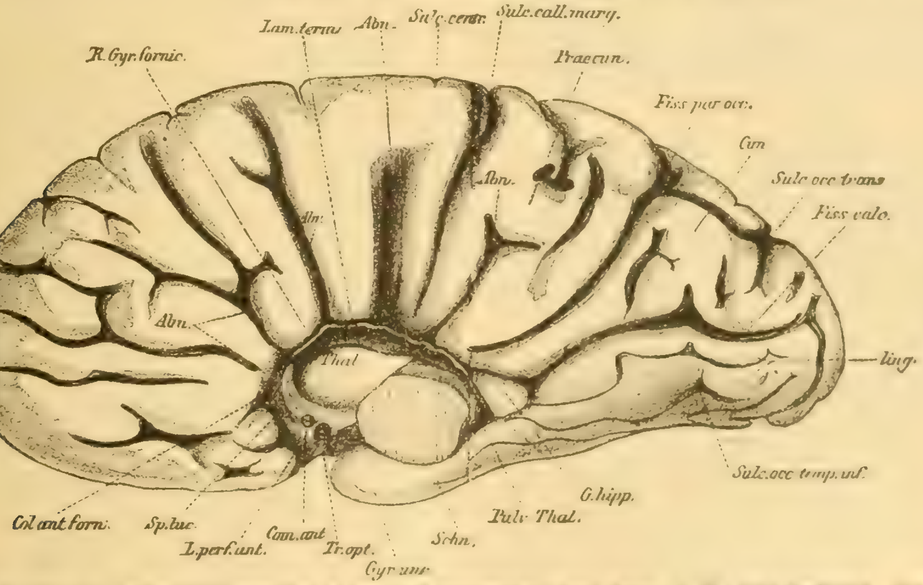

FIG. 4834.—Mesal Aspect of the Right Hemicerebrum of an Incallosal, Microcephalic, Adult Brain. × .93. From Onufrowicz. *Abn.*, abnormal radiating fissures; *Col. ant. forn.*, fornicolumn; *Com. ant.*, precommissure; *Cun.*, cuneus; *Fiss. calc.*, calcarine fissure; [illegible] fissure; *G. hipp.*, hippocampal gyre; *G. unc.*, uncus; *L. perf. ant.*, precribrum; *Lam. term.*, terma [illegible] gyre; *praecun.*, precuneus; *Pulv. Thal.*, pulvinar (of the thalamus); *R. gyr. fornic.*, margin of the callosal [illegible] surface between the diencephal (thalami, etc.) and mesencephal (gemina); *Sp. luc.*, hemiseptum [illegible]; *Sulc. centr.*, central fissure; *Sulc. occ. temp. inf.*, collateral fissure; *Sulc. occ. tr.*, "transverse occipital fissure" [illegible]

Preparation.—This was the brain of a male idiot, thirty-seven years of age, who had never [illegible] obtained fresh early and well preserved; the paper ("Das balkenlose Mikrocephalengehirn Hofmann," *Arch. f. Psychiatrie*, [illegible], pp. 1-24), from which the figure is taken, is by Onufrowicz, but this and most of the other figures are by Forel. [illegible] of distinct indication of endymal continuity renders them less instructive than they might have been. [illegible]

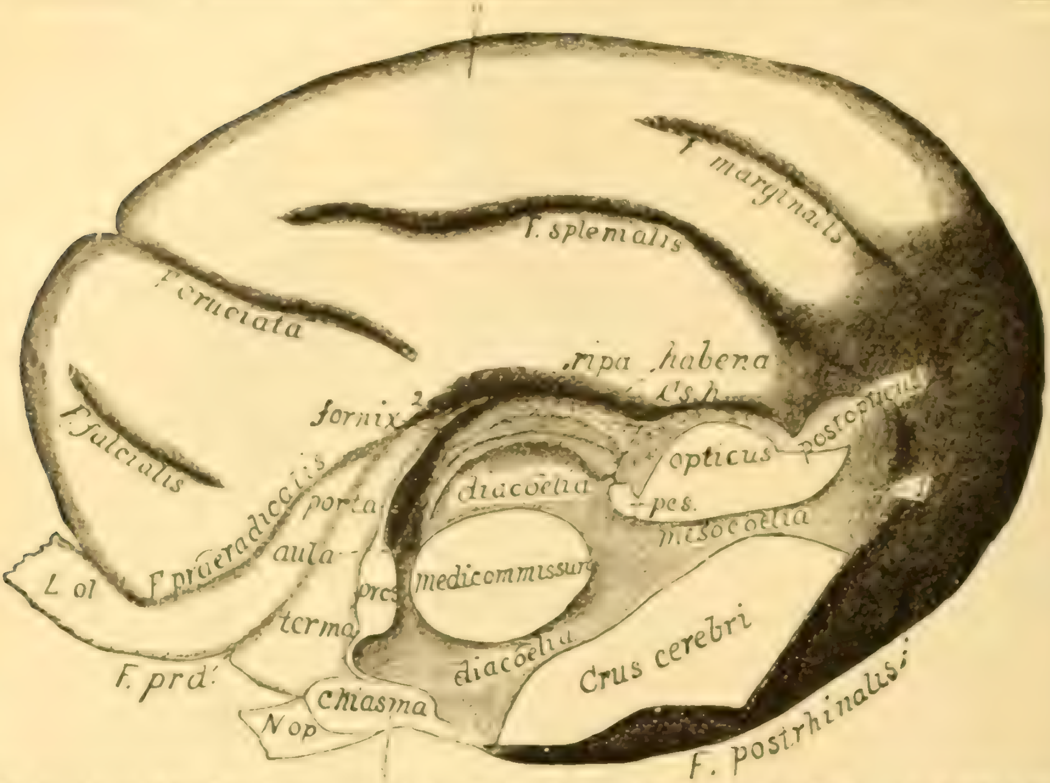

Fig. 4885.—Mesal Aspect of the Right Hemicerebrum of an [illegible] Cat's Brain. 381 × 4. From the writer's paper in American Journal of Neurology and Psychiatry, August, 188[illegible]. [illegible]

[illegible]

dorso-ventral diameter, and the medicommissure 3.8 × 4.2. In this [illegible] brain the length of the hemicerebrum is 33 mm., 2 mm. less than the other, yet the commissural dimensions are all greater, viz., 2.2, 4.2, and 5.2.

§ 11. Prop. V. The cerebrum is sometimes represented by a mass exhibiting only a partial division into a mesal and two lateral portions. This is the case with the not very rare cyclopian monsters, and with the brain described by Turner (Fig. 4887). Such brains are comparable with the earliest condition of the mammalian prosencephal and with the corresponding region in fishes.

§ 12. Points illustrated upon Fig. 4886.—A. The increase of the first (prosencephalic) vesicle in size and in the thickness of its parietes. As shown in Fig. 2 of the original paper, the floor and cephalic wall of the mesal region are seven to eleven millimetres thick, supposing the parts to be of natural size.

B. The subordination of the lateral extensions to the mesal portion of the prosencephal; they do not, as in the normal brain, extend cephalad of the mesal boundary, but merely laterad, caudad, and to a certain extent ventrad, so as to partly overlap the mesal portion.

C. The partial formation of fissures, one of which may represent the Sylvian.

D. As stated in the text, the prosencephalic cavity is single, i.e., not divided by constricted orifices (portas or "foramina of Monro") into a mesal aula and lateral paracoeles. In this respect, the cyclopean brain may be compared to the normal brain of fishes (Ganoids and Teleosts).

E. As also stated and shown in the paper, but not upon this figure, what the author regards as the [illegible] forms a very large and thin-walled vesicle on the dorsal aspect.

§ 13. Points illustrated upon Fig. 4887.—A. The possibility that an individual should reach maturity with a cerebrum so nearly undivided. Substantially, the presen-

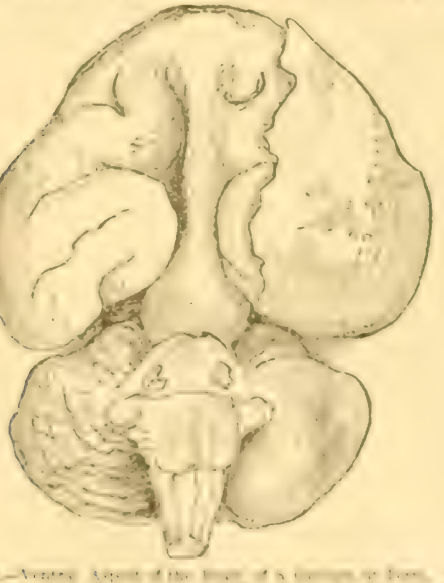

Fig. 4886.—Ventral Aspect of the Brain of a [illegible]

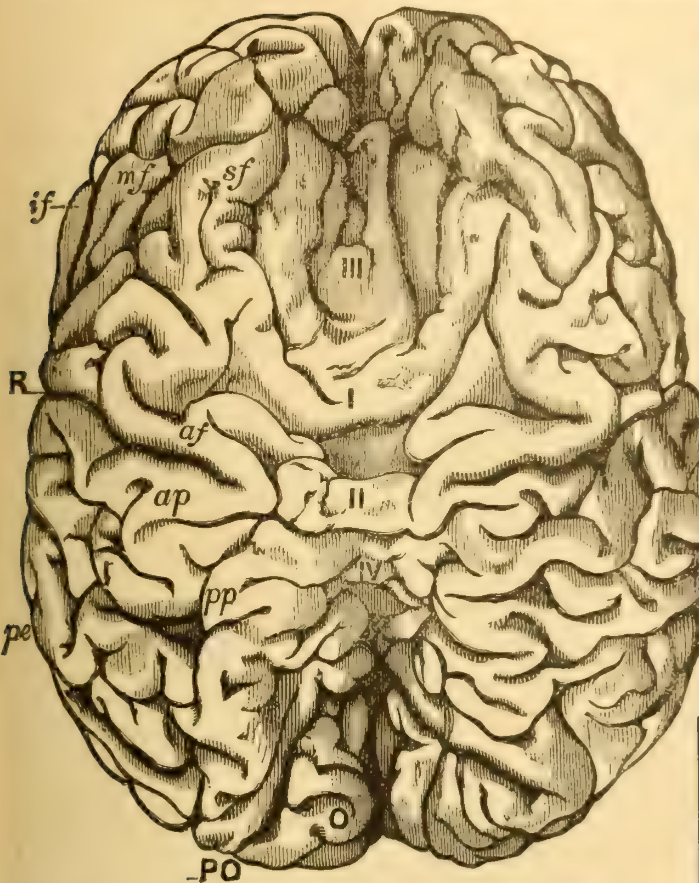

FIG. 4837.—Dorsal Aspect of an Imperfectly Divided Cerebrum; × .7. (From Turner, *Journal of Anatomy and Physiology*, xii., January, 1878, pp. 241 253.) *af*, Precentral gyre; *ap*, postcentral gyre; *if*, subfrontal g.; *mf*, medifrontal g.; O, occipital lobe; *pe*, "convolution of parietal eminence"; PO, occipital fissure; *pp*, "postero-parietal convolution"; R, central fissure; *sf*, superfrontal gyre; I, II, mesal transverse gyres, nearly at the level of the adjoining hemicerebrum; III, sloping cortical surface; IV, mesal gyres at a lower level than I and II.

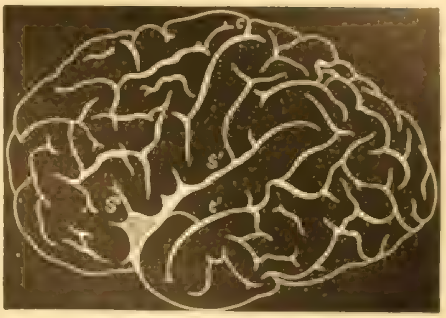
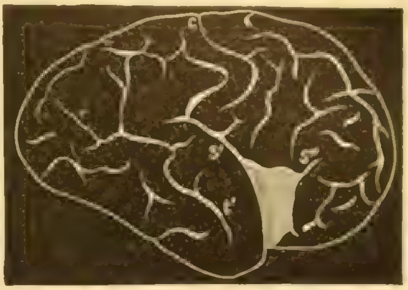
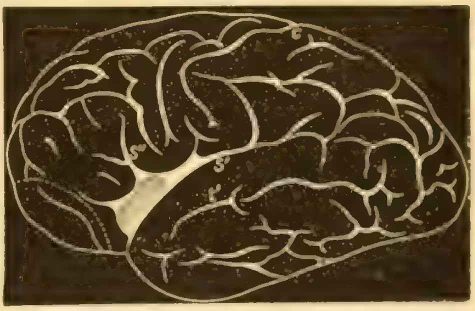
Preparation.—The brain was taken from an epileptic imbecile, male, forty-eight years of age, 146.7 centimetres (four feet ten inches) high, and weighing 55.7 kilograms (123 lbs.). The entire brain weighed 1,111.7 grams (39¼ oz.), of which the cerebrum constituted 978 grams (34.5 oz.). Most unfortunately this rare, if not actually unique, specimen was simply placed in alcohol, which was not changed; hence the base was ill-preserved and the ental features, although described in some detail by Turner, cannot be fully understood. A transection disclosed a single, mesal, cerebral cavity, about five centimetres wide, the floor of which is said to have been "formed of the upper surfaces of the corpora striata and optic thalami, which bodies were related to each other and to the *tænia semicircularis*, as in a normal brain;" yet "the third ventricle opened freely into the cerebral cavity along the middle of the floor." It is to be hoped that figures and more detailed descriptions may be published respecting the structure of this remarkable brain. A good abstract of the original paper is given in *Brain*, I., 133-134, April, 1878.



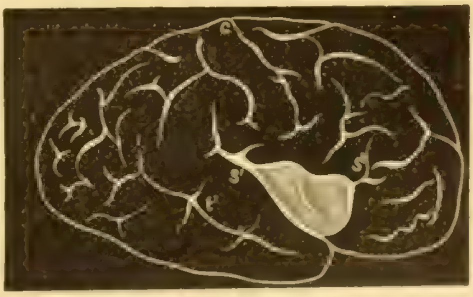
A. Left head, left hemicerebrum.



B. Left head, right hemicerebrum.



C. Right head, left hemicerebrum.



D. Right head, right hemicerebrum.

FIG. 4838.—Lateral Aspects of the Four Hemicerebrums of a Male Human Dicephalous Born at Term. (From the writer's paper in *American Assoc. Science Proceedings*, [illegible].) C, Central fissure; S', Sylvian fissure; S'', presylvian fissure; t', supertemporal fissure; the shaded area represents the insula. The dotted line on C indicates a part [illegible] in the removal.

Preparation and Defects.—The hemicerebrums were placed separately in alcohol, resting upon [illegible]; hence they flattened somewhat [illegible] the two right hemicerebrums were [illegible] the insulas are too much exposed. The [illegible] permit the representation of [illegible].

cephalic vesicle has not only increased in size and in parietal thickness, with but slight differentiation into a mesal and lateral masses, but the entire mass has developed fissures and gyres after the usual pattern, in general, excepting that certain gyres cross the meson; *a priori*, indeed, it is not clear why such a brain should not be efficient for mental as well as bodily manifestations.

§ 14. Prop. VI. It is well known that in no two individuals are the fissures and gyres exactly alike in all respects; also that the two halves of the same brain always present differences more or less decided, although they are seldom described or figured in detail as was done by Mills for several peculiar brains (*Journal of Nervous and Mental Disease*, XIII., September and October, 1886). Between individual variation and lateral variation within the same brain, come a group of variations which are seldom noted, viz., those that distinguish the two sides of the two brains of a monster with two heads (Fig. 4839).

§ 15. Points illustrated upon Fig. 4838.—A. The usual lack of fissural and gyral symmetry between the two sides of the same cerebrum.

B. The readily recognized distinctions between the two cerebrums of these closely associated individuals.

C. The superior fissural complexity of the two left hemicerebrums.

D. The resemblance of the right hemicerebrum of the left head to the left hemicerebrum of the right head, in the parieto-occipital concavity of the central fissure.

E. The right hemicerebrums were really the larger, but are shown smaller because they dried and shrank somewhat while drawing. The weights are as follows:

Left head	Left hemicerebrum,	182	372	768
	Right "	190		
Right head	Left "	196	396	
	Right "	200		
Two right hemicerebrums		390		
Two left "		378		

The entire body weighed 5,000 grams, the ratio being about as 1 to 6.5. The greater size of the right brain may be associated with the greater size of the entire right body, and with the fact that the intermediate leg, although approximately symmetrical and belonging, of course, to both sides, is projected toward the left of the single body, and is therefore more decidedly a left leg of the right child, than a right leg of the left child.

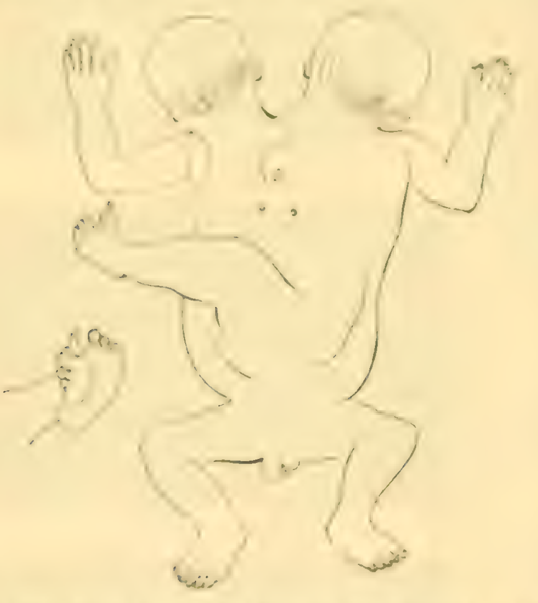


FIG. [illegible].—Dorsal Aspect of the Dicephalus, the [illegible] [illegible]

§ 16. Points illustrated upon Fig. 1839.—A. The greater size of the right head and body, and the sinistral projection of the third, common, leg.

B. The presence of two nipples on the dorsal aspect, caudal of the arm pits.

C. The partial duplicity of the right pelvis.

Burt G. Wilder.

BRAIN: PACCHIONIAN BODIES. These granulations, also falsely called glands, were perhaps first mentioned by Willis (1676), then by Meyer (1701), and almost simultaneously described by A. Pacchioni. They start as minute spheroidal, partially vesicular outgrowths (villi of Luschka) from the arachnoidal layer of the pia—where it bridges fissures as well as where it rests on the gyres—retaining its epithelial covering. They must not be confounded with granulations of the choroid or ependyma, with vegetations notably in the cavernous sinus (Hyrtl, 1862), nor with granular cauliform excrescences of the meninges seen in inflammations. They are often clustered, become pedunculated, penetrate the opposed dura, and finally project into the overlying venous channels, and even excavate (in part repel) the bone. They are usually most abundant opposite the middle of the falcial sinus—more correctly opposite the largest parasinual spaces—but may occur on both sides, along nearly the whole length of this sinus, beside the transverse and tentorial sinuses, and even beneath the latter, also in the temporal fossa opposite the trunks of the meningeal vessels and the frequently present temporal sinus. They occur not rarely (Luschka) and even further from the sinus along the line of large [illegible] veins after the latter have left the pia, and also at one point near the frontal border of the parietal bone, probably where a meningeal artery bends to connect through the skull with temporal vessels. Hence, in general, they occur opposite intradural blood-channels of some size, and especially those subject to continual variations in calibre (pulsation, ebb and flow). Their prevalent growth toward and into venous spaces has led to the assumption that the granulations themselves were venous structures or opened into such (Key and Retzius, Krahmer, and others). It is not true that Trolard claimed this. But it is now generally recognized that the injection of the spaces through the granulations must have been effected by the rupture of granulation vesicles.* From the intimate connection of the older granulations with the spaces they become darker colored, or, on tearing the two structures apart, flecked with blood. But the younger free corpuscles are pale, whitish.

The parasinual spaces are said rather to diminish with age, while the granulations certainly increase. Up to the twentieth year they are rarely developed to any extent. In congenital defect of the heart, they appear early and excessive (case of Luschka, 1860, one of the writer). However, at all ages continuous or intermittent compression of the brain space, of whatever origin, is the most frequent cause of their over-development. Under this head fall intra-cranial tumors of any kind or seat. Repeated congestion, as in chronic alcoholism, is also an accepted factor, doubtless acting mechanically. Various systemic troubles, as nephritis and diabetes, favor the enlargement of these bodies, possibly by unusual variations in the encranial pressure.

In view of all the facts—viz., that while these corpuscles regularly occur opposite intradural (extra-arachnoidal) blood-channels (not necessarily venous), their growth is especially favored on the one hand by venous stasis, on the other by pressure from the side of the cranial space—it is evident that they result from the oft-repeated local oscillation of the arachnoid. As the cerebrospinal fluid is subarachnoidal, it, especially when under pressure, forces that membrane at its weakest points into any depression, as that beside a dilated vessel; *the granulations always grow away from the cranial cavity, never toward it.* When, then, the favoring condition—be that even negative instead of positive—relaxes, the granulations to the extent that they have formed press against and penetrate superimposed structures, the continuous alternation of the conditions as continually favoring the process. This, as we believe, clear and simple explanation suffices for all the main features of these little growths.

PATHOLOGY, CLINICAL HISTORY, ETC.—(a) Like the wrinkling of the skin, the turning gray and falling out of the hair, and many other processes, the granulations themselves should only be considered pathological when they become excessive or develop prematurely. (b) Calcification or ossification of these bodies is not unusual. They may contain deposits of so-called brain-sand and even fat-globules. (c) When they penetrate into blood-spaces and even a sinus, they so far interfere with the return current, and also favor thrombosis (only one case of the latter, Förster's, has been attributed to this cause). (d) Foveæ glandulares, sharp depressions or excavations in the inside of the skull (preceding e and f), quite analogous to that seen in aneurism of a dural artery, are sometimes found. From their more or less intimate relations with the sinus-walls, Allen advises avoidance of the middle line in all operations upon the skull-cap. However, the diploë itself is never opened by these growths, as a new layer of bone always forms around the foveæ. (e) Small flat elevations of the external plate of the skull, opposite the foveæ, and hence near the superior median line, are mentioned by many. (f) Very rarely complete perforation of the cranium occurs.

---

* This is a matter of interest in connection with the theory of [illegible] [illegible] [illegible] through the granulations [illegible] ignores or argues against the existence of such discharge.

1. Case of Weber-Ribes (1819; v. Pozzi); hole small, and covered by ligamentous membrane. 2. Luschka (p. 116); perforation of squamous portion of temporal bone. 3. Lecat (v. Heineke in Pitha-Billroth); pneumatocele capitis; skull at some points perforated by granulations of the dura. 4. Demme (1862; v. Mastin, "Venous Blood-tumors of the Cranium." Reprint, 1886). "On the left of the sagittal suture (posteriorly) was a sharp-edged opening the size of a cherry-stone, through which protruded a Pacchionian granulation." 5. The writer's observation. Man of forty; had suffered over three years from a tumor of the brain; autopsy, August, 1887. At the favorite spot near the frontal border of the parietal, somewhat removed from the sagittal suture, there was a clean-cut, complete perforation of the skull by Pacchionian granulations. This was circular, fully ½ ctm. across, surrounded even in the diploic portion by smooth continuous bone, and covered by periosteal membrane. At the border there was a very trifling over-projection of the outer bone-plate.

It is recognized that such perforations—even when incomplete—may, from local injury, lead to the formation of epicranial blood-cysts, inasmuch as the causative granulations usually traverse some blood-channel.

(g) In a few cases growths of this class have pressed on passing nerves, causing local neuralgic or paretic symptoms. Though it has been claimed that at times these growths induce headache, it is probable that they are then but co-effects of some other cause. (h) In animals generally these corpuscles are not present (brains of sheep, calf, rabbit, dog, and cat examined). Luschka found them only in the horse.

William Browning.

BRAIN, REMOVAL, PRESERVATION, AND DISSECTION OF. § 1. This article has no direct reference to microscopical or pathological requirements;* nor is it designed for neurological specialists, or for those who may have the benefit of their counsel or access to large libraries; but physicians and students at a distance from medical centres, who desire to attain a real and personal acquaintance with the gross anatomy of the human brain as an aid to the comprehension of its minute structure, its functions, diseases, and mental relations, may profit from an account of the methods found useful in a laboratory where most of the students are preparing for a medical course.† That the procedures in vogue six years ago were not altogether satisfactory is evident from the vigorous animadversions in *The American Journal of the Medical Sciences* for January, 1883, pp. 228 and 229, by Professors Harrison Allen and Charles K. Mills. Notwithstanding evidences of progress in certain metropolitan schools the writer apprehends that his "pen-picture" of five years ago (*New York Medical Journal* and *Medical Record*, February 23, 1884) may not be altogether without warrant at the present time.

§ 2. The more important of the macroscopical methods of studying the brain, pursued in the Anatomical Laboratory of Cornell University, are summarized in the following paragraphs; from the nature of the case a strictly logical sequence is impracticable; certain of them are subsequently described in detail.*

§ 3. Before dealing with the human brain the various processes of removal, preservation, and dissection are practised upon the much more accessible brain of the domestic cat (Figs. 4698, 4710, and 4729): "*Fiat experimentum in corpore vili.*"†

§ 4. Fœtal and infant brains are utilized not only for what is learned from them as such (Figs. 4697 and 4715), but also as preliminary to dealing with the less readily procured and removed adult organ.

§ 5. Skulls—which may be purchased or easily prepared under nearly all circumstances—are less esteemed than brains; the "kernel" is more highly valued than the "shell."

§ 6. The infant cranium is divided with scissors and nippers (Fig. 4881), or softened by ten per cent. nitric acid‡ so as to be cut with the knife; Fig. 4748.

§ 7. The common method of dislodging the calva (calvaria or skull-cap), after the circular cut with the saw, by "inserting a strong hook and giving a quick jerk," is held to be artistically brutal and anatomically futile; a second, sagittal, section is made, and the calva removed in two pieces; § 66.

§ 8. Excepting for special reasons the dura is retained until the calva is removed and, if possible, is extracted with the brain; Fig. 4711. With care and anatomical knowledge the dura may commonly be retained excepting over a limited central area of the base of the brain.

§ 9. The fresh brain is removed over brine (saturated and filtered), supported in it during the operation, and kept in it until its final disposition is made.

§ 10. A fresh brain in the dura is lifted by the latter and supported in liquid by attaching cords to the dural edges, the other ends of the cords being carried over the rim of the pail or other vessel and wound about hooks, or otherwise attached.

§ 11. A fresh brain deprived of its dura, if it is to be either studied from any aspect or injected into the arteries or the cavities, is supported and steadied in a pail of brine by passing under it a towel or broad strip of cloth, the ends of which are secured to the pail by hooks.

---

* See the articles Histological Technique (Vol. III.), Post-mortem Examinations (Vol. V.), and Histology of the Brain, this volume; also the volume by Bevan Lewis (1882), and papers by F. H. Dercum (1886), C. K. Mills (Med. and Surgical Reporter, February 3, 1883), and Spitzka (Jour. Nerv. and Mental Disease, July, 1883, p. 84).

† That these methods are fairly successful may be concluded from the facility with which these students receive the more advanced or specialized instruction imparted at the great medical schools, and from the nature of the preparations (more than 300 in number from the human brain and about 700 from animal brains) in the museum of Cornell University, some of which are represented in the article Gross Anatomy, pp. 107–164 of the present volume. Yet there is hardly one of these methods that is not susceptible of change for the better. Indeed, the constant effort to improve them has been a serious, and well nigh absolute, hindrance to the completion of this article.

* For fuller accounts of others, see the New York Medical Journal for February 23, March 1, and June 14, 1884, and (somewhat less complete) the New York Medical Record for the same dates; also the second edition of "Anatomical Technology."

Did space permit, the writer would gladly specify the sources of such of these methods as are not original, and the points in which efficient aid has been rendered by his students, past and present, in either carrying out his own ideas or in improving upon them; the following deserve particular mention: Professors S. H. Gage, B.S., M. J. Roberts, M.D., Theobald Smith, M.D., and H. F. Summers, B.S., Dr. W. C. Krauss, and Messrs. F. L. Kilborne, B.V.S.; B. L. [illegible], B.S., and [illegible].

† The dog's brain is recommended by Howell and by Foster and Langley, and that of the sheep by Morrell. The gross anatomy of the cat's brain and the modes of examining it are described in "Anatomical Technology," pp. 400–503; the extent to which the [illegible] material is utilized in imparting the elements of [illegible] may be seen from the fact that, in addition to the [illegible] supplied for examination to the laboratory [illegible] university, the general class in physiology [illegible] prepared cat's brain for every two members.

‡ Ordinary commercial acid is about 70 per cent.; the desired reduction is accomplished by adding five parts of water to one of the acid (by weight), or seven of water by volume. The specific gravity of the mixture is about 1.057. In any case the percentage of acid may be determined by the method recommended by Fresenius, second American edition, p. 688.

sacks, or otherwise, the brain may then be kept at any height in the brine, and rotated without removing it.

§ 12. The fresh brain is never allowed to bear its own weight or to rest upon a flat surface, but is supported in the calva[*] or in a bowl of appropriate shape, or in a liquid of equal or greater specific gravity.

§ 13. The use to be made of a brain is, if possible, determined upon in advance. If only part is to be employed for a specific purpose, the rest is cut away and preservative effort concentrated thereon.

§ 14. If the capillary and pial attachments are to be investigated, the arteries are injected and the parietes hardened by injection of strong alcohol into the [illegible] (§ 30 and Fig. 4686).

§ 15. If certain portions of the cavities are in question, free access of alcohol is gained by widely opening some other region, as, e.g., by cutting off a frontal, temporal, or occipital lobe.

§ 16. Unless there are special reasons to the contrary, brains are transected in the narrow region of the mesencephal (crura or optic lobes); the cerebral and cerebellar portions are then removed separately with greater ease and less risk of laceration. Each of these regions is medisected, if desired, more accurately than the entire brain can be, whether before or after hardening, and the two divisions of either half are subsequently apposed for study, or even attached for exhibition.

§ 17. When the mesencephalic region itself is to be preserved intact, by lifting the occipital lobes a little more the transection is made through the diencephal (thalami).

§ 18. For the study of fissures and gyres, the cerebrum (with the thalami) is commonly medisected (§ 19), and each half hardened by placing it on its mesal surface in a dish of forty-eight per cent alcohol (§ 64) in a cool place; a thin layer of cotton covers the bottom. After two days the specimen is turned upon its convexity, and cotton built up about it so as to obviate sagging and flattening so far as possible (Fig. 4778). The strength of the alcohol is increased by about five per cent at intervals of two days until it is ninety-five per cent.

§ 19. The fresh cerebrum is medisected as follows: A bed of cotton is made in a pail or dish of brine, and the cerebrum placed upon it, about one-third above the surface. With the fingers and scalpel-handle the arachnoid, which connects the opposed hemicerebral surfaces just dorsad of the falx (Figs. 4684, 4711, and 4750), is torn, and a layer of cotton introduced to keep the fissure slightly open down to the callosum. The cerebrum is then turned so that the chiasma (Fig. 4689) is uppermost; this, being broad, is first divided with a very sharp large scalpel; then the terma, fornicommissure, callosum, etc., by successive sweeps.

§ 20. When a separated head is obtained the brain is usually hardened in place by the continuous injection of alcohol (§ 68); it shrinks somewhat, but retains its natural proportions. Such a head, medisected with a sharp saw, is instructive in many respects (Fig. 2684). Sometimes sections are made in other directions or the calva removed as with the fresh brain (§ 60).

§ 21. For macroscopic purposes freezing is avoided, as tending to leave the mass friable.

§ 22. When the brain is to be hardened by immersion in alcohol without injection, as low a temperature as is attainable, above freezing, is maintained; see § 18.

§ 23. Alcohol is commonly employed as the initial preservative, excepting when it is necessary to differentiate the two kinds of nervous tissue.

§ 24. When the brain is to be preserved entire, alcohol (or other preservative liquid) is injected into the arteries by continuous pressure, and thus carried directly to the tissues (§§ 69 and 70).

§ 25. The surface of a fresh brain is never exposed to strong alcohol without a previous wetting with salt solution or water.

§ 26. The alcohol in which brains are stored is maintained at not less than eighty-two per cent, upon the alcoometer scale of Tralles (§ 64). Weaker alcohol is employed for the immersion of fresh brains, for soaking out the dark coloring matter from brains that have been hardened in Müller's or Erlicki's liquids, or for the preservation of other specimens requiring a less strength.

§ 27. When it is desirable to retain approximately the form of a brain that has been already deprived of its dura, it is hardened in some heavy liquid, e.g., Müller's or Erlicki's liquid (Vol. III., p. 663), or a saturated solution of zinc chloride ("Anat. Technology," p. 445).[*]

§ 28. Hydrocephalic brains, and those of fetuses between the second and seventh month, are alcoholized in place from the aorta or other artery, and also have the more or less abundant endolymph replaced by strong alcohol. This direct, encephalic alcoholization is done as soon as possible after the arterial has begun; it is most conveniently accomplished by making a slit at the margin of the prefontanelle large enough to permit the introduction of a cannula and the escape of liquid at its side. The injection need not be continuous, and, of course, should not be under pressure, but may be repeated at intervals of an hour or two.

§ 29. When a hydrocephalic or fetal brain is wanted for a special object involving the integrity of the entire cerebrum, or the complete distention of the metaporencephalic cavities, then the undesired region is cut away, the desired region left in the cranium, and the alcohol injected through the aqueduct, continuously, in order to make up for the non-injection of the arteries.

§ 30. Removed embryo and hydrocephalous brains are relieved from pressure during hardening by inflating the cavities (Fig. 4850). The buoyancy of even an adult normal brain is sometimes increased by injecting air into the arteries through a bulb-syringe.

§ 31. When it is desirable to differentiate the two kinds of nervous tissue, the brains are immersed in, or injected with, Müller's liquid or Erlicki's liquid, or a solution of bichromate of ammonium (Vol. III., p. 663) or a fine gelatine or glue mass (§ 32, note).

§ 32. When the larger vessels are to be studied Gage's modification of Pansch's starch mixture is employed ("Anatomical Technology," 2d ed., p. 140); if the ultimate vascular supply is in question, a fine gelatine mass is used.[†]

§ 33. When practicable the pia(arachnoid) is removed as soon as it loosens from the surface, which is commonly within two days after immersion; but this is not essential, for it may be removed at any subsequent period with merely somewhat more care against breaking or wounding the hardened brain.

§ 34. Alcoholic brains are examined before fresh ones.

§ 35. The encephalic cavities are explored and their connections and circumscription determined before the details of the parietes are considered.

§ 36. The size and form of the cavities are maintained and the preservation of their immediate parietes is assured by injecting alcohol into them (Fig. 4740).

§ 37. The forms of cavities are ascertained by making solid casts (Fig. 4741).

---

[*] For the [illegible] of a [illegible], see § 62.

[*] By Giacomini and others a zinc chloride solution has been employed [illegible] preservation of the brain. [illegible] (Vol. [illegible], 541, 542).

[†] [illegible]

§ 38. Before attempting to comprehend large sections, involving perhaps several parts but distantly related excepting by topographical contiguity (Fig. 4751), the beginner makes dissections for the exposure of parts in their structural continuity; Figs. 4694, 4698, and 4711.

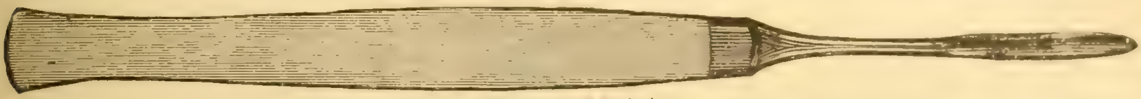
§ 39. Delicacy of manipulation is cultivated and a prompt check put to all forms of anatomical Philistinism, whether in word or deed; the student is urged to practise self-control, to restrain what Hyrtl calls the "*furor secandi*," and never touch his specimen except for a good and sufficient reason. From the ecclesiastical standpoint, perhaps, the "laying on of hands" cannot be overdone, but in practical anatomy its excess is likely to prove the reverse of a blessing. These cautions are called for in respect to the dissection of muscles, etc., to which the examination of the brain is as watchmaking to the wielding of hammer and tongs.

§ 40. In brain dissection, as in surgery, the knife is made the last resort; blunt points and blow-pipes are employed as long as possible. When cutting is to be done the aphorism of Dr. Holmes is recalled: "Let the eye go before the hand, and the mind before the eye."

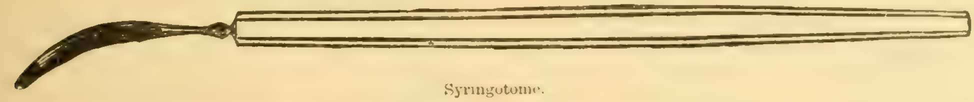
§ 41. Specimens that might be injured by falling upon a hard surface from the height of even a decimetre (four inches) are held during examination over a pad of cotton or a dish of alcohol, and carried from room to room in a vessel and not in the hand.

§ 42. Embryos and delicate brain preparations are dissected under alcohol, and sometimes pinned to a piece of cork loaded with sheet-lead; see Fig. 4748. Preparations including the medicommissure (Fig. 4727) are supported upon cork while making and for exhibition.

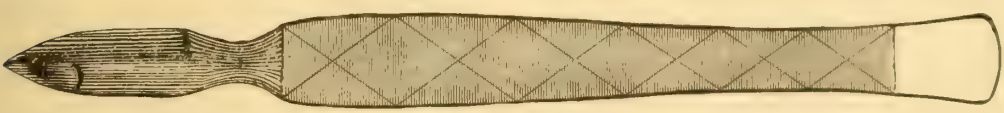
§ 43. To facilitate discrimination of natural from artificial surfaces, especially upon permanent preparations,



Blunt-pointed Scalpel.

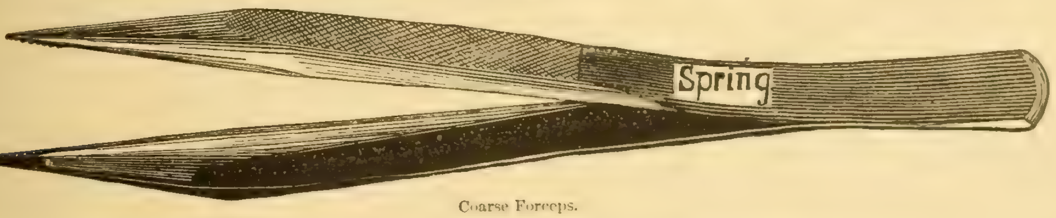


Syringotome.

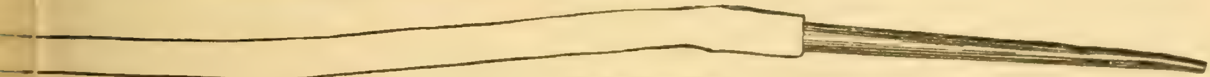


Arthrotome.

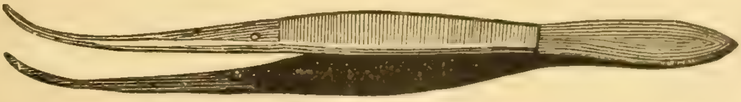
Tracer



Coarse Forceps.



Flexible Blow-pipe.



Fine Curved Forceps.

FIG. 4880.—Some of the Instruments Useful in the Removal or Dissection of the Brain. All of actual size. (From "Anatomical Technology.") The two upper are eye-knives; the syringotome is commonly called *canaliculus knife*; it is of great use for exploring orifices, the portæ ("Foramen of Monro") and the metapore ("Foramen of Magendie"), and for dealing with membranes and plexuses where a point or a prominent edge might do injury; it has been the writer's favorite instrument since 1866. The tracer may be employed sometimes in place of the [illegible] syringotome, but its chief use is in isolating nerves and vessels by tearing the connective tissue. Most forceps are too stiff and soon tire the hand or hinder delicacy of manipulation; the coarse "Coxeter" forceps represented have the blades excavated so as to be lighter than usual. The flexible blow-pipe is most readily made by attaching to a piece of rubber tubing, thirty to forty centimetres long, the smaller half of the metal blow-pipe commonly sold with dissecting instruments. The length of the tube enables the object inflated to be held at a convenient distance from the eye; since inflation is temporary injection, the advantages of witnessing the effects are obvious. A larger volume of air may be obtained by using the larger half of the metal pipe, and glass cannulas of any size may be employed. The arthrotome has the handle continuous with the blade, and the edge of the blade is rounded, excepting near the tip; it is practically a cartilage knife.

Besides the instruments shown in Figs. 4880 to 4882, the following, more familiar, are indispensable. Scalpels of three sizes, large for [illegible] medium for ordinary dissection; small ("Charrière") for finer dissection. Scissors, curved flatwise, three sizes. A hand lens, [illegible] or "linen-tester." A bone-chisel, or ordinary chisel of moderate width, or even a screw-driver sharpened slightly. A [illegible] bulb. Absorbent cotton; if common cotton is used it must be first thoroughly wet in alcohol or water. Caoutchouc rubber tubing [illegible] or T-tubes for branching of injection tubes may be had of dealers; the smaller end of a straight [illegible] methods of making and securing cannulas, and of making injections, are described in Vol. III., p. 684, and detailed in [illegible] pp. 137–148. Cheap and efficient pinch-cocks may be had in the form of the wooden, spring clothes-pin, which [illegible] wire cranes or used independently upon the tubes. As a guide in all operations involving the location of the [illegible] the cranium, figures are much less serviceable than either of the following: an entire brain hardened in the [illegible] *papier maché* model; a plaster model; a plaster cast of the cranial cavity. Excellent plaster casts of the cranial cavity [illegible] human races as well as of many other mammals, may be had at the Natural History Establishment of Professor H. A. Ward at Rochester, N. Y.

incisions always follow straight lines and meet at angles rather than join by curves; see Figs. 4880 and 4882.

§ 44. So far as possible, incisions of the brain are made in liquid or while the scalpel is irrigated: with hardened brains alcohol is used; with fresh a salt solution.

§ 45. Specimens which have become dry and distorted are immersed for a day in weak spirit (twenty-two per cent.), and then replaced in the strong alcohol.

§ 46. When part of a thin brain preparation (e.g., a hydrocephalous cerebrum like that shown in Fig. 4880) has dried, it is restored by placing on the spot a bit of absorbent cotton wet in water.

§ 47. To remove a delicate specimen from a vial, the vial is immersed in a dish of alcohol and the specimen floated out; to replace it, if the alcohol is clear, the vial is immersed and the specimen floated in; if turbid, the specimen may be transferred upon a bit of paper, a watch-glass, spoon, or upon card between the points of the fine curved forceps (Fig. 4880).

§ 48. Friable specimens are infiltrated with paraffine: see the paper by W. C. Krauss (*Buffalo Medical and Surgical Journal*, November, 1888) and publications therein referred to.*

§ 49. Defibrillation—the tearing of brain substance in the direction of the least resistance, so as to make "cleavage preparations"—is not regarded as affording conclusive evidence of fiber arrangement; but it is practised in illustration of facts determined by more exact methods, microscopical, pathological, and experimental.

§ 50. **The fresh brain is weighed as follows:** A vessel partly full of water, salt solution, or brine is balanced upon the scales; the brain is lifted from the liquid in which it has been, in the hollowed hands; they and the brain are rinsed with water, and the brain is transferred to the vessel on the scales. If the dura remains the weighing cannot be accurate, even by deducting its weight when removed.

§ 51. An effort is made to determine the usual or average loss of weight in alcoholic hardening by weighing the brain when fresh and after thorough hardening; see this volume, p. 163, § 285, etc.

§ 52. **Fresh brains, especially if in the dura, are transported** long distances in cool weather in a small pail of supersaturated brine; in warm weather even, if the brain is well cooled in advance and the smaller pail set in a larger and surrounded with rather large pieces of ice, a day's journey may be accomplished safely. Such open packages should be plainly marked "Specimens of Natural History. This side up with care."

§ 53. Already hardened brains are transported either in a small pail of alcohol with cotton as a padding; or in a soldered box; or in a jar (the rubber of which must then be well covered with vaseline *to be afterward removed*); or simply wrapped in alcoholic cotton covered with paper and oiled silk or rubber sheeting, and packed in a box with soft material. Glass and metal packages are always boxed in wood.†

§ 54. **Embryonic fragments, and poorly preserved or** distorted specimens serve for preliminary dissections, so that the perfect material may be more completely utilized.

§ 55. **Every brain is numbered upon a list; and the** same number is affixed to it and to each part of it as soon as separated. **The numbers are written with India ink** upon bits of paper and attached by small (ribbon) pins.

§ 56. The list or catalogue gives the principal original data respecting the brain. Additional information, details of preparation, places of publication, points to be elucidated, etc., are recorded on slips the size of the U. S. postal card, filed in Manilla paper portfolios secured by an elastic band.‡

§ 57. Drawing the natural and dissected surfaces is insisted upon. These drawings should be, primarily at least, in outline only; shading, like charity, "covereth a multitude of sins."

§ 58. In beginning the study of a difficult region, the student is advised to determine at once some prominent feature as a landmark, as a "base," so to speak, of intellectual supplies, from which he may explore in any direction, and to which he may return when doubts arise.

§ 59. No observation involving either complex manipulation or novel results is published until it has been submitted to at least one other trained observer.

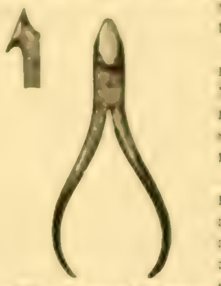


FIG. 4881.—Surgical [illegible] Bone Nippers. [illegible] tear the brain or its meninges.

§ 60. It is freely admitted that rarely, if ever, is all possible information gained from a specimen at one examination or by a single observer; hence specimens are preserved.*

§ 61. *Sawing.*—This (which might be called a macrotome) is a coverless box made of boards about 2.5 ctm. (1 inch) thick, and with the following inside dimensions: Length 30 ctm. (12 inches); height at middle, 25 ctm. (10 inches) sloping to 15 ctm. (6 inches) at the ends; width according to the length of the neck attached to the head, 25–40 ctm. All the parts must be accurately squared and put together with screws. The sides should go outside the bottom and ends and the bottom have a cleat at each end. Each side is to be divided at the middle of its length by a saw of the same thickness as that with **which the head is to be cut; the bottom** also is to be sawn to the depth of 1–2 mm. When finished the box should be thoroughly oiled inside and out with linseed or olive oil, to prevent warping when it is wet. For dividing the cranium any small saw will answer, but the edge should be rather wide so as to make a broad kerf. For medisection of the head, however, the saw should be very large, fine-toothed, narrow (*i.e.*, make a narrow kerf), have a removable back and be very sharp and free from rust.

§ 62. *Agate-ware Pans.*—The brain anatomist will find most convenient and in the end most economical one or two "nests" of iron pans "enamelled" so as not to rust, with plates of the same for covers. For the largest size (11 × 4) covers of glass or tin must be provided; these last will accommodate a half head.

§ 63. *Alcohol.*—Unless otherwise specified, the alcohol mentioned in this article is of the usual strength, ninety-five per cent. The admixture of alcohol with water in the following proportions gives various percentages: Alcohol 6, water 1 = 84 per cent.; 5 : 1 = 82; 4 : 1 = 78; 3 : 1 = 75; 2 : 1 = 67; 1.5 : 1 = 62; 1.25 : 1 = 60; 1.1 : 1 = 55; 1 : 1 = 48; 1 : 1.25 = 45; 1 : 1.5 = 42; 1 : 2 = 35; 1 : 3 = 30; 1 : 4 = 22; 1 : 5 = 18.4.

FIG. 4882.—Steel-bladed Spatula. × 0.5. (From catalogue of Whitall, Tatum & Co.) [illegible] when the calvaria is to be removed. § 66.

---

* [illegible]

† [illegible]

‡ [illegible]

* [illegible]

* [illegible]

§ 64. *Alcoömeter (Alcoholometer).*—This form of hydrometer, for determining the percentage of alcohol in a given liquid, should be marked with Tralles' scale. With the slender jar for containing the tested liquid, the cost is about $2.50, but its employment is to be recommended upon the ground of ultimate saving of alcohol.

§ 65. *Circular Division of the Cranium.*—Reflect the scalp as directed in Vol. V., p. 789, or remove it altogether. Tie a cord around the head just dorsad of the ears, the frontal portion passing about 15 mm. from the brows; mark this line with a pen, or cut the periosteum to the bone. If the fresh calva is to be secured in place after the extraction of the brain, leave the fibrous cephalic and caudal margins of the temporal muscles for the stitches to be taken in; otherwise these muscles may be removed entirely.

In sawing,* three points are to be observed: (1) The thicker frontal and occipital regions should be taken first; (2) at four places, preferably what might be called the four corners of the cranium, the bone is not to be divided completely until the calva has been sagitally divided (§ 66); (3) if the ectal features of the brain are to be preserved intact, a medisected cranium should be consulted in order to estimate the thickness at various points, and frequent trials should be made by pushing a point, like the probe end of the tracer, into the kerf at the middle of that part of the convexity; when it can be pushed through, the sawing should proceed with care in each direction.†

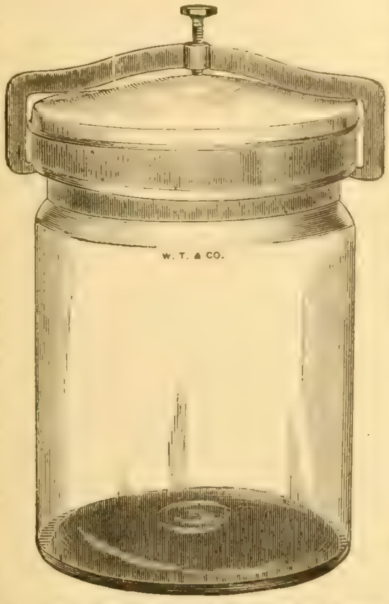

FIG. 4883.—Specimen Jar, with Glass Top, Rubber Ring, and Clamp. Made by Whitall, Tatum & Co., New York City. Fourteen sizes are made, ranging from 3 to 9 inches in diameter, and of various lengths. The size here shown is 6 × 8, and will receive a hemicerebrum or an entire half-brain; for undivided brains and for medisected heads the size 9 × 8 suffices. These two sizes cost, respectively, $10.00 and $18.00 per dozen. The prices given in the catalogue are subject to a discount of fifty per cent.

§ 66. *Sagittal Division of the Calva.*—After the circular kerf has been completed, but before the calva has been loosened by the chisel, carry a cord from the brows to the occiput, over the head, at about 13 mm. (half an inch) from the meson; along this line cut or mark the periosteum, and saw completely through the bone. Then, with taps of the hammer upon the chisel, sever the remaining attachments of the smaller part of the calva along the circular kerf. Sometimes that piece will come off readily; if not, introduce the spatula in the temporal region, where the bone is thin, keep its point pressed against the bone and so detach the piece; in some cases the spatula must be introduced at other points, always with the minimum amount of pressure upon the brain.

The mesal adhesions along the sinus are now directly accessible, and a sharp edge may be employed if necessary. The location of any other adhesions may commonly be inferred from what existed upon the first piece, and the operation is completed without difficulty.

If necessary, at once, or at any time, the two parts of the calva may be united by wires, or even cords, passed through holes at the middle and at each end; such holes may be made with a common awl of medium size, if a suitable drill is not at hand.

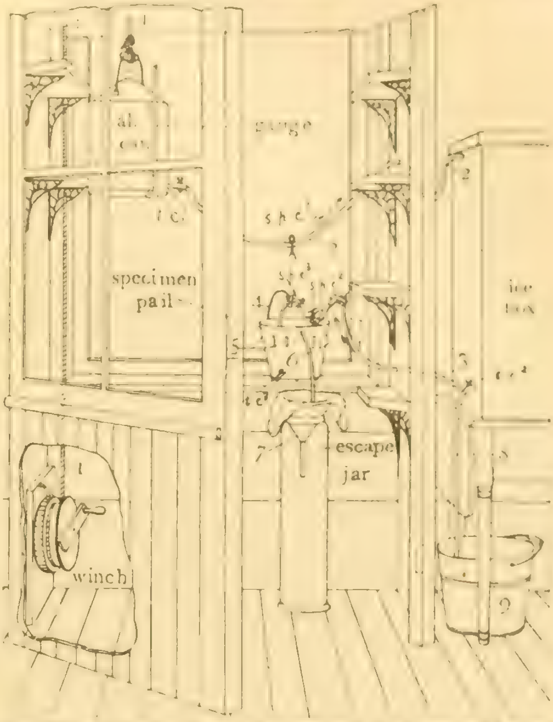

FIG. 4884.—Alinjection Closet and Apparatus in the Anatomical Laboratory of Cornell University; drawn from a photograph. 1, 1, 1, Successive parts of the cord supporting the alinjection can, passing up through a pulley (unseen), and down to the winch; 2, 2, parts of the tube leading to the "worm" in the ice-box (only half of which is shown); 3, 3, tube leading from the "worm" to the brain in the pail; 4, wire "crane" supporting that division of the tube, 3, which is connected with an artery; 5, socket, unoccupied, for a crane; 6, escape-tube; 7, tunnel for filtration in the escape jar; 8, waste pipe from the ice box; 9, waste-pail; *s. p. c.* ^{1}, ^{2}, ^{3}, screw pinch cocks controlling the flow in, respectively, the main tube, the artery tube, and the tube to the dura; *t. c.* ^{1}, ^{2}, ^{3}, turn-cocks at, respectively, the alinjection can, the ice box, and the specimen-pail. The closet door has been removed; the upper part is not shown, and part of the wall of the lower is represented as if cut out so as to expose the winch. The farther side is a window for light, and—in winter—cold. See § 22 for the consideration of temperature, and § 70 for certain details. The alinjection closet and apparatus here shown were constructed and employed under what may prove to be a misapprehension as to the necessity of maintaining a low temperature of the alcohol and the specimen during the operation. In warm weather the alcohol was conducted through a spiral coil and lead pipe within the ice box, and the specimen itself or the pail in which it was, was surrounded by ice or kept in a refrigerator perforated for the passage of the tubes. In winter the window was opened sufficiently to effect the purpose. Notwithstanding the present doubt respecting the advisability of maintaining a low temperature during alinjection, such a closet is a desirable adjunct to a laboratory for many purposes. The winch and pulley are convenient, but it is by no means certain that all necessary changes in the pressure might not be made by having two sets of shelves, side by side, alternating so that by moving from one to another the can might be raised or lowered for only half its height. The can itself is an ordinary five-gallon, tin oil can, with a cock, and, in addition, an L-shaped tin tube let in near the bottom for the insertion, with cement, of a glass tube graduated so as to indicate the litres contained at any time, and thus the amount that has passed to the brain. The cocks [illegible] and the tube still smaller, and connected with the cock by a tapering glass piece. The rubber tubes near the brain are [illegible] size made. A smaller can may, of course, be used. The [illegible] may be of wood, holes bored for turn-cocks, and the [illegible] porting the cannulas pushed into holes [illegible]

§ 67. *Removal of the Metencephal.*—After the removal of the cerebrum (§ 16) this is comparatively easy; the tentorium is divided at its periphery and lifted

---

latter purpose are supplied by E. N. Cook & Co., of Buffalo, N. Y. For official information, see Section 3297, U. S. Rev. Statutes, Treasury Circulars of January 2, 1886, and March 26, 1889 (this last is comprehensive), and a ruling as to the use of untaxed alcohol in a hospital, New York Medical Journal, March 30, 1889, pp. 363, 364.

* Most of the sawing should be done by an assistant, that the chief may better accomplish the later operations.

† For the method of Féré, see *Bulletin de la Société Anatomique de Paris*, ii., 206, 207; for that of Spitzka, Journal of Nervous and Mental Disease, July, 1883.

carefully from the membranes, vessels being divided as they appear; the cranial nerves and the dura may be cut away more completely if necessary; by tilting the brain half one way or the other in the trough the nerves may be seen and divided, and the myel is finally cut as far down the spinal canal as possible. For some purposes, as when the ependyma is especially to be studied, the brain may be suspended in the preservative by a string tied about the myel, or about a pin passed through it from side to side; most securely, especially with infant brains, by retaining one or two vertebræ.

§ 68. *Hardening the Brain in Situ by Continuous Arterial Injection.*—The head should not be more than twenty-four hours old, and should have been kept cool, without freezing. Note the relations of the carotid and vertebral arteries on a preparation or model, or in Figs. 1190, 2441, 2448, 2449, 2441, 2444, and 2445, and in the article, Vessels of the Brain.

§ 69. *Clearing the Vessels.*—Inject normal salt solution (sodium chloride, 15 grams; water, 2 litres) into a vertebral and either carotid artery (preferably on the same side) until the liquid runs clear from the other arteries. Place in the aspirator can about five litres of twenty-two per cent. alcohol strained through absorbent cotton or filter-paper; raise the can to about one metre. In connecting the tubes let all air-bubbles escape. Small arteries that leak must be tied or secured with serres-fines (Fig. 2460). The liquid should escape in six to eight hours, and be quite bloody. If the last of it is nearly free from blood, the strong alcohol may be used; if not, repeat, using half the quantity of twenty-two per cent.

§ 70. The strong (ninety-five per cent.) alcohol may now be used at the same pressure; it will pass through at a rate varying from one-third to eight-tenths of a litre per hour, and be reduced to seventy-five or eighty per cent. At the end of the third day, and perhaps earlier, the strength of the alcohol will be but little reduced; the pressure may then be lessened by lowering the can to one-half the height. By the sixth day the loss in strength may be no more than three per cent., and the discoloration insignificant. The injection may then be discontinued, and the head sawed (§ 71) or otherwise prepared. If desired, a colored injection mass may be thrown into the arteries of either the face (external carotids) or the brain (internal carotids and vertebrals), or of all.

§ 71. *Marking of the Head.**—Determine the plane of section by the following mesal points, some of which, of course, are subject to variation: (1) Interval between the central incisors in each jaw; (2) dimple at tip of nose; (3) occipital protuberance (inion); (4) nasal; (5) vertebral ventrum; (6) notch in cephalic margin of larynx; (7) dimple of chin; (8) middle of top of head. This last is ascertained by carrying a piece of inelastic cord over the top of the head, securing each end in an auditory meatus by crowding cotton in with it, and then finding the middle of the cord. At each mesal point make a short but deep incision. Knot one end of a cord long enough to surround the head and neck at the meson; place the knot mesad of the central, maxillary (upper) incisors, carry over the nose, head, neck, and chin back to the mandibular incisors, between which it may be secured by a wedge or otherwise. With the [illegible] divide the scalp, etc., along one side of the cord. Remove the cord, and at the occipital convexity (about at the site from 3 in Fig. 2884) bore a hole at the meson deep enough to permit a screw to be firmly fixed.

§ 72. *Adjusting the Head.*—Place the head in the saw-box and mark with a pencil the points where the bottom and one side are in contact with the occipital region and the vertex; at these points bore a hole in the kerf large enough to admit one of the screws. Replace the head in as nearly as possible the same position; pass the spatula through the kerf above the hole in the side opposite the vertex, and adjust the head so that the end of the spatula is in the cut in the scalp. While steadied in that position pass the gimlet or awl through the hole and bore into the skull for a short distance, 3 to 5 mm.; insert the screw at that point. Repeat the operation for the occipital region; this screw should bring the head firmly against the bottom of the box; if it is necessary or desirable to remove the head in order to bore the holes, when the head is replaced the holes may be found by means of the probe-end of the tracer.

§ 73. *Packing.*—Draw through the kerfs in the two sides a cord just large enough to fit tightly, and pull it down so that it coincides with the cut in the skin of the face. Pack the cotton first in the angle between the two screws, then under the neck, keeping the whole constantly adjusted by means of the thread and the kerf at the near side of the box. When firmly packed, pour over the cotton some water until no more is absorbed.

§ 74. *Sawing.*—Remove the cord from the kerf; insert the saw so that the handle is close to the side of the box, and make the first few strokes by drawing only; then saw in the usual way; a fine stream of alcohol (fifty per cent. alcohol forty-eight) should irrigate the blade during the entire operation. The back of the saw should be retained as long as possible, and screws not removed until nearly reached by the saw. Let a gentle stream of water flow over the sawn surfaces and place at once in alcohol.

§ 75. *Removal of the Hardened Hemicerebrum.**—Remove the falx and [illegible] tentorium. At the base divide the infundibulum close to the [illegible], leaving the hypophysis to be removed separately. Note the location of the optic nerve, and divide by carrying the scalpel point latero-cephalad from the infundibulum for 1 to 2 cm. close to the dura, lest the olfactory area be injured. Dislodge the olfactory bulb with the [illegible], turn it just over the margin of the hemicerebrum, and secure it by a small pin at either side.

§ 76. *Transection of the Hemicerebrum.*—Recognize, if possible, the dorsal end of the central fissure, nearly dorsad of the splenium. Place a strip of paper or a card across the hemicerebrum, between points about 5 mm. caudad of the fissure and the splenium. The half-head should be in alcohol or the cords should be flooded. The vertex should be toward the operator. Note on the empty half head the angle formed by the tentorium with the meson, or observe on the preparation at hand. Pass the scalpel into the brain close to the tentorium, and with a gentle sawing movement carry its point as far as it will go; continue the movements dorsad, making sure that the broad edge of the half of the scalpel does not bruise the brain. The completion of the transection is announced by the loosening of the occipital region. Probably the greatest difficulty will be the division of the extreme ventral part. To remove the occipital part push the probe-end of the tracer or a very narrow-bladed scalpel (Fig. 2880) into the brain 10–12 mm. caudad of the section plane, near the tentorium and between two fissures; the direction should be dorso-lateral at an angle of 45 degrees, thus nearly perpendicular to the cut surface of the cranium toward which it is pointing. Dislodge the tip of the occipital lobe by coaxing with the scalpel handle; lift the whole piece slightly with the inserted instrument; it will come out for a certain distance and then be checked by veins which may be divided with scissors.

§ 77. *Mesencephalic Transection.*—From Figs. 4724 and

---

* The following instruments and apparatus should be provided (see § 67): [illegible]

* The following instruments and materials should be provided: [illegible]

4728 note that (1) the crusta projects considerably ventrad of the mesal cut-surface and (2) that the greatest width of the crus is not more than 15 mm. Hold the scalpel with the flat side at an angle of about thirty degrees with the meson, let the ink-mark be at the ventral margin of the crus, and cut dorsad with sawing strokes. Place the specimen so that the depths of the incision are illuminated, and divide whatever may appear; the hemicerebrum will float up, and be readily removed if the dorsal margin be first disengaged and the prominence of the temporal lobe kept in mind.

§ 78. *Removal of the Metepencephal.*—If the tentorium is to be retained, divide it by cutting laterad from a point just caudad of the angle between the natural, curved margin and the cut, straight margin; it is more convenient to remove it entirely. The half-head may now be placed upon a tray and supported, or held by an assistant. Crowd the edge of the round scalpel-handle between the dura and the myel for 2–3 mm., beginning at whatever point a slight interval already exists, and continue the separation by gentle, yet firm pressure; special difficulties will be encountered at and near the occipital foramen, requiring perhaps the scalpel-edge. Do the same for the cerebellum and pons, keeping in mind the natural curvatures of the surfaces and the locations of the larger nerves, especially the trigeminus and the auditory and facial. Specific directions are hardly possible for the rest of the operation.

§ 79. *Arterial Alinjection of a Brain in the Dura.*—The vessels must first be washed out (§ 69), and the small arteries tied or secured with *serres-fines* (Fig. 1736).

§ 80. *Entocœlian Alinjection per Luram.*—Four points are to be kept in mind: 1, The smallness of the orifice (Fig. 4689), which may be enlarged if desired with the probe or by clipping the infundibulum shorter; 2, the general dorso-caudal direction of the passage (Fig. 4711); 3, the danger of wounding the parietes, and especially the medicommissure: the cannula should therefore be short, the tube small and flexible, and the cannula pushed through a disk of rubber so as not to enter more than 1 ctm.; 4, the weakness of the encephalic substance after death: hence no more pressure should be exerted than suffices to fill the cavities and cause a slight elevation of the tips of the temporal lobes; the alinjection-can should be just above the level of the brain, and the cannula fit loosely in the lura so that the excess of alcohol may escape.

§ 81. *Combined Arterial and Entocœlian Alinjection.*—This very effectual method of preserving a brain removed in the dura for any macroscopic purpose was employed with the specimens shown in Figs. 4740, 4742, and 4833. A separate reservoir must be used for the entocœlian alcohol (§ 80), or the branch-tube leading to the lura must be small and kept compressed so that—when the cavities are once filled—the flow will be very slight.

Burt G. Wilder.

BRAIN, SURGERY OF THE. [Cerebral surgery is so new, and its progress so rapid, that the opinions here expressed must be considered as only tentative, and as only representing my opinions at the time of writing it (December, 1888). It may possibly be the case that, even when it is published, a larger experience will have very materially modified my views on a number of points.]

History.—Although in 1871 Broca located a cerebral abscess in the speech centre, and greatly relieved the patient by trephining, modern Brain Surgery begins properly with a modest report of a case by Macewen in the *Glasgow Medical Journal* for 1879, xii., 210, and a later more elaborate paper, by the same author, in *The Lancet* for 1881, ii., p. 541. In these papers he narrates three cases occurring in 1876 and 1879, in which cerebral disease was located by focal symptoms. The first was a case of convulsions of the face, arm, and leg, in the order named, following a fall on the right side of the head. A trephine opening of the dura evacuated two oz. of blood, and the boy recovered without any febrile movement.

In the second case the symptoms pointed to a lesion of the frontal lobe, and, after trephining, a tumor of the dura mater was dissected out. The patient died eight years subsequently, from Bright's disease.

The third was a case of cerebral abscess existing, not at the site of a prior injury marked by a distinct cicatrix, but correctly diagnosticated in a totally distinct position, that is, in Broca's convolution, by the focal symptoms. The parents declined an operation, and the child died. After death an operation was done precisely as it would have been done during life, and an abscess was found the size of a pigeon's egg at the spot indicated by the localizing symptoms.

In spite, however, of this remarkable paper, the surgical world seemed blind to its opportunity. But in *The Lancet* for December 20, 1884, Dr. Hughes Bennett and Mr. Godlee narrated a case of subcortical tumor of the brain, diagnosticated by the localizing symptoms alone and before operation. When the dura was opened no tumor was visible; but so certain were they that a tumor existed, that an incision was made in the apparently healthy brain tissue, and a morbid growth the size of a walnut was found one fourth of an inch below the surface. This case, though ultimately unsuccessful because of suppurative meningitis, instantly arrested the attention of the surgical world by the precision of the diagnosis, the success of the operative technique, and the evidence it afforded that we could successfully cope with heretofore hopeless cases. Its very failure, like the failure of the first Atlantic cable, but pointed the way to success.

The first American paper on cerebral tumor, by Hirschfelder and Morse, of San Francisco, appeared in the *Pacific Medical and Surgical Journal* for April, 1886. The case was that of the successful localization, but unsuccessful removal, of a brain tumor.

Two most remarkable papers on brain surgery, however, were published soon afterward by Mr. Victor Horsley, in the *British Medical Journal* for October 9, 1886, and April 23, 1887. In these papers ten cases were related, all of which were correctly localized; only one died, and the remainder were either benefited or cured. These were cases of removal of brain tumor, and even of portions of diseased brain-tissue, the cause of epilepsy, intense headache, etc. Since then a large number of papers have appeared, and among them one in the *British Medical Journal* for August 11, 1888, by Mr. Macewen again, which has but confirmed the sanguine expectations created by his brilliant paper of 1881. I shall refer in the course of this paper to a number of other publications, but I have thought it right to sketch thus briefly the historical development of the subject.

In this country, besides many excellent publications that I have not space or time to enumerate, the most noteworthy papers published have been those by John B. Roberts, read before the American Surgical Association in 1885; two by R. W. Amidon, in the *Medical News* for January 21, 1884, and the *Annals of Surgery*, vol. i., 1885, both of these authors putting forth strong pleas for more heroic surgical interference in affections of the brain; and one by Seguin and Weir, in the *American Journal of the Medical Sciences* for July, August, and September, 1888. I have also published two papers to which I may allude, one in the *American Journal of the Medical Sciences* for October and November, 1888, and another in the *Medical News* for December 1, 1888. In Germany perhaps the most elaborate and important paper is that by v. Bergmann, in *Langenbeck's Archiv*, Bd. xxxvi., Heft 4.

In addition to these, Mr. Horsley has published, in the *British Medical Journal* for June 16, 1888, an account of the removal of a tumor from the spinal cord, and Mr. Macewen, in his paper last referred to, published six cases in which the posterior arches of the vertebræ had been removed for tumor and compression of the cord, and for an abscess in the posterior mediastinum, two of which (paraplegia from Pott's disease and fractured spine) had been published as early as 1886 (*Glasgow Medical Journal*, xxv., 210). (See article on Surgery of Spinal Cord, farther on.)

Two things have made such brain surgery possible. First: the accurate localization of the functions (especially the motor centres) by Ferrier, Horsley, Fritsch,

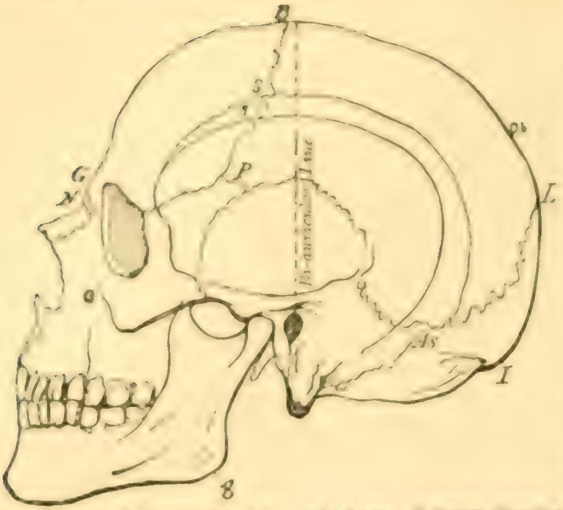

Fig. [illegible].—Skull showing Points named by Broca. N, Nasion [illegible]

Hitzig, and others) by means of which we can with fair accuracy determine the site of a tumor, abscess, cyst, etc., by the focal symptoms. Secondly, the impunity with which we can trephine and **open the dura mater, and interfere with the** brain-tissue itself, is due almost entirely to the introduction of antiseptic surgery. To Horsley more than to anyone else we owe the formulation of rules for successful brain surgery, rules which will be given at length hereafter.

The Danger of Trephining.—For the technique of trephining I refer the reader to the paper under that head by Dr. Park in Vol. VII. of this HANDBOOK. But it is important further to consider the question of the danger involved in this operation. In St. Bartholomew's Hospital Reports for 1882 Dr. Walsham published a paper entitled "Is Trephining of the Skull a Dangerous Operation per se?" In this article he analyzes 686 cases, of which 417 survived, the mortality, therefore, being 39.2 per cent. Dividing these large numbers into classes: first, those in which preventive trephining was used (mostly all for fractures), there being no cerebral symptoms, the mortality was 21.9 per cent. Second, trephining in which severe cerebral symptoms existed, the mortality was 48.4 per cent. Third, trephining in which moderate cerebral symptoms were present, the mortality was twenty-seven per cent. Fourth, late trephining, mostly after inflammation had set in, the mortality was 58.6 per cent. Fifth, late or secondary trephining showed a mortality of twenty-two per cent.

Walsham showed that in 172 cases of late trephining in which there was no condition endangering life, only 10.6 per cent. died. Amidon, in the paper referred to, analyzes 100 cases of trephining reported since 1879, in most of which antiseptics were employed. Of these 100 cases 26 died, but of these 23 presented at the time of operation symptoms already endangering life. He therefore concluded, and most later writers practically concur in his conclusions, that the mortality of trephining per se is but three per cent., a conclusion which would seem to be confirmed by Prunières and Robert Fletcher, by their investigations, which show the frequency of recovery in cases of prehistoric trephining. Seydel ("Antiseptic und Trepanation") even estimates the mortality as only 1.6 per cent.

Not only have antiseptics thus diminished the danger of simply opening the cranium, but the numerous cases which have been reported of opening the dura, followed by removal of tumor and also of more or less brain-substance, clearly show that but little danger is added in any case by such novel surgical procedures. "Heretofore," says Amidon, "the boldness of the surgeon to open the cranium seems audacity as compared with his hesitation in piercing the dura mater. The cerebral cortex seems to be a 'dead line' inside the prison walls of conservative surgery, across which even the most daring are tempted, or the most unwilling are dragged, only by sure indications or desperate chances."

The future danger seems to be, however, that temerity may take the place of timidity, and that many patients will either die or go about with mutilated brains that ought never to have been touched. This word of caution, therefore, at the outset may not be out of place.

TOPOGRAPHY OF THE BRAIN IN ITS SURGICAL RELATIONS.—The relation of the chief fissures and convolutions of the brain to the surface of the skull has assumed of late the greatest possible importance. It is essential that we shall be able, from fixed landmarks on the skull, to locate the various fissures and convolutions, and by them the various cortical centres. The subject has recently been studied by Reid,[1] Horsley,[2] and Hare,[3] each of whose methods of research has its own merit.

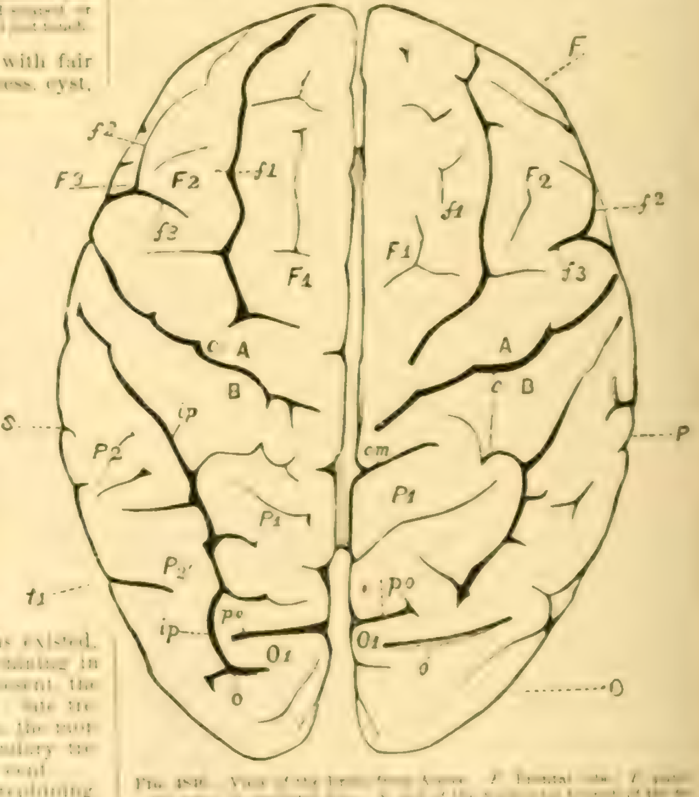

Fig. [illegible].—View of the Brain from Above. F, frontal lobe; f, [illegible]

I shall give a brief outline of the three methods, and in doing so, I must take it for granted that the reader is fairly well acquainted with the chief outlines of the cerebral cortex. In order, however, to facilitate the study of the external topography of the brain, I have introduced cuts.

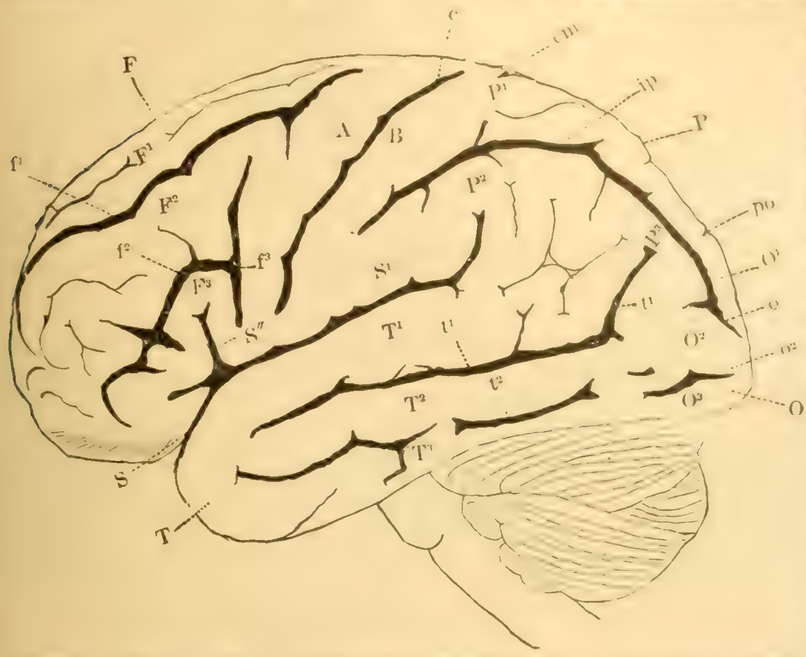

Fig. 4847.—Outer Surface of the Left Hemisphere. F, Frontal lobe; P, parietal lobe; O, occipital lobe; T, temporo-sphenoidal lobe; S, fissure of Sylvius; S', horizontal, S'', ascending ramus of the same; c, central sulcus or fissure of Rolando; A, anterior central or ascending frontal convolution; B, posterior central, or ascending parietal convolution; F^1, superior, F^2, middle, and F^3, inferior frontal convolutions; f^1, superior, f^2, inferior frontal sulcus; f^3, præcentral sulcus; P^1, superior parietal or postero-parietal lobule; P^2, P^3, inferior parietal lobule, viz.: P^2, supra-marginal gyrus; P^3, angular gyrus; ip, intraparietal sulcus; cm, termination of the calloso-marginal fissure; O^1, first, O^2, second, O^3, third occipital convolutions; po, parieto-occipital fissure; o^1, transverse occipital sulcus; o^2, inferior longitudinal occipital sulcus; T^1, first, T^2, second, T^3, third temporo-sphenoidal convolutions; t^1, first, t^2, second temporo-sphenoidal sulci. (Ecker.)

First: Fig. 4845, from Broca, giving the points named upon the skull.

Secondly: Figs. 4846–4848, from Ecker, giving the names of the principal sulci and convolutions.

I have also appended two figures from Ferrier's "Functions of the Brain" (Figs. 4849 and 4850) in order to fix as nearly as possible the relations of the various centres, so far as known at present. The figures in these two cuts are placed as follows:

(1), On the postero-parietal lobule (precuneus), the centres for movements of the opposite leg and foot in locomotion. (2), (3), (4), At the upper end of the fissure of Rolando, and hinder part of the first frontal convolution, the centres for various complex movements of the arms and legs, as in climbing, swimming, etc. In this area Horsley states that the arm and leg of the same side are involved together. (5), At the posterior part of the superior frontal convolution—extension forward of the arm and hand, as in putting forth the hand to touch something in front. (6), On the ascending frontal [pre-Rolandic] convolution, just behind the upper and hinder end of the middle frontal convolution—movements of the hand and forearm in which the biceps is particularly engaged, viz., supination of the hand and flexion of the forearm. (7) and (8), Respectively for the elevators and depressors of the angle of the mouth. (9) and (10), As one mark the centre for movements of the lips and tongue, as in speech. This especially occupies the posterior portion of the inferior frontal (generally known as Broca's) convolution. Disease of this region on the left side produces aphasia. (11), The centre for the platysma, retraction of the angle of the mouth. (12), A centre for the lateral movements of the head and eyes, with elevation of the eyelids and dilatation of the pupils. (13) and (13'), On the supra-marginal lobule and angular gyrus, including also the occipital lobe, indicate the centre for vision. (14), On the superior temporo-sphenoidal convolution, indicates the centre for hearing. (*a*), (*b*), (*c*), (*d*), On the ascending parietal [post-Rolandic] convolution, indicate the centres for movements of the fingers and wrist. The centre for smell is situated in the hook of the hippocampal region (Fig. 4848, *U*). In close proximity, but not exactly defined as to limits, is the centre for taste. The centre for touch is situated in the hippocampal region (Fig. 4848, *H*) and gyrus fornicatus (*Gf*).

To this I also add Figs. 4851 to 4859 from Horsley's article (*Amer. Jour. of the Med. Sciences*, April, 1887) for the same purpose. I also add a figure from Gowers (Fig. 4860) to show the relations of the convolutions to the skull.

The reader desirous of further information will find

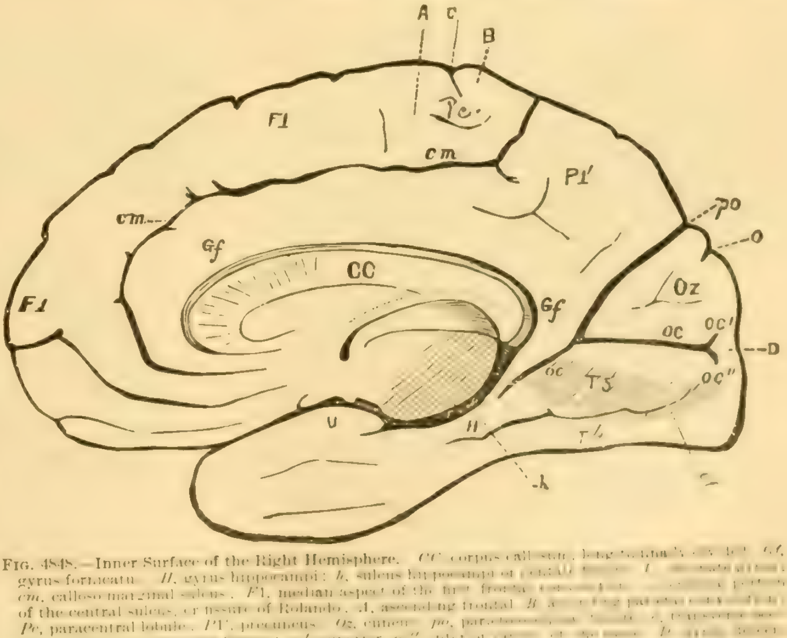

Fig. 4848.—Inner Surface of the Right Hemisphere. *CC*, corpus callosum, longitudinally divided; *Gf*, gyrus fornicatus; *H*, gyrus hippocampi; *h*, sulcus hippocampi or [illegible]; *U*, [illegible]; *cm*, calloso-marginal sulcus; *F1*, median aspect of the first frontal [illegible]; *c*, [illegible] of the central sulcus, or fissure of Rolando; *A*, ascending frontal; *B*, ascending parietal [illegible]; *Pc*, paracentral lobule; *P1'*, precuneus; *Oz*, cuneus; *po*, parieto-occipital [illegible]; *o*, [illegible] occipital sulcus; *oc*, calcarine fissure; *oc'*, superior, *oc''*, inferior [illegible]; *D*, gyrus descendens; *T4*, gyrus occipito-temporalis lateralis (lobulus fusiformis); *T5*, gyrus occipito-temporalis medialis (lobulus lingualis); *ct*, collateral or occipito-temporal fissure. (Ecker.)

is briefly stated in the last American edition of "Gray's Anatomy," pp. 881 et seq., as very fully in the works already referred to, together with Ferrier's "Functions of the Brain" (see also article "Skull, etc.," in Vol. VI.).

It must be borne in mind that, as pointed out by Stokes,* the relations between the brain and the skull vary at different ages, a fact reinforced by Cunningham's models of the brain hardened in situ, and then exposed by removing the bones of the skull, leaving bridges at the sutures. Symington* points out that the Sylvian fissure lies much higher above the squamo-parietal suture in the child than in the adult, and is from half an inch to even an inch above it. He thinks that they attain their adult relations at about the eighth or ninth year.

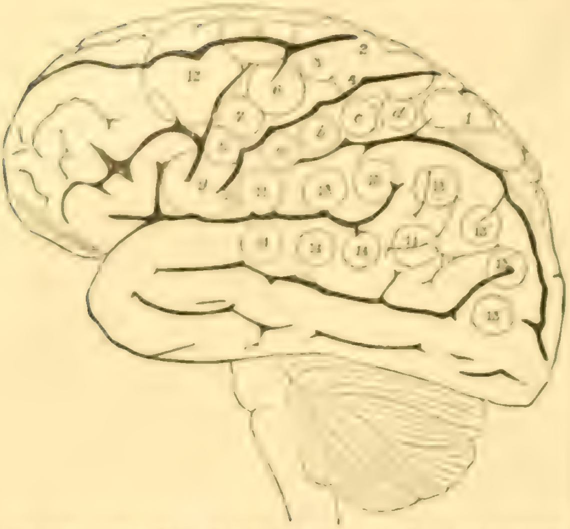

Fig. 4849.—Side View of the Brain of Man. (Ferrier.) (For references see p. 203.)

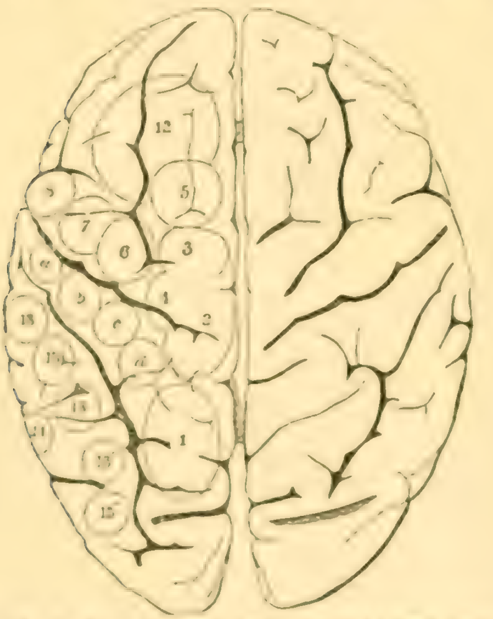

Fig. 4850.—Top View of the Brain of Man. (Ferrier.) (For references see p. 203.)

The fissure of Rolando is also much more oblique in its direction (52°, Hare) in the child, and lies farther forward on account of the imperfect development of the frontal lobes. Gradually as these are developed, especially the third frontal convolution, the lower end of the fissure is pushed back and it assumes its adult angle and position.

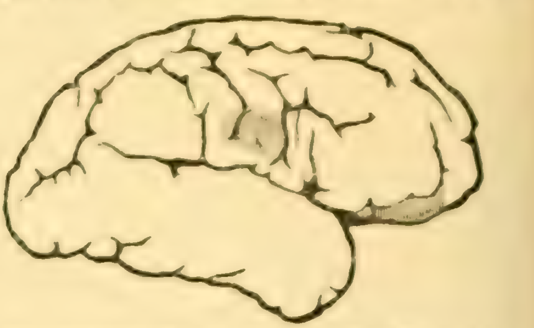

Fig. 4851.—Representation of the Centre for the Upper Face and Angle of the Mouth. (Horsley.)

First. *Landmarks on the Skull.* Most of these are readily determined by reference to the foregoing figures, but there are some which must be more minutely described.

The temporal ridges (Fig. 4845) are two in number: the upper for the temporal fascia, the lower for the upper border of the temporal muscle. The upper is the better marked and can be easily followed by the finger from the external angular process backward. It marks the sudden change in the slope of the skull, from the curve of the upper surface to the more vertical direction of the side. The lower one is best made out by closing and relaxing the jaw, when the upper edge of the temporal muscle can be located by the finger. Like the upper it begins at the external angular process, but runs at a lower level than the fascial ridge. Its middle is about two-fifths of an inch below it. The points where the coronal suture crosses these two ridges are called respectively the upper and lower stephanions (Fig. 4845, S and S').

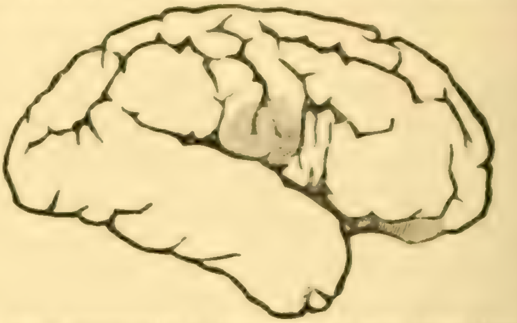

Fig. 4852.—Representation of the Centre for the Vocal Chords (Adduction). (Horsley.)

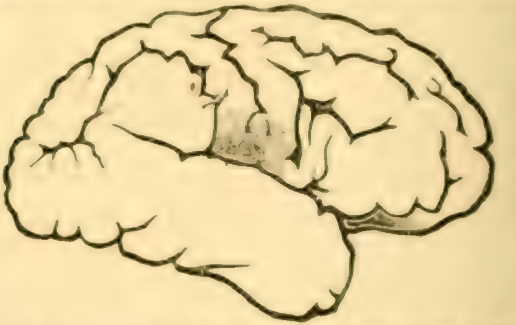

Fig. 4853.—Representation of the Centre for the Lower Face and Floor of the Mouth. (Horsley.)

The *coronal suture* starts at the bregma (Fig. 4845, *B*).

Drawing the bi-auricular line (Fig. 4845), measurements on 185 skulls have given me as a mean result, that in the adult the *bregma* lies 0.375 of an inch in front of this line. The greatest distance was 1.2 inch. In 16 of these skulls, the bregma coincided with the point where the bi-auricular line crosses the sagittal suture. In only 7 did it lie behind it, the maximum being 0.9 inch. Starting from the bregma, by shoving the scalp backward and forward, the finger can perceive (but with some difficulty, especially in the aged) the irregularities of the coronal suture, but toward the stephanion they become more marked and can be pretty well appreciated. The *parieto-squamosal* suture lies beneath the temporal muscle. The highest point of its curved line is at the junction of the upper and middle thirds of a vertical line drawn from the upper border of the zygoma to the ridge for the temporal muscle in front of the temporo-maxillary articulation.

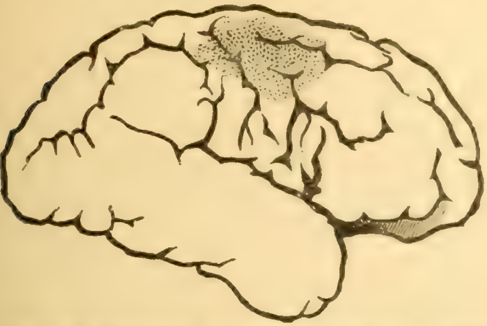

FIG. 4854.—Representation of the Centre for the Shoulder. (Horsley.)

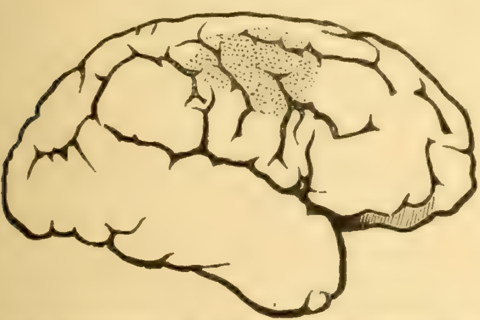

FIG. 4855.—Representation of the Centre for the Elbow and Wrist. (Horsley.)

The point of junction of the great wing of the sphenoid, frontal, parietal, and squamous bones is called the *pterion* (Fig. 4845), and is about half-way between the superior stephanion and the zygoma. It is usually H-shaped.

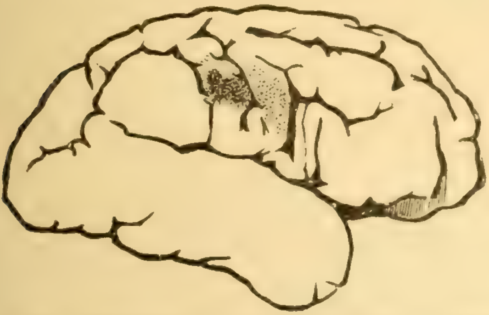

FIG. 4856.—Representation of the Centre for the Thumb. (Horsley.)

The Relation of the Fissures and Convolutions to the Landmarks on the Skull.—There are five great fissures of the brain to be localized.

First. The *great longitudinal fissure* separates the two hemispheres of the cerebrum. This does not lie precisely in the middle line, but in consequence of the slightly larger size of the left hemisphere, it lies about an eighth of an inch to the right of the middle line.

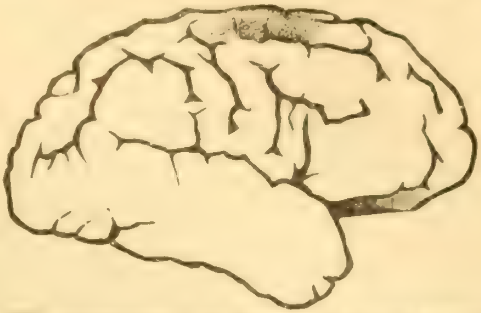

FIG. 4857.—Representation of the Centre for the Combined Synergic Action of Both Limbs. (Horsley.)

Second. The *great transverse fissure*, or the fissure of Bichat, between the cerebrum and the cerebellum. This lies in a line from the external auditory meatus to the *inion* (or external occipital protuberance). This marks also the position of the tentorium and of the lateral sinuses. The other three great fissures (viz., the *fissure of Sylvius*, the *fissure of Rolando*, and the *parieto-occipital fissure*) will be given under the following rules.

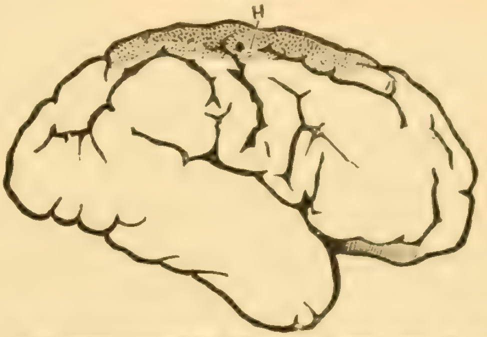

FIG. 4858.—Representation of the Centre for the Lower Limb. H, Focus of representation of the Hallux. (Beevor and Horsley.)

Horsley's Method.—The *fissure of Rolando*, in relation to the motor region, is the most important in the whole brain. As will be seen by reference to Figs. 4849 and 4850, almost all the motor centres lie clustered about it. As Thane has shown, it runs downward and forward from

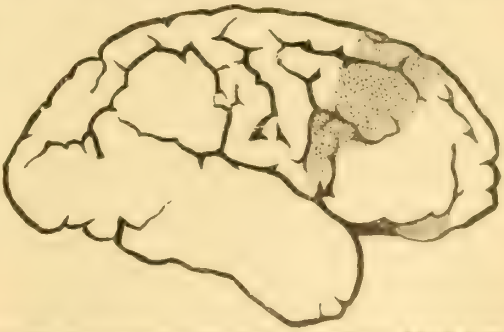

FIG. 4859.—Representation of the Centre for the Head and Neck, together with Conjugate Deviation of the Eyes. (Horsley.)

a point half an inch behind the middle of the distance from the glabella to the inion. This point being fixed, if a line be drawn forward at an angle of 67° (as shown by Hare) for a distance of 3¾ inches, it will indicate the fissure of Rolando, the lower third of the fissure, however, changes to a somewhat more vertical direction, thus forming a knee-like bend. To fix this important fissure Horsley uses a strip of metal or of parchment paper, say

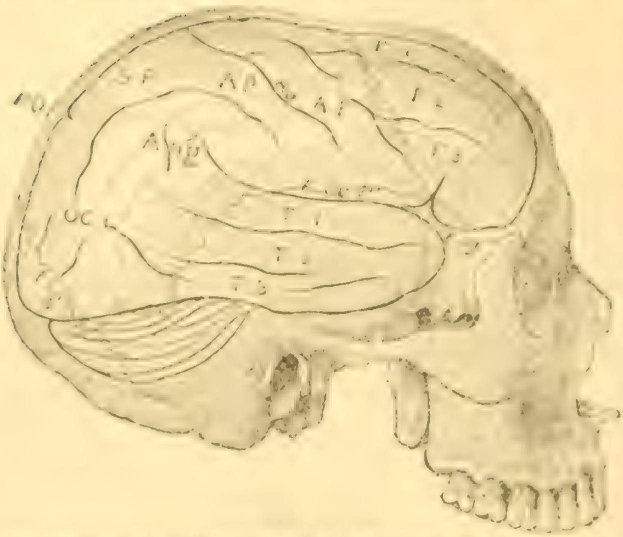

FIG. 4860.—Diagram of the Relations of the Convolutions to the Skull. F 1, 2 and 3, Upper, middle, and lower frontal convolutions; A F, A P, ascending frontal and parietal convolutions; S P, sup. parietal lobule; A g, angular gyrus; O C, occipital lobe; T 1, 2, 3, the temporo-sphenoidal convolutions; P O F, parieto-occipital fissure; F Sy and F Sy P, fissure of Sylvius and its posterior limb. (Horsley.)

fourteen inches long, with a second strip firmly fixed to it at an angle of 67° (Fig. 4861).

The zero point of the scale of the longer piece (as suggested by Dr. Morris J. Lewis of Philadelphia) is placed half an inch in front of the angle formed by the two arms. From this zero point the scale (in quarter inches) reads both forward and backward. The longer arm is placed in the middle line of the shaven head in such a position that the readings of the two scales at the glabella and at the inion shall be identical. The lateral strip will then mark the fissure of Rolando (3¾ inches), the direction of the lower third being slightly changed, as above indicated.

The *fissure of Sylvius* commences at the pterion, the anterior branch running upward and forward, continuing the line of the squamo-sphenoidal suture, but one or two millimetres in front of it. The posterior branch passes upward and backward half a millimetre above the squamo-parietal suture, as far as its highest point, and from there curves slightly upward toward the centre of the parietal eminence, which it nearly reaches. This fissure limits the motor region anteriorly by its anterior limb, and postero-inferiorly by its posterior limb.

The *precentral or vertical sulcus* is of great importance also, as it divides two convolutions of very different functions, and on each side of it has convolutions of great motor importance. It runs parallel to and just behind the coronal suture, and is almost vertical to a horizontal tangent at the bregma (hence its second name). Its upper end reaches to the level of the middle of the fissure of Rolando. From it, about on a level with the superior [illegible], the *superior frontal sulcus* runs forward. Above the origin of this latter sulcus, the precentral sulcus continues vertically half-way across the root of the middle frontal convolution. Its lower end is separated from the fissure of Sylvius by a horseshoe-shaped convolution of great importance (the *operculum*), which is nearly always one centimetre wide, and overlies the island of Reil.

The *superior frontal sulcus* starts from the ascending frontal [pre-Rolandic] convolution midway between the fissure of Rolando and the line of the precentral sulcus. Its posterior end, therefore, lies behind the precentral sulcus. The *superior* and *inferior frontal sulci* run forward and slightly downward, practically parallel with the great longitudinal fissure.

The *intra-parietal sulcus* lies behind the fissure of Rolando and bounds the motor area posteriorly. It begins opposite the knee-like bend at the junction of the middle and lower thirds of the fissure of Rolando. As it goes upward it lies about midway between the line of the Rolandic fissure and the parietal eminence. It then separates farther from the fissure of Rolando and so widens the area of the ascending parietal [post-Rolandic] convolution, that its upper end is known as the *superior parietal lobule*. In the middle of its course it runs about parallel to the great longitudinal fissure, and midway between it and the parietal eminence. Further on it passes by the external end of the parieto-occipital fissure, and goes downward and backward into the occipital lobe.

The *parieto-occipital fissure* on the upper surface of the cerebrum is a short fissure about an inch long, at right angles with the great longitudinal fissure, and two or three inches in front of the *lambda* (the junction of the lambdoidal and sagittal sutures) (Fig. 4845, *h*). This fissure, on the median surface of the cerebrum (Fig. 4848, *po*), is a long fissure running downward and forward. It is joined at its middle by the *calcarine fissure* (Fig. 4848, *ca*). Between these two fissures is the *cuneus* (*Cu*, Fig. 4848), in which lies the centre for sight. Injury to the cuneus, therefore, produces blindness in the half of each retina on the side corresponding to the injury.

In front of the parieto-occipital fissure, on the middle surface of the hemisphere, lies the *præcuneus* or *quadrate lobule* (Fig. 4848, P), bounded in front by the upper end of the *calloso-marginal fissure* (*cm*).

In front of and behind the fissure of Rolando (Figs. 4846 and 4847) are two most important convolutions. The one in front is chiefly known as the ascending frontal or precentral or, as I prefer to term it, the *pre-Rolandic convolution*. The one behind the fissure of Rolando is known as the ascending parietal or postcentral, or, as I prefer to term it, the *post-Rolandic convolution*. At their upper ends they fuse into the *paracentral lobule*, and at their lower into the *operculum*. The two frontal sulci divide the frontal lobe horizontally into three convolutions, viz., the first, second, and third, or respectively the *superior*, *middle*, and *inferior frontal convolutions*. The third or inferior convolution is frequently known as *Broca's convolution*. On the left side the *centre for speech* is located (in left-handed persons this speech centre lies in Broca's convolution on the right side). For the location of other centres in these various convolutions the reader is referred to Figs. 607, 617, 4846, 4847, and 4848.

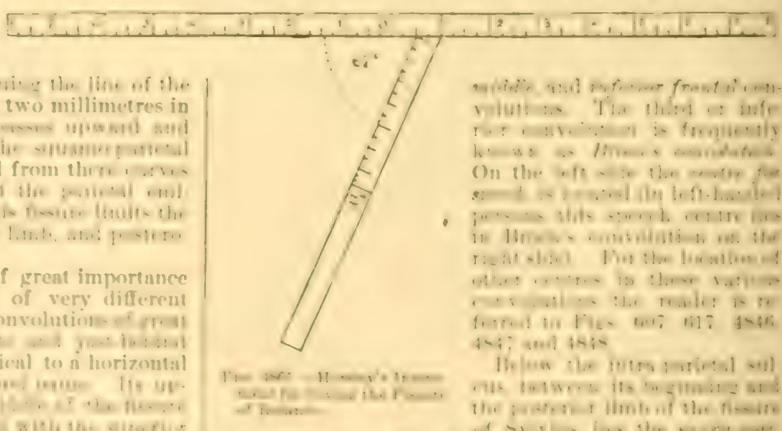

FIG. 4861.—Horsley's Instrument for Finding the Fissure of Rolando.

Below the intra-parietal sulcus, between its beginning and the posterior limb of the fissure of Sylvius, lies the *supra-marginal convolution* (Fig. 4847, P²). Below the posterior portion of the intra-parietal, and behind the superior extremity of the horizontal limb of the Sylvian fissure, lies the *angular gyrus* (Fig. 4847, P³).

The *temporo-sphenoidal lobe* is divided horizontally, by the *superior* and *inferior temporal sulci*, into three convolutions, first, second, and third, or *superior*, *middle*, and *inferior temporo-sphenoidal convolutions*. On the median aspect of the hemispheres the *calloso-marginal fissure* (Fig. 4848) has above it the *marginal convolution ;* below it, and immediately above the corpus callosum, lies the *gyrus fornicatus.*

Reid's Method.—Reid's "base line" (Fig. 4862) is a line running backward from the infra-orbital ridge through the middle of the external auditory meatus, and prolonged to the middle line of the head posteriorly. The *fissure of Sylvius* runs from a point an inch and a quarter behind the external angular process of the frontal bone to a point three-fourths of an inch below the most prominent point of the parietal eminence. Measuring from above backward, the first three-fourths of an inch will represent the main fissure; the rest indicates the horizontal limb. The ascending limb starts at a point three-fourths of an inch back of the anterior extremity, that is, two inches behind and slightly above the external angular process, and runs vertically upward and forward about one-fourth of an inch.

To find the *fissure of Rolando,* draw the base line and the lines for the great longitudinal fissure and the fissure of Sylvius. Then draw two lines perpendicular to the base line; one from the depression in front of the external meatus (Fig. 4862, D E) and the other (F G) from the posterior border of the mastoid process at its root. We shall thus have on the surface of the head a four-sided figure, bounded above and below by the lines for the longitudinal fissure and the horizontal limb of the fissure of Sylvius, respectively, and in front and behind by the two perpendicular lines just described. Next draw a diagonal line (F H) from the posterior superior angle to the anterior inferior angle. This corresponds to the fissure of Rolando, which, however, as a rule, does not quite join the fissure of Sylvius.

Cunningham[6] states, however, that this (Reid's) mode of locating the fissure of Rolando is not reliable, and I much prefer Horsley's or Hare's myself, both as more accurate and much more easily applied.

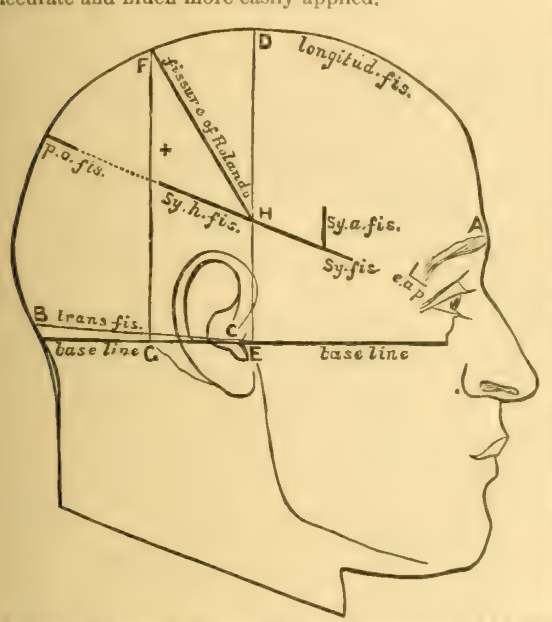

FIG. 4862.—A, Glabella: B, external occipital protuberance; *e.a.p.*, external angular process of frontal; B C, transverse fissure; A B, longitudinal fissure; *Sy. fis.*, Sylvian fissure; *Sy. h. fis.*, horizontal limb of fissure of Sylvius; *Sy. a. fis.*, ascending limb of fissure of Sylvius; D E, perpendicular line from depression in front of external auditory meatus to middle line of top of head; F G, perpendicular line from posterior end of base of mastoid process to middle line of top of head; F H, fissure of Rolando; *p. o. fis.*, parieto-occipital fissure; +, most prominent part of parietal eminence. (Reid.)

To find the *parieto-occipital fissure* continue the line for the horizontal limb of the fissure of Sylvius (Fig. 4862, *Sy. h. fis.*) to the line of the longitudinal fissure. The portion of this line, about an inch long, next to the longitudinal fissure, will usually approximately correspond to it. The position of the various convolutions can now be readily indicated by reference to Fig. 4863;

(Reid.)

Hare's Method.—Mr. A. W. Hare has pointed out that neither the cranial sutures nor the prominences of the face are available for mapping out the brain; the former, because they are too indistinct or obliterated, the latter, because they have no direct relation to the cranium as a whole on account of the unequal development. The same observation, he points out, is true of the bony landmarks on the lower portion of the skull. If the external auditory meatus or mastoid process have lines drawn on them over the convexity of the skull they will give inconstant results according as the anterior or posterior portions of the head are more or less developed. Four points, however, are of value, viz., 1, the glabella, which corresponds to the base of the anterior lobe of the brain; 2, the inion, which corresponds to the base of the posterior lobe of the brain, and also to the junction of the falx with the tentorium; 3, the third constant landmark is the external angular process of the frontal which limits the cerebrum laterally and has also a uniform relation to the fissure of Sylvius; 4, finally, the parietal eminence is valuable, since it marks the greatest lateral expansion of the brain, and bears a special relation to the supramarginal convolution. While its cranial relations vary considerably, its cerebral relations are much more constant. The distance from the glabella to the upper end of the *fissure of Rolando* will be 55.7 per cent of the total distance from the glabella to the inion. For instance:

If the distance from the glabella to the inion is	The distance from the glabella to the upper end of the Rolandic fissure will be
11 inches	6.1 inches
11½ ..	6.4 ..
12 ..	6.6 ..
12½ ..	7.0 ..
13 ..	7.2 ..

In other words, however the proportions of a head may differ, the pre-Rolandic and post-Rolandic regions of the brain are uniformly proportionate to one another, the pre-Rolandic being 55.7 per cent., and the post-Rolandic, 44.3. Moreover, the fissure of Rolando runs downward and forward at an angle of 67°, and its average length is 3½ inches.

Dr. Charles Wilson, of Tunbridge Wells, has introduced a cyrtometer (Fig. 4864) consisting of two strips of flexible metal forming a letter T, with a tape to secure the short horizontal limb in place, the mode of using which is shown in Fig. 4865. On the antero-posterior arm it will be noticed that there are two scales. The posterior scale is lettered in capitals from A to Q. The anterior scale is lettered in small letters from a to q, and they are so placed that from the glabella the distance from the glabella to small a, b, c, etc., is 55.7 per cent. of the distance from the glabella to capital A, B, C, etc. The instrument being placed on the forehead, so that its inferior border corresponds to the glabella, if the capital letter A falls over the inion, then the small a will correspond to the beginning of the fissure of Rolando, and so on for the other letters. The small strip for marking the fissure of Rolando is movable on the antero-posterior limb, and is [illegible] to [illegible]. This is now slid along until it corresponds, for instance, to the small a, when its anterior border marks the line of the fissure of Rolando. Similarly, if the inion corresponds to B or C, the Rolandic strip is slid to b or c, etc.

The Fissure of Sylvius.—To find this fissure a line is drawn from the external angular process backward to the occipital protuberance (Fig. 4866, Eap to OPr) by the shortest route between these points. This line dips a little toward the external auditory meatus in escaping the great convexity of the skull, which convexity lies in the course of the above horizontal line between these two bony prominences. It usually passes about half an inch above the meatus, and thus closely corresponds to the floor of the middle fossa at this point. In front of the meatus it lies above the level of the floor of the middle fossa; behind it, it runs parallel to, and nearly coincident with, the attachment of the tentorium and the posterior half of the lateral sinus. A point 1¼ inch posterior to the external angular process on this line marks the commencement of the fissure of Sylvius, [illegible] in heads of the most varied shapes and sizes this measurement remains constant. From this point a straight line to the centre of the parietal eminence marks accurately the course of the posterior limb of the fissure, and nearly corresponds in part with the squamo-parietal suture (Fig. 4866, SF). The ascending limb of the fissure corresponds closely with the squamo-sphenoidal suture in its entire length, and is continued upward in the same line for half an inch (A). The middle meningeal artery is also shown in Fig. 4866 in its relation to the Sylvian and Rolandic fissures. To expose the tip of the temporo-sphenoidal lobe, trephine behind the upper extremity of the great wing of the sphenoid (TS). To expose Broca's convolution, trephine immediately in front of the great wing of the sphenoid (B).

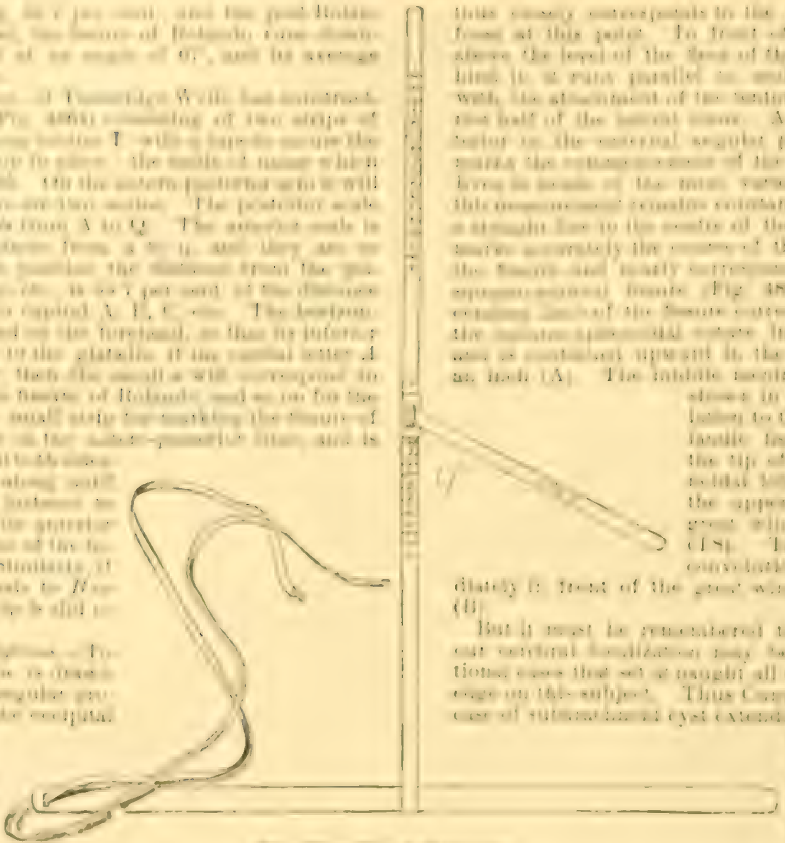

FIG. 4864.—Wilson's Cyrtometer.

But it must be remembered that however exact our cerebral localization may be, there are exceptional cases that set at naught all our present knowledge on this subject. Thus Cunningham[1] reports a case of subarachnoid cyst extending from the fissure of Rolando to the occipital lobe with neither motor nor sensory disturbance, and Bramwell[2] reports a case of sarcoma of the [illegible] destroying the greater part of the motor centre without any paralysis. These and a small number of

other such cases should make us careful not to be too dogmatic until we learn much more.

Percussion of the Skull.—Here, perhaps, as well as elsewhere, may be noted a point to which Macewen[9] has called attention, viz., that percussion of the skull may afford valuable evidence of the condition of its contents, and, as I have pointed out,[10] of the condition of the skull itself, and as I have observed in a recent case, of the overlying tissues.

Macewen does not state the character of the percussion note, but presumably it is that when an abscess or tumor exists, there will be a local, increased dulness on percussion with a lower tone. Macewen states that it has been verified post-mortem, and that it will probably be of especial value in early life in the diagnosis of tumors of the cerebellum. In a case of hydrocephalus I have lately observed a markedly increased dulness of one side on percussion, and the post-mortem showed that the ventricular distention was far more marked on this side.

In simple fracture of the skull the "cracked-pot" sound described on p. 223 of this paper may be of service, and I would urge that it be tested and reported on in future cases.

In a case of syphilitic necrosis of the skull above the left ear, with a Jacksonian epilepsy in the left arm and leg, and therefore a presumable lesion (gumma ?) on the right side of the brain, I have recently tested the percussion note. Over the necrosed bone the tissues were somewhat thickened, but not to any excessive degree. The percussion note was so much duller on the left side, half way between the sagittal suture and the ear, that two of my assistants with their backs turned to the patient correctly stated which side was percussed, and the same difference was noted as between the same site and the forehead well above the frontal sinus. In a paper[11] published in 1884, I have pointed out the similar value of percussion in the so-called abscess in the frontal sinus and the antrum.

GENERAL TECHNIQUE OF OPERATIONS ON THE BRAIN.—This has been carefully formulated by Horsley.[12] In a few minor points[13] I have added to it from my own personal experience, as well as that of others.

I. *Shaving the Head.*—This is not only important for the operation, but should always precede a definite diagnosis, and, in fact, be one of the means of making it. So important do I regard this, that I should consider no diagnosis as assured, and no operation warranted, that had not been preceded by shaving. The unexpected and the unknown scars found have surprised me in several cases. Besides this, no reliable mapping on the head of the fissures and convolutions can otherwise be made. These should always be marked on the skull by an aniline pencil.

II. *Antiseptic Preparation of the Patient.*—The day before the operation the patient's head should again be shaved, scrubbed by a nail-brush with soap and water, next with ether, and then be covered with a wet sublimate dressing (1 to 2,000), retained in place by a bandage till the time of operation. Formerly I used, as Horsley advises, a solution of 1 to 1,000, but I have found that the recently shaved scalp is so tender that an eruption was often caused by it—a dangerous prelude to an intra-cranial operation. This scrubbing must be gentle, but thorough. The operation-room should be uncarpeted and should contain only necessary furniture, the walls and ceiling should be carefully wiped the day before, and all the wood-work and furniture scrubbed with carbolic solution. Clean sponges that have been disinfected and kept in a carbolic solution (1 to 20) should be used, and best with a sublimate solution (1 to 1,000) at the operation. The instruments may be disinfected either by boiling for fifteen minutes, or by lying for an equal length of time in a carbolic solution (1 to 20), and then transferred to boiled water sufficiently cooled to permit of their being handled. The spray may be entirely omitted—on this point I speak advisedly. The head should be washed with soap and water, ether, and sublimate solution, a second time just before the operation. The hands, and especially the finger-nails of the operator and of everyone of the assistants, should be most carefully cleaned and then disinfected by soap and water then dipped in alcohol, and while wet be scrubbed with a sublimate solution and nail brush. So efficient is this disinfection that in one of my brain cases both I and my chief assistant being compelled to operate upon a case of fecal fistula the day before the brain operation, we repeatedly disinfected our hands before the operation on the brain, and the patient was out in the street on the eighth day.

III. *Anæsthetic.*—Horsley specially advises the use of chloroform, but in the eleven cases that I have thus far operated upon, I have used ether and found no reason to regret it. Horsley[14] cautions us that when the dura is opened there is a special sensitiveness to the action of an anæsthetic (chloroform only ?) and that special care should therefore be used not to give too much.

As a preliminary Horsley advises that a quarter of a grain of morphine be injected under the skin from a half hour to an hour before the operation, both because a smaller quantity of anæsthetic will be required, and also because it produces contraction of the arterioles, and consequently diminishes hæmorrhage. As Nancrede has pointed out, however, the use of opium, at least in cases in which a small definite cortical centre is to be removed and but little hæmorrhage is anticipated, is not advisable. Horsley[15] states that it is dangerous to operate upon patients under the influence of drugs, and especially the bromide of potassium ; why, I do not know ; but I should be inclined to follow so high an authority. In my own operations I have also used (and I think with advantage) ergot by the mouth, of which I would advise a dose of from two to four drachms.

IV. *Marking the Bone.*—This can be done in two ways : 1. The site of the scar or other lesion is easily marked by making a small incision down to the bone and then marking it by an aniline pencil as done by Weir ; or better, I think, as I have proposed, by nicking the bone by a gouge. To mark the Rolandic and other fissures of the brain, the same method may be employed by means of two or more small nicks. These nicks may also be useful in other ways. In my first case (tumor), as I was not able to replace the button of bone, I utilized the nick to fix accurately the location of the tumor. There was a scar, the situation of which was exactly determined by measurements. A nick on the button of bone was made at the site of the scar. After the operation the button of bone was fitted to the tumor, and the dimensions of the tumor measured from the nick. These measurements were afterward transferred to another skull, upon which the site of the scar was accurately fixed, and upon which, also, the fissures of the brain had been marked. I was thus able to locate, with great accuracy, the position of the tumor. 2. Another method of marking the fissures (especially the Rolandic) is by drawing them on the scalp with an aniline pencil, and prolonging the lines above and below the limits of the intended flap. When the flap is raised all the other external landmarks are practically lost ; but a nick in the bone, or an imaginary line adjoining the aniline lines of the Rolandic fissure beyond the limits of the flap, will give us this important landmark.

V. *Access to the Brain.*—Instead of the old crucial incision Horsley has recommended a large horse-shoe-shaped flap, which will usually be about three inches or more in diameter. This incision must be carried vertically down to the skull, and must be so made, first, as to favor drainage in the supine position. Secondly, its base should be so placed as to retain the most favorable blood supply to the flap. Horsley has recommended that the periosteum be not raised with the flap, but reflected by a later crucial incision. I have, however, always reflected the periosteum with the flap, and have found no ill results. It is a cardinal principle in the new cerebral surgery, that both the flap in the scalp and the opening in the bone shall be ample. The mode of dealing with the bone will be mentioned later ; but let it once for all be stated that a large opening in the bone has been amply proved to be no more dangerous than a small one, and an immense advantage can be gained in locating the fissures and the convolutions (and therefore the lesions), and, so to gress in the direction of "silent areas" for operative procedures. This is of the greatest practical service.

Different methods, however, may be adopted for making the opening in the bone. A large trephine, one and one-half, two, or even two and one-half inches in diameter, may be used. If the smallest of these sizes be used, it may necessitate the removal of two adjacent buttons, and even then the opening may have to be enlarged in any given direction for access to the lesion. This is best done by the ordinary rongeur forceps, or by Hopkins's modification of them. These forceps have

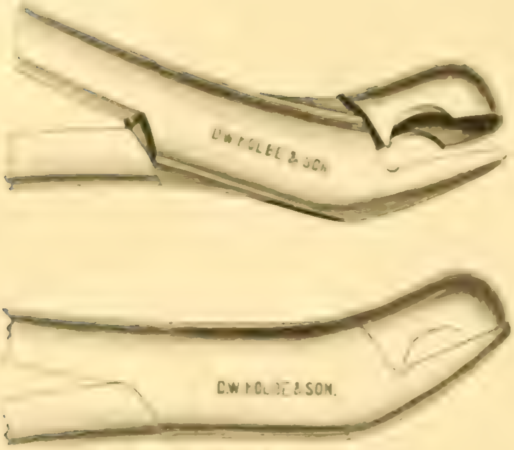

FIG. 1867.—Hopkins's Rongeur Forceps.

been further modified (and I think with advantage) by Weir, by making the bend at right angles to the handles of the forceps instead of in their plane.

Another method is one that Mr. Horsley has lately used, and which has the advantage of abridging the time required for the operation. He makes a one-inch opening with a trephine, and by this determines the thickness of the skull. He then outlines the piece of bone to be removed, by Bonwill's surgical engine, cutting almost through the bone. Complete division of the bone is then effected by stout bone-forceps.

The German surgeons frequently use the chisel and hammer, but this I certainly consider dangerous, both on account of the possible contusion of the brain and also from the mechanical violence required by the chisel.

Of course, in trephining for abscess only a three-fourth inch trephine would be necessary, and the opening can be enlarged, if necessary, by the rongeur forceps. For tapping the ventricles a half-inch opening is ample. V. Bergmann has declared himself opposed to operative interference with a cerebral tumor which would require a large opening in the bone, on account of the probable subsequent œdema. The best answer to this is that success has practically followed operations in which large openings have been made and, as a rule, no œdema has followed. Horsley has thus successfully removed a tumor of four and a half ounces, and I have done the same in a case of a tumor weighing [illegible]. Indeed, in some cases pre-existing œdema has been relieved.

It is quite surprising how far beyond the limit of the opening in the bone and dura we can feel and see. The brain admits gentle pressure very readily. A finger can be inserted for nearly an inch all round the opening, and the eye can reach as far if the brain be gently depressed by any flat instrument.

Before enlarging the opening the dura mater must be separated from the bone. This can be done with a blunt probe, but the best instrument is one devised by Horsley (Fig. 1869), for it uses the under-surface of the surrounding bone as a fulcrum for any lever-like use.

The dura should, as a rule, be opened. Unless this is done important information may be lost, and the case be improperly treated. Occasionally it may be allowed to remain intact, when, for instance, a sufficient lesion has been discovered. But it is a rule, with rare exceptions, that if we trephine at all, the membrane should be examined. The opening in the dura should not be by a crucial incision except in case of a small opening for abscess of the brain or draining the ventricles, but by a horseshoe-shaped incision at about a quarter of an inch away from the margin of the bony opening. The dura should first be lifted by a tenaculum and slightly opened by a scalpel, and the incision then be completed by a pair of blunt-pointed curved scissors. The dura should be carefully lifted by forceps so as not to wound the veins beneath, and the same caution applies to the scissors. Should it be necessary to cut across the trunk or any branches of the meningeal arteries, they should be secured by ligatures passed through the dura mater by a needle, and tied before the vessel is cut across, the dura being well lifted meantime, lest the needle wound the large veins in the brain. When the operation is terminated, if the dura has not been removed, it should be replaced and secured by catgut. To facilitate this I have had made a small curved needle with an eye in the point. This, I find, answers admirably. The ordinary needles are of too large a radius.

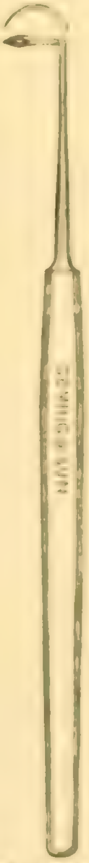

FIG. 1868.—The Author's Dura Needle.

VI. *Hæmorrhage.*—Hæmorrhage from the scalp will be very free. It can to a large extent be prevented in many cases by the use of the narrow band furnished with Esmarch's bandage, as has been suggested by Dr. M. Allen Starr. Hæmostatic forceps, however, can with safety grasp the entire thickness of the scalp and quickly control any large vessels. Such as need it, of course, should be ligated at the end of the operation. To control hæmorrhage from the vessels of the brain, one of the most difficult of all the operative questions, I have already alluded to the use of morphine and ergot. I have also used a solution of cocaine applied directly to the brain. I have also suggested the use of antipyrin, which has been employed by [illegible] with advantage. Such solutions, together with the sponges and the bottles, should be sterilized. These applications have certainly proved advantageous in checking hæmorrhage from the smaller vessels, nor could I see any harm resulting from them when I have used them. The cocaine should be a ten per cent. solution. Another means is boiling water cooled to 110° or 120° F. This I have used very liberally and have found no disadvantage from the comparatively high temperature. Pressure is another means which can be constantly and successfully applied by sponges or by iodoform or other gauze.

But after all, the chief reliance is to be placed on ligatures of catgut. They should not be chromicized, but prepared after the manner of Kocher or Martin. The method of applying them is very important. While the larger arteries in the brain can be ligated in the usual way, the veins, which are very large, very full, and very fragile, are a much more troublesome source of hæmorrhage, and require much more delicate manipulation. The greatest gentleness must be used during traction; and in tying, the traction on the two ends of the ligature must be exactly even or the vessel will be torn. In addition, the knot must only be drawn tight enough to stop the hæmorrhage, for if drawn too tightly it will easily cut through the fragile vessel. Weir has suggested in some cases the application of clamps to the vessels for twenty-four hours. My experience makes me doubt whether they would hold in such fragile tissue. The tossing of the patient's head might also displace them and involve a possible danger to the brain itself. Besides this, they would interfere with the immediate closing of the wound, which is especially to be sought in order to avoid a hernia cerebri and secure the most rapid healing possible of the wound.

It is occasionally necessary to trephine very near, or even over, one of the great sinuses of the brain, and in doing so it might easily be wounded. The sinus, however, may be avoided if due care be used. The trephine should be applied far enough from the sinus to be in a region of absolute safety. The opening can be enlarged later toward, or even over, the sinus with safety. In a recent case I recognized when I was near the lateral sinus by feeling the bony groove in which it is lodged by my finger introduced through the trephine opening. I could then separate the dura and sinus from the bone and could have trephined safely over the sinus, had it been necessary. In addition to this we may have to deal with a primary wound of a sinus itself. If the opening in the sinus is small, lateral ligation of the sinus may be practised, as has been done by Parkes[16] and Brinton.[17]

Pressure by a tampon of iodoform or other gauze has controlled it in a number of instances.[18] In some cases the sinus has been tied by two ligatures, one in front and one behind, thus cutting off all possible hæmorrhage, and the sinus excised as by V. Bergmann and Küster.[19] Barr[20] has even suggested that in cases of thrombosis of the lateral sinus we may purposely open it after ligation, clean out the clot and remove this portion of the sinus. Considerable further experience will be necessary before we can decide whether this will be of any advantage. Its possibility, however, as a surgical procedure seems well assured. Care should be taken that no air enters the sinus lest sudden death should follow, as in Volkmann's case.[21] In the same volume a series of nine experiments are reported on dogs by Genzmer, in which there was aspiration of air in six. See also Senn's experiments.[22]

VII. *Treatment of the Brain.*—The first practical point to notice, after the dura is opened and hæmorrhage controlled, is whether the brain *bulges* into the trephine opening. If it does so, it indicates a pathological increase of the intracranial pressure, a fact of the highest importance, since it will indicate either a tumor, abscess, blood clot, or dropsy of the ventricles. Bulging of the dura before opening it, is, of course, equally significant.

Next, the *color* of the brain should be observed. A yellow tinge or lividity will probably indicate a tumor beneath the cortex. If the brain tissue be the seat of an old laceration its color will be altered, usually a dirty yellowish-brown. Next, the condition of the vessels and the perivascular lymphatics must be observed, and particular notice be taken if there are any yellow-white patches on them that may indicate any old mischief. Sometimes the membranes and convolutions will be densely matted into a yellowish cicatrix. In a number of cases I have seen *œdema of the membranes* sometimes so great as to obscure the sulci and convolutions to a marked extent. Precisely its significance, how far it is normal and how far pathological, I do not yet know. Nicking or snipping the membrane allows the serum to escape, and the sulci and convolutions to be recognized.

Next, the *density* of the brain must be appreciated by the touch. If there be an abscess or dropsy of the ventricles the elastic tension will be increased, but, at least in dropsy, it will be very soft. If there be a large tumor the brain substance will be more resistant and dense than normal. But it must be remembered that a small cerebral tumor at any distance beneath the cortex can scarcely be detected by this means. Should any hardness be detected, the brain substance must be incised and careful search instituted by the finger for the tumor or other pathological condition. If the finger be used it should be the little finger by preference, and great gentleness should be employed, or serious laceration of the brain substance will be produced. If abscess or dropsy be suspected the brain may be explored by a needle, knife, or grooved director. (For their comparative value, see p. 217.) Wright,[23] after trephining over the occipital lobe, even thrust a trocar through the tentorium down into the cerebellum and evacuated an abscess—a procedure I should not employ; trephining over the cerebellum itself would have been safer and better.

Next, the presence or absence of *pulsation* in the brain is to be noted. If a large tumor, abscess, or cyst exist it will be absent, but if a small tumor, cyst, or abscess be separated from the surface by any considerable layer of normal brain tissue, pulsation may be present. Altered brain tissue from old lacerations, etc., will generally pulsate.

In incising the brain, the knife should be carried down vertically into the corona radiata in such a manner as to avoid damage to the fibres coming from adjacent portions of the cortex, and the incision should run as nearly as possible parallel with the cerebral vessels which are "terminal."

Should the brain tissue be abnormal, the whole abnormal portion must be removed. It is important in doing this to remember that, while we should guard against producing any needless paralysis by removing healthy brain tissue, yet it is of prime importance that *all* of the diseased portion should be removed. If there be a cortical tumor (unless it is encapsulated or otherwise definitely limited), the necessity of removing a portion of adjacent and apparently healthy brain tissue, so as to get beyond the limits of infiltration, is of the greatest importance. If the tumor be subcortical, it can be sought for by the finger with great gentleness, and be removed either by a sharp spoon or other similar means, together with a suitable adjacent zone of healthy brain tissue. In all this removal of tissue adjacent to the tumor we can cut much more freely antero-posteriorly than vertically. In the vertical direction we encroach far more quickly upon adjacent additional centres than we do in the antero-posterior direction.

VIII. *Recognition of the Brain Centre Sought for.*—In certain cases of Jacksonian epilepsy the object sought for is the removal of the centre whence the discharging lesion starts. In this case it will be necessary to recognize such centres by definite methods. In some cases the membranes and the convolutions are so matted together, and the brain substance so altered, that it will be impossible to recognize the sulci and the convolutions. But in these cases it is scarcely necessary to do so, inasmuch as all the damaged tissue should be removed, and, as before stated, we must even encroach to some degree upon apparently healthy brain tissue. In other cases, however, it is important and also possible to recognize the individual sulci and the convolutions, and to determine the precise part of the brain that is the seat of the discharging lesion, and therefore to be removed. The prolonged aniline lines on the undisturbed portion of the scalp, indicating the position of the fissure of Rolando, or the reapplication of the cyrtometer will here assist us very materially.

In only four published cases, up to the writing of this paper (December, 1888), has this been done, viz., by Horsley,[24] Keen,[25] Deaver and Lloyd,[26] and Nancrede,[27] and in each case most satisfactorily. This is best accomplished by means of an ordinary faradic battery. In order more handily to use this means of diagnosis, I have had made a little rubber handle with two insulated points, the stems of which, being flexible, can be bent toward each other or separated as far as desired (Fig. 1870).

A very important point in this relation is stated by Horsley as the result of his experiments on animals. The cortex of the brain soon loses its excitability to electricity almost when bathed with antiseptic solutions. In any such case, therefore, it is desirable that the search for such cortical centres, by means of electrical stimuli, should be done immediately after the opening of the dura, and before any antiseptics have been applied. Possibly hot water may be necessary to check the bleeding; but experience will have to decide whether this also may not dull the excitability of the cortex, though it does not seem probable that it does. When such centre is found, I have suggested, in order to prevent the need for repeated and possibly injurious applications of electricity, that the desired centre be marked by an aniline pencil or a stitch. If the centre is to be preserved the latter would do no harm.

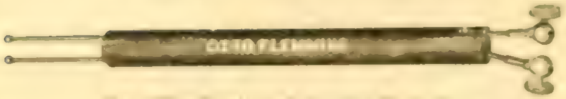

FIG. [illegible].—The Author's Insulated Electrode.

IX. *Photography of the Brain.*—This can readily be done by an ordinarily expert amateur. Dr. Morris J. Lewis and Dr. J. K. Mitchell have helped me in the several cases which I have photographed, and we were of the opinion that the exposure should be practically instantaneous, and with the most sensitive plates made. Even with such plates there may be difficulty on a cloudy day, and the danger of the patient's moving and the constant oozing of the blood, make it necessary to have the shortest exposure possible. "Flash powder" (Blitz Pulver) or the very handy magnesium flash-lamp may be used; but if employed, the possible firing of the ether should be borne in mind. In the hands of a competent assistant, the photographing is scarcely any interruption to the operation. But I have been disappointed in the results. It has given me no good details of the field of operation, owing chiefly, I think, to the wet, glistening curved surfaces, and the deep shadows at the point of excision. I would prefer to have a rapid sketch made by a good artist, who is at the same time an anatomist.

X. *Drainage.*—The question of drainage of the brain is a most important one, but should be conducted on precisely the same principle as drainage for other parts of the body. It can be dealt with in two different ways. How important it is may be seen by the fact that in 20 cases of trephining reported by Amidon, in which free drainage was employed, 18 (ninety per cent.) recovered; while in 29 fatal cases, in only 2 (6.8 per cent.) was drainage specifically mentioned, and in the other 27 (93.2 per cent.) no mention is made of it; but it should be added that 11 of these were almost certainly fatal.

(1) In case of removal of a tumor or of a portion of the brain substance for epilepsy, or for oedema, the best results are obtained by combined tubular and capillary drainage, as described by me in a paper read before the Philadelphia Academy of Surgery.

Mr. Horsley has insisted that, in such wound cavities, drainage should not be carried on by the tube for more than twenty-four hours. The arguments that he presents in his papers above referred to, and from which I have freely drawn, are in favor of this method of procedure, and have been verified by results in a number of cases. Drainage is especially important in cerebral surgery, where we wish to secure union by the first intention, and thus to secure a certain amount of counter-pressure on the brain, which is tending to force itself out of the opening by intracranial pressure, and produce hernia cerebri. We also desire that the flap of skin shall be separated from the brain beneath by a cushion of soft connective tissue. These conditions are best obtained by allowing a certain amount of [illegible] in the wound [illegible] within the cavity. During the first twenty-four hours there is steady oozing of blood and serous fluid from the cut surfaces. This is best removed by a rubber drainage-tube at the most dependent point of the incision, as the patient will lie in bed. Before closing the wound, I therefore always introduce a rubber tube of about the calibre of a lead-pencil, and alongside of it a bundle of horse-hairs. As is my habit in all other wounds, I dress it at the end of twenty-four hours, and at that time remove the tube, leaving the horse-hairs in place. If the wound fluids subsequently collect in the cavity to any extent, so that the patient complains of pain and throbbing in the wound, Mr. Horsley gently opens the track of the drainage-tube with a probe, and relieves the tension in this manner, without at the same time producing an opening large enough to permit a hernia cerebri. My own method is to retain the horse-hairs in place for about three to five days. They are not irritating, and they serve the purpose of slight capillary drainage, after the same fashion as the probe. In his later operations for the removal of tumors or epileptogenous centres, Horsley has even omitted all drainage except by the omission of a stitch or two, and has trusted that the arachnoid, like the peritoneum, will absorb the effused fluids. Of course, in case of abscess, wounds, intracranial haemorrhage, etc., drainage must be most carefully provided for even by counter-openings, and be much longer maintained, as pointed out in those sections.

In cases of operations on the brain I have usually, but by no means always, found considerable bulging of the flap during the first few days after the operation. This bulging, if it does not become too great, is not to be interfered with. If the wound is reopened, at the end of a few days (as I did in my case of tumor, and I now think unadvisedly), we shall find a cavity filled with delicate, spongy, pink, connective tissue, which forms an elastic barrier between the scalp and the brain. The horse-hairs pass through this tissue, and by their slight drainage remove any undue exudation.

(2) In cases of abscess, gunshot wounds, haemorrhage, etc., or in cases where there is danger of infection, the drainage must be more prolonged, and is best accomplished by rubber tubing. For the method of drainage in these conditions the reader is referred to other portions of this paper under the headings mentioned.

XI. *Replacement of the Bone.*—The wisdom of replacing the bone is still a question *sub judice*. Mr. Macewen first showed the possibility of replacing the bone by mincing it up into small pieces and spreading it over the surface of the reunited dura. Clark, of Glasgow, was the first, I believe, to replace the entire trephine button with success. In the case of replacement the utmost care, however, must be given to the button from the moment it is removed to its replacement. The instant that it is removed it should be placed in a cup containing a warm solution of bichloride (1 to 2,000), or an equivalent solution of carbolic acid (1 to 40), or artificial blood serum, as suggested by [illegible]. This cup should be placed in a large basin in which lies a thermometer, and hot water be poured into the outer basin from time to time to keep the temperature always between 105° and 100° F. It should be the duty of one assistant to attend to nothing else but to the water in this basin. All small fragments are also placed in this cup, and when the dura has been sutured the large disks of bone may be replaced, together with a suitable number of the small fragments bitten away by the rongeur forceps. If there be more than one large button, unless it is absolutely necessary, the triangular spur or spurs between the trephine holes should not be removed unless necessary to get more room, as they assist materially in keeping the buttons in their proper places. Should the pericranium be removed, the bone cannot be thus replaced. In one case, I successfully adopted the following expedient: I bored the centre-pin hole completely through the bone, and at the margin of the disk made another hole, also by the centre-pin of the trephine. The two ends of a chromic catgut ligature were passed through these openings, and by needles these two ends were passed through the scalp and tied on the outside. The union to the scalp was complete, and the aperture in the skull was almost entirely closed by the callus. If the opening, after removing the disk of bone, has been enlarged by the rongeur forceps, the small fragments cannot be secured in this manner, but it is entirely possible to fill up any small gap by a button from the back of a lamb's skull, trimmed by a rongeur forceps to suit the opening, and secured in the same way; I find that the back of a lamb's skull has nearly the same curve and thickness as a man's. One good button can be gotten from it, and it is possible that two might be obtained at a pinch.

In my third case I replaced a large button and about fifteen pieces bitten out by a rongeur forceps, and the skull was so completely restored that, excepting for the scar and a slight flattening of the skull, one would not know that it had ever been trephined. Figs. 4871 and 4872, in the so far unique case of Burrell,[31] show how complete the union may be after replacement of a trephine button. Further experience will prove whether the restoration and integrity of the skull, together with the slight flattening which probably will always accompany it, is more desirable than leaving the aperture protected only by the scalp. The restoration of the skull to its natural condition would seem to be most desirable, but inasmuch as some flattening may, and in most cases does, take place, whether this will do any harm is a question which must be decided by a larger experience. If the skull prove to be very thick, and chiefly of compact tissue, I should certainly very much question the advisability of replacing the button of bone. One such case I have known to become necrosed after seeming union for about ten weeks, but there were other complications in this operation which vitiated the result, independently of the character of the bone-disk. In case the bone is not replaced it will be well for the patient to wear a skull-cap into which is sewed a metal plate somewhat larger than the opening, as a protection against blows and falls. If a drain-tube has to be placed under the bone, a piece should be bitten out of its edge by the rongeur forceps to allow for the passage of the tube.

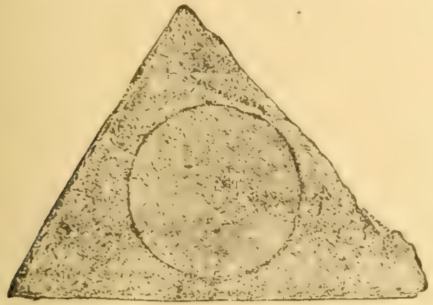

FIG. 4871.—Replaced Button of Bone. Inner surface.

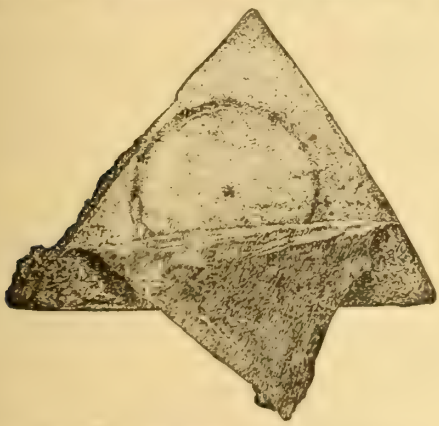

FIG. 4872.—Outer Surface of the same Button.

XII. *Closure and Later Treatment of the Wound.*—Hæmorrhage having been checked, the dura sutured as described on p. 210, and the bone replaced with provision for drainage, the scalp should now be replaced and secured with either catgut or disinfected silk sutures, with a number of strands of horse-hair placed between the scalp and the bone. An abundant dressing covered with "rubber dam" or "mackintosh" (though on account of the cloth in the mackintosh I prefer "rubber dam") is to be applied and retained in place by suitable bandages. The dressing will most probably be saturated with blood and serum at the end of a few hours. If so, the wound should be redressed. At the end of twenty-four hours the wound should always be redressed, when, as already directed, the drainage-tube is to be removed. The next dressing should not be done until the wound fluids have saturated the dressing to its margin. Should this not occur, however, by the fifth day, it is my rule then to redress the wound for the purpose of removing the horse hair, and also any stitches that may be no longer needed. In operations on the brain in which the bulging above referred to has produced some tension on the stitches, it is best not to remove them too early; but usually they may be taken out by the seventh or eighth day, and some of them by the fifth. If by the fifth day primary union has been secured, a mere protective sublimate dressing may be applied. In a few days this may be dispensed with, but the patient, on account of his shaven head, should wear a skull-cap, or some other means against taking cold.

XIII. *Rapidity of Recovery.*—If the case be not one with active inflammation, and if union by first intention has been secured, the patient should be well within a week or ten days, without an elevation of temperature much above 100° F., and possibly not even up to that point. The bowels and the diet should receive the ordinary care.

One thing is of the greatest moment after such operations. No excitement, study, business, household cares, or mental worry should be permitted for several weeks, or, better, for several months, after the operation. As yet, it is too early in the history of cerebral surgery to dogmatize upon this point, but we should certainly keep on the safe side and bar out any possible cause for harm for a long time.

XIV. *Secondary Operations.*—A few of these have been done. Mr. Horsley has referred to some in his paper. Nancrede[27] has reported one, and Stokes[4] another by Franks. The membranes will commonly be found to be quite adherent to each other and to the brain tissue, and if it be necessary to dissect them off the latter, it is almost inevitable that some portion of the outer layer of the cortex will be removed along with them, producing paresis in the centres thus encroached upon; hence, it should be done with the greatest gentleness and care. The cicatricial tissue between the brain and the bone very likely will be quite vascular, and, possibly, traversed by large veins. Should the dura not have been opened at the first operation, it will still be adherent to the brain itself, and probably covered by a layer of granulation and cicatricial tissue, which must be dealt with according to the needs of each case.

XV. *The Limits of Operative Interference with the Brain.*—Just how far we can safely interfere with the bones of the skull and with the brain, is as yet a question *sub judice.* Twelve years ago I perforated the squamous bone and passed a probe between the dura and along the petrous bone to a depth of two inches, in a search for an abscess. I found no pus, but the search did neither good nor harm. Weir[32] has proposed, in a case of aural disease with subsequent cerebral mischief, in a similar manner to lift the dura to a point corresponding to the roof of the tympanum; and if need be, in suppurative meningitis of the middle fossa, to open the dura and drain the fossa. He has well likened the petrous bone to the appendix vermiformis, as a focus of inflammation followed by suppurative processes in the dura or arachnoid, either local or general. It is followed, therefore, by external pachymeningitis and extra-dural abscess, internal suppurative meningitis, or cerebral or cerebellar abscess, all of which he suggests may be similarly relieved by operation. (See Extra-dural Abscess, p. 217, for the realization of this suggestion in that form of disease.) The same [illegible] has [illegible] and I have verified the [illegible] partly on the living and partly on the cadaver, that the cerebellum can be lifted far enough to obtain a view nearly to the foramen magnum; the same foramen can be reached by the finger on the inside, and from the outside both by the eye and finger; the longitudinal and lateral sinuses can be safely uncovered and separated from the skull, and the frontal lobe can be lifted far enough to expose the anterior clinoid processes.

Horsley has reached an aneurism of the artery almost at the optic foramen, and has stated that the tumor of the auditory nerve reported to the Neurological Society of London by Dr. Sharkey, could have been removed by division of the tentorium and ligature of the lateral sinus.

Other cases, in this paper and elsewhere, show that the sinuses may be torn and crushed; a very large part of the surface of the skull, up to even the size of the palm, or even more, may be taken out; large tumors, up to over four ounces, may be successfully removed, and considerable areas of brain tissue may be cut away with safety and advantage. How far this latter interference may be carried we cannot yet say with certainty, but in the at present so-called "latent zones," at least, it is probable that the interference may be much larger than is now believed.

A large portion of the base of the brain can certainly be explored by the finger, the eye, and the probe or director, and the substance of the brain can be punctured almost with impunity, repeatedly and to a depth of two and one-half inches, without leaving any injurious trace behind.

I have shown also that the lateral ventricles can be safely reached. Baldwin's case (p. 229) shows that even a wound involving them is not necessarily fatal.

Experience will doubtless add much to the above possibilities.

CEREBRAL ABSCESS.—In the first volume of this HANDBOOK there is a valuable article on Abscess of the Brain, to which I must refer the reader for more detailed information than I shall be able to give. But in the three years that have elapsed since that paper was published we have made great progress in the diagnosis, and especially in the treatment, of cerebral abscess, and this will justify somewhat of a seeming repetition.

Causes.—Nearly one-half of the cases of abscess of the brain arise from a suppurative process in the ear. Occasionally they arise from its acute inflammation; but much more frequently they are a sequel of chronic ear disease. Occasionally they will follow even a few weeks after suppuration, but they are far more commonly a sequel years after scarlet fever, or some other exanthem, has set up a discharge from the ear. The situation of such abscesses is most frequently in the temporo-sphenoidal lobe.

Barr, in 76 cases of cerebral abscess following disease of the ear, found 55 in the temporo-sphenoidal lobe, 13 in the cerebellum, 4 both in the cerebrum and cerebellum, 3 in the pons, and 1 in the peduncle. When situated in the temporo-sphenoidal lobe they are not necessarily directly in contact with the petrous bone, but may be separated from it by even an inch of apparently healthy brain tissue. They reach the cerebellum usually by the track of the lateral sinus, in which very often thrombosis occurs. The mastoid cells are very frequently, but not always, involved. The discharge is almost always fetid.

The next most frequent cause is injury. Frequently this injury has not been very severe, but even a small scalp wound, if it becomes septic, may involve the bone, the veins, or the [illegible], and then the encephalon. Moreover, if recovery apparently takes place, the patient is by no means safe, as a number of instances are on record where several weeks or months, and in some instances even a number of years, have elapsed between the infliction of the injury and the development of the abscess. A most remarkable case of late development of abscess, and of its correct localization, is given by Mr. Reginald Harrison in the *British Medical Journal*, April 21, 1888. A boy, aged *fifteen*, had received a severe blow on the *left* side of the head when *four or five years of age*. No severe symptoms followed the accident, but nine or ten years later, for about a year before his admission, twitching and flexion of the wrist, biceps, and deltoid, had been observed. Eight days before his admission he had received a blow on the right side of the head from a pair of tongs. Three days after this accident a convulsion on the right side of the body suddenly set in, beginning in the arm, then spreading to the face and leg, and followed by paralysis of the right side of the body. Repeated convulsions followed his admission. Mr. Harrison trephined the boy, *not* at the site of the last, but at the *site* of the *first* injury, and eventually evacuated four drachms of fetid pus, and the boy made an uninterrupted recovery. Macewen (loc. cit.) reports a remarkable case in which an acute abscess developed later in the periphery of an old encysted abscess. After evacuating several ounces of pus, the old abscess appeared "like a tennis-ball floating in a sea of pus." Wagner (loc. cit.) gives two cases of abscess arising seven and nine years respectively after falls without any external wound; and [illegible] reports one of abscess arising eleven years after a fracture of the skull.

If the injury is followed by meningitis, this will usually develop within three or four days; but should it result in abscess rather than in meningitis, it will not usually form earlier than at the end of the first week. The situation of an abscess after a blow or fall is almost invariably under the site of the injury, but, as is shown by Macewen's earliest case, Harrison's, and others, the location of the abscess must be fixed by considering not only the site of the injury, but the focal symptoms as shown by cerebral localization—*e.g.*, in Macewen's case the abscess was in Broca's [illegible], but the cicatrix was on the forehead.

Still another occasional cause is localized meningitis. Of this perhaps the most instructive case yet recorded is that found in the very able paper of Mr. A. E. Barker,[36] in which the pus, accumulating [illegible] between the island of Reil and the operculum, produced upward pressure on the motor centres for the face and arm. Complete recovery followed the operation.

Metastatic abscess occurs not infrequently in the brain as a result of various conditions, even in distant organs, such as gangrene of the lung, fetid bronchitis, and bronchiectasis. Tubercular abscesses, also, are sometimes seen, but in both these cases the abscesses are usually multiple, and hold out but little hope for any successful surgical treatment. Wernicke and Hahn and Fränkel have reported two cases of tubercular abscess which were single.

Symptoms.—The symptoms of cerebral abscess may be arranged in three categories. First. Those due to the suppurative process itself. Secondly. Symptoms arising from general pressure. Thirdly. Focal symptoms.

First: Among the symptoms arising from the suppurative process itself, the most important is fever, and it is especially noteworthy that the temperature is either normal or subnormal most of the time, even when the gravest cerebral symptoms exist. The temperature, however, does sometimes rise, especially towards the end, often attended by delirium, but will generally subside quickly, only to rise again after an interval if the patient survive long enough. V. Bergmann and others state, however, that the local cranial temperature in abscess will rise. If, therefore, symptoms of serious intracranial pressure exist, if the general temperature is normal or subnormal, while the local temperature shows a rise and the pulse is slow, the first thought of the surgeon should be to seek for evidence of abscess of the brain. A chill not uncommonly occurs, but may be absent. Of course, there will be loss of appetite, vomiting, general malaise, etc. [illegible] has stated that when pus is present in the brain, the chlorides in the urine will be below the norm and the phosphates above, but I know of no confirmatory examinations of this important assertion.

Secondly: Among the pressure symptoms, headache holds an important place. It is almost invariably present, and not uncommonly of an extreme and severe type, so that the patient will constantly moan ; and if he be sufficiently intelligent, this will be the one thing of which he will complain. It is apt to become worse, and when the temperature occasionally rises it is often located distinctly at the focus of the lesion, but sometimes is general. It does not, therefore, always serve as a guide to the situation of the abscess. The pulse is almost always slow, and may even fall to thirty or forty in the minute. Respiration is often of the Cheyne-Stokes type. The mental condition is very soon impaired, and gradually, as the pressure increases, becomes worse and worse until the patient may become comatose. Not seldom the bowels and bladder will be evacuated involuntarily. Convulsions of an epileptic type often occur, but not usually when the abscess is situated in the temporo-sphenoidal lobe. Sometimes convulsions will be the very first acute symptom. Muscular twitchings may occur, and if so, their occurrence will often point to the cortical centre involved. Sensation is not usually much impaired.

The presence or absence of choked disk does not seem to be pathognomonic, as it is sometimes present and sometimes absent. When present, even if bilateral, it is almost always more marked on the side of the lesion, though this is sometimes reversed. Not uncommonly there will be ptosis, and sometimes paralysis of the entire third nerve, while the sixth may escape ; though sometimes the reverse is the case. The pupil of the same side is generally dilated, and more or less immobile. Almost all the symptoms of pressure vary from time to time, and the patient's general condition fluctuates in a remarkable degree, sometimes simulating recovery, soon to relapse again into a worse state than before. Theoretically, there should probably be deafness of the opposite ear if the first or second temporal convolution is involved ; but this symptom is very uncertain.

When the abscess is situated in the cerebellum, the diagnosis is apt to be very obscure. Occipital headache and rigidity of the neck muscles often exist. Incoordination of movement, and especially an unsteady, drunken gait, indicates pressure upon the middle lobe. Vomiting and vertigo are frequent and persistent. If these symptoms exist with tenderness on pressure and pain on percussion over the cerebellum, they may point definitely to the cerebellum. Optic neuritis is not frequent in cerebellar abscess. But here, above all other localities, the remark of von Bergmann eminently applies : "The technique of the evacuation of brain abscess no longer deters us from operating. All progress in treatment must depend chiefly upon diagnosis." It is, therefore, especially important that all cases of brain abscess should be observed and reported with the minutest and most exact detail, especially if there is any suspicion of the cerebellum being involved, in order that we may learn how to make a more exact diagnosis.

At present the condition of the reflexes is not known with sufficient accuracy to be of much value in diagnosis, though they are probably increased on the side of the lesion. Their study is therefore all the more important, not only in abscess but in all other cranial lesions.

Thirdly : The symptoms by which the locality of an abscess may be inferred are chiefly those which are so admirably described in general by Dr. M. Allen Starr, in Vol. I. of this HANDBOOK, under the head of "Brain, Diagnosis of Local Lesions in the." I need, therefore, only briefly recall a few leading facts. The left temporo-sphenoidal lobe being adjacent to Broca's convolution, a very common result of abscess in this lobe would be motor aphasia. If the abscess is of such size as to press upon the inferior centres of the motor region, paralysis or paresis of the opposite side of the face would probably be first induced, followed by paralysis of the arm, and occasionally even complete hemiplegia of the opposite side. If the ear disease has implicated the seventh nerve in its passage from the petrous bone, there will be, of course, palsy of the same side of the face. Sometimes there will be a distinct squint from paralysis of the sixth nerve. Especially are all localizing symptoms valuable in those cases, which are not altogether rare, in which there is a suppurative discharge from *both* ears.

Mr. Barker has suggested that at the operation the mastoid foramen, through which passes a small vein to the lateral sinus, should be laid bare and an examination for pus be made. Should pus be found exuding from this foramen, it would certainly be a most valuable sign ; but thus far I do not know that its examination has proved to be of positive value. The foramen (Figs. 4873 and 4874, *i*) lies one and one fourth inch behind, and about one-fourth inch below, the external meatus, at the base of the mastoid process.

Should the abscess exist in the frontal lobe, as is sometimes the case from nasal disease, but little information can be derived from localizing symptoms, this lobe being a "latent" region. In the occipital lobe the same is true, unless the cuneus is involved, when hemianopsia on the same side of each retina would certainly follow. Should the angular or supramarginal gyrus be involved in the lesion, the state of the pupil may possibly give valuable information. In the *American Journal of the Medical Sciences* for October, 1888, pp. 349 and 355, Dr. Oliver has described a species of monocular Argyll-Robertson pupil, which seems to promise to be of value in lesions of this region.

The temperature of the two sides of the head should always be carefully taken, and in doing so it should be remembered that the left side is normally hotter than the right (Gray and Seguin, *Arch. Med.*, December, 1879). Should abnormal variation of the local temperature be observed, it would be a valuable indication, but one that as yet is not sufficient to localize an abscess with absolute certainty.

Percussion and pressure on the head are also valuable, but alone are not to be relied on absolutely. Taken with other symptoms, they may assist materially in the localization of an abscess. Hulke[40] records an instance of a tender spot above the ear in a case of abscess in the cerebellum ; and another of a tender spot over the occiput with an abscess in the temporo-sphenoidal lobe. Pain on *percussion*, but *not spontaneously complained of*, in the opinion of Ferrier, is of greater value than mere tenderness on pressure. Pressure and percussion are of value in diagnosticating cerebellar abscess from cerebral in many cases. Should the abscess, as occasionally happens, be extra-dural, its locality would almost certainly be indicated by œdema of the overlying scalp. This, therefore, should always be looked for.

Differential Diagnosis.—First, ***Meningitis :*** This is often a very difficult differential diagnosis. In meningitis there will usually be delirium, delusions, photophobia, contraction of the pupils, convulsive facial twitchings, high general temperature, and marked rigidity of the neck muscles, all developing rapidly after an injury or from disease of the ear, or in a strumous patient.

Secondly : ***Mastoid disease***, following purulent otitis media, sometimes gives rise to serious cerebral disturbance. Trephining the mastoid—which in nearly all cases of cerebral abscess, at least from ear disease, will precede the opening of the skull—will, in general, quickly differentiate this from intracranial abscess. As a rule, th emastoid region will be swollen, œdematous, and painful ; in other words, will present the usual evidences of mastoid disease. For the diagnosis from extra-dural abscess arising from mastoid disease, see p. 217.

Thirdly : *Thrombosis of the lateral sinuses and pyæmia* would most likely involve the internal and external jugular veins, into which, most probably, the thrombus would extend. They would be hard, cord-like, and painful, and the veins of the face would almost certainly be turgid and swollen. Besides this, very probably, there would be general symptoms of pyæmia, such as involvement of the joints, lungs, liver, etc. The axillary temperature also would never, as in abscess, be near or below the normal. There would almost certainly be rigors, profuse sweating, and great general prostration, without such marked dulling of the intellect as exists in abscess

Fourthly : *Tumor* While in most cases the diagnosis between abscess and tumor can be pretty clearly made, yet, in not a few cases, the diagnosis is difficult and sometimes impossible. Usually the development of a tumor is very slow, and is attended with distinct focal symptoms from the time when its existence is first manifested. While the development of abscess may be deferred in its outbreak, yet once started, it usually runs a much more rapid course than does tumor. Moreover, abscess has usually some evident cause, as recent injury, aural or nasal disease, etc. Tumor sometimes develops as a result of injury, but more commonly without. In tumor the optic neuritis is almost always double, and usually more intense than in the case of abscess. In abscess optic neuritis is much rarer, and if present, it is not rarely unilateral instead of bilateral, and may be on the side opposite to the abscess rather than on the same side (Gowers and Horsley's, Barker and Gowers's cases).

While tumor sometimes exists in the temporo-sphenoidal lobe or in the cerebellum, yet abscess is far more common in these situations. In other parts of the brain tumor is far more common than abscess. If syphilis exist as a cause, it is far more likely to give rise to tumor than to abscess. The temperature is not apt to rise in either case. Rapid and sharp fluctuations in the general condition of the patient would be more suggestive of abscess than of tumor; slow fluctuations are more common in tumor. Emaciation without sufficient cause sometimes attends abscess.

Surgical Treatment.—The almost uniform mortality that attends abscess of the brain, if not relieved, renders any means that holds out a reasonable prospect of relief a necessity. Very many such cases of abscess have been operated upon successfully by trephining, even so long ago as when Dupuytren and others boldly punctured the brain. So early as August, 1849, Detmold[4] even punctured the ventricle itself and evacuated an abscess, and Dr. George R. Morehouse, of Philadelphia, informs me that he did the same during the late Civil War. All this was done with boldness, it is true, but we must also add, that in the majority of cases it was rather the result of happy chance than of scientific precision.

The operation has entered upon an entirely new career since the establishment of the doctrines of cerebral localization. Abscesses in the brain, in the last few years, have been frequently and accurately localized, and successfully operated upon, by a number of surgeons.

When abscess from ear disease is suspected, the mastoid should, in most cases, first be trephined and carefully washed out. Should this operation not give relief, then we must proceed further and trephine the skull. But before this is done, the ear and mastoid should be most carefully cleansed with a bichloride solution and filled with powdered [illegible], in order to prevent any possible infection of the brain. The head should be shaved certainly over a large area, or better, entirely, and the scalp cleaned and disinfected in accordance with the method already described.

The question as to where the trephining shall be done is an important point. As already related, even in cases of abscesses arising from injury, the scar is not always over the point at which the abscess exists. It must be located by cerebral localization quite as much as by the site of the external lesion. Moreover, tenderness on pressure is not always a reliable indication of the site at which the trephining should be done, though tenderness on percussion is a more reliable sign.

In order to attack an abscess in the temporo-sphenoidal lobe two points are advocated. Mr. Caird,[5] who operated on Greenfield's case, applied the centre-pin of the trephine 1¼ inch behind the external angular process, and nearly one inch above the zygoma. This seems to me a very undesirable point, because it would generally strike the middle meningeal artery at or just below the antero-inferior angle of the parietal bone, where the artery not infrequently passes through a bony canal, and might give rise to hæmorrhage which would at least be troublesome.

A point ¾ of an inch in front of the meatus and 1¼ inch above Reid's "base line" was the spot I selected in a case of trephining for supposed cerebral abscess[6] for reasons there given. It is better than Mr. Caird's, I think, as it avoids the artery and even its posterior branch, and gives access to the temporo-sphenoidal lobe at about its middle; but the danger of wounding the middle cerebral artery, if the brain is incised or punctured, is possibly even a more serious objection. In certain other cases where the symptoms seem clearly to point in such a location, this point might, however, be selected with advantage.

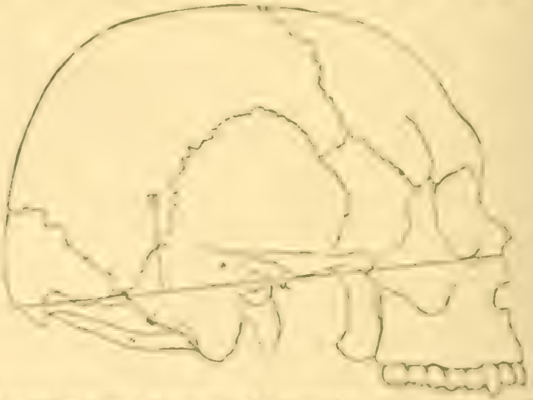

FIG. 873.—From a Photograph of a Cranium [illegible] Reid's "base line" running from the lower border of the orbit through the centre of the auditory meatus; x, the exact point at which the pin of the trephine was applied [illegible] cerebral abscess [illegible] the mastoid antrum [illegible] (Barker.)

In the majority of cases, however, I should agree with Mr. Barker[7] that the best place for trephining is 1¼ inch behind the external auditory meatus, and the same distance above Reid's "base line." (Figs. 873, x, and 874.) This is just above and behind the junction of the petrous with the squamous portions of the temporal bone. Even in children the distance above Reid's "base line" should be the same. I find that at a lower point the upper border of the petrous bone would greatly and suddenly thicken the inferior edge of the button of bone and might give some trouble in its removal. A director thrust downward, forward, and inward in the direction of the opposite ala of the nose, would pass through the axis of the temporo-sphenoidal lobe, and be almost certain to strike an abscess of any size. Should it fail to do so, punctures may be made in various other directions in order to reach possible small abscesses. As pointed out later, this same trephine opening can also be utilized for tapping the lateral ventricles, if necessary.

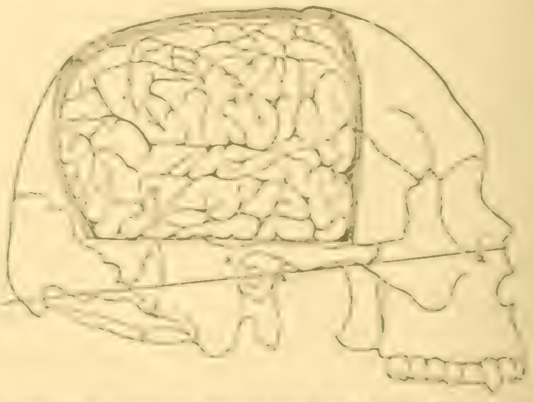

FIG. 874.—Photograph from the same Skull, with the Brain exposed in situ. The lettering is the same as in Fig. 873. [illegible] (Barker.)

In the report of the operation above alluded to, I have shown that repeated punctures may be made with a grooved director or hypodermic needle without any serious damage to the brain substance. I have there stated at some length my reasons for preferring the grooved director to either the knife or needle for *exploration* alone. A needle sucks up healthy brain tissue, even when the suction power does not exceed seven to ten minims, and the danger of wounding the vessels is not an imaginary one. With the director we feel much more safe, and will, therefore, be proportionally bolder and more thorough in our explorations. Such boldness and thoroughness, combined with safety, will often result in success, when timidity from possible danger would result in failure. In a recent case I punctured the frontal lobe four times with a director, and to the depth of 2½ inches, without any evil symptoms as a result. Rivington,[45] in 1881, was, I believe, the first to use the director boldly in this manner. He thrust it two inches into the brain. The remarkable paper of Spitzka[46] shows how freely we may puncture the brain without evil result. In many cases no trace of the puncture could be found, and where it existed there was only usually a trace of blood. Even the filthiest mud was injected into animals' brains, with but little damage as a rule.

For *incision*, however, as distinguished from *exploration*, the *knife* is certainly to be preferred. As soon, therefore, as the abscess cavity is reached the knife should be used, and then a pair of hæmostatic forceps be introduced, closed, and drawn out expanded to a reasonable degree, in order to afford free vent for the pus. Should the wall of the abscess cavity be lined with granulation tissue, it should be removed by the sharp spoon or otherwise, just as in case of an abscess in other parts of the body, care being taken not to encroach on any important neighboring centre or vessel. The abscess cavity may now be very gently washed out with weak bichloride or carbolic acid solution, and a rubber drainage-tube then be inserted. This should be passed through a good sized button-hole opening in the flap, and secured to the scalp by a long catgut thread tied in a bow-knot. The bone should not be replaced. If the first trephine opening does not afford good drainage a second should always be made in the proper place. An ample sublimate dressing should then be applied. The drainage-tube should be kept in place, but gradually shortened until the discharge has diminished to such an extent that it is safe to remove it. The catgut thread may be untied, secured to the tube, and retied at will. Even with the greatest care it will happen every now and then that the wound, after apparent healing, will have to be reopened to give vent to a reaccumulation of pus, as in a number of cases already reported. Thus McCutcheon[47] trephined his patient five times for as many different objects: 1, after the accident; 2, for compression; 3, for epilepsy; 4, for atrocious headaches; 5, for necrosed bone; each operation being followed by benefit, and the final one by recovery. Fenger and Lee[48] operated three times, Rivington[45] operated four times, and Schede[49] operated five times. All of these cases recovered. In Westmoreland's case[50] the blow was received in 1879, and repeated attacks of suppuration occurred in 1881, 1883, and 1886. In each case reopening the wound and redraining resulted in recovery.

Of course, if a fistula be discovered, even a small one, as in the case reported by Truckenbrodt,[51] and operated on by Schede, the trephine opening would be made at the site of the fistula rather than at any of the points above described, and would lead to the abscess. Weir[52] has suggested the injection of an aniline solution to discover the route and extent of the sinus.

If the abscess is in the cerebellum the proper place to trephine is well below the superior curved line, so as to avoid the lateral sinus, the centre-pin being placed midway between the tip of the mastoid process and the inion. A ¾-inch trephine or the chisel should be used. It must be remembered that the skull is quite thin and easily penetrated at this point. The opening can be enlarged later if necessary.

The flap in the dura should have its base upward. Of course, the occipital artery will have to be ligated. As pointed out by Weir,[52] "with the use of a spatula to lift it up slightly, the cerebellum can, if necessary, be viewed with an electric light nearly to the foramen magnum." With a grooved director or other appropriate means, the cerebellum can now be punctured and the abscess evacuated in a favorable position for drainage. Even should the abscess be upon the opposite side of the cerebellum, it would be easy, as I have shown, to reach it obliquely through such an opening. In making any puncture, however, care should be taken not to injure the superior vermiform process. A drainage-tube should be used and the abscess treated as before described.

If an abscess exists in any other place than in the temporo-sphenoidal lobe or in the cerebellum, the trephining should be done immediately over the site, as determined by cerebral localization, and the cavity treated as above described.

Should no abscess be found at the first trephine opening, and there is a possibility of its existence at another point, there is no objection to a second trephine opening, and even a third, should the necessity arise. The danger from an additional trephining is so slight, and the danger from abscess, if it exist, so great, that we should seek for it at a second or even a third place, if not found in the first. It is, however, scarcely necessary to add that this additional trephining should not be done without good and sufficient reasons. In such cases, when the abscess is found to be encysted, and encapsulated by a thick membrane, the membrane should, of course, be removed, as was done by Bergmann.

EXTRA-DURAL ABSCESSES.—Besides the abscesses in the substance of the brain, another variety exists that it is very important to recognize; that is, an abscess between the dura and the bones of the skull.

These almost always arise from ear disease by involvement of the bone and subsequent pachymeningitis externa followed by suppuration. The pus may accumulate in an abscess, or may be diffused between the dura and the skull.

Symptoms and Diagnosis.—They cannot be distinguished from cerebral abscesses proper, or from leptomeningitis or thrombosis of the lateral sinus, by the eye symptoms or headache, but other means may enable us to do so. The temperature, in marked contrast to cerebral abscess, will rise to 102°–104° F. The pain in extra-dural abscess is usually fixed either above or behind the ear, and is increased by percussion and pressure. The mastoid, of course, will be involved, but the tenderness on pressure or percussion will extend both further back and higher up than the mastoid. Usually there will be œdema of the overlying scalp. If the mastoid has already been opened and no improvement has followed, and no marked symptoms of the other cerebral diseases mentioned above be present, such as the pronounced cerebral irritative lesions of leptomeningitis, the localizing or focal symptoms and low temperature of cerebral abscess, or thrombosis of the internal jugular, and other signs of pyæmia in plugging of the lateral sinus, we should suspect extra-dural abscess. Pressure symptoms are rarely seen in extra-dural abscess, and especially if it arise from aural trouble. If evidence exist of caries of the bone, extra-dural abscess should be suspected, and especially if the pus well up through such a sinus and show any pulsation communicated from the brain. Not seldom a sequestrum or carious bone will be found.

Treatment.—The ordinary operation for trephining the mastoid will usually have been done for the earlier symptoms. If not, it should be done at once, and further operative procedure be carried out, if so indicated. If the operation be limited to opening of the mastoid, and this does not speedily bring relief, the skull itself should be opened either by the trephine or by the rongeur forceps. The probe or escaping pus will indicate to us any fistula, and this must be followed up till the carious or necrosed bone is discovered and the dura laid bare. This last can usually easily be recognized by its texture, relation to the bone, and its pulsation. Should the lateral sinus be exposed, care must be taken not to wound it. Should a thrombus exist in it, Horsley has suggested that it might be ligated and the clot evacuated. That recovery may take place after thrombosis of the sinus and without interfering with it, is shown by a case of Hoffmann. The abscess cavity having been reached, it should be cleaned out, the granulations from its walls removed, and free drainage provided, all carious or necrosed bone having, of course, been first removed. Unless such efficient operative measures be taken, the case is almost sure to prove fatal. Hoffmann, whose paper (loc. cit.) is the best study of the subject I have found, gives a statistic table of 107 fatal cases in which the diagnosis was established by a post-mortem examination, and its impressive lesson is but reinforced by the 10 additional cases diagnosticated during life. Four of these were reported by others, of which 2 recovered after operation; 6 are reported by himself, of which 5 recovered after operation, one dying six weeks later from bronchitis. No other commentary as to the absolute necessity for an operation can be needed. The causes of death were usually meningitis, cerebral abscess, and pyæmia, with and probably from thrombosis of the lateral sinus.

INTRACRANIAL TUMORS.—The causes of intracranial growths are various, but in the majority of cases the cause can scarcely be ascertained. Injury occasionally plays an important rôle, but much more frequently they arise without any apparent local cause. The statistics of Hale White and Bernhardt, quoted by Seguin and Weir, give a sufficient number of cases to draw approximately correct conclusions from. They number 580, and are as follows:

	Number.	Per cent.
Nature of tumor not stated	[illegible]	[illegible]
Tubercular tumors	157	[illegible]
[illegible]	76	[illegible]

Total	580	

This shows that tubercle is nearly twice as common as any other one known cause. Tubercular tumors are most frequent in early life, three-fourths of them occurring before twenty, and one-half before ten years of age (Gowers). The various forms of cancer, including sarcoma, would exceed even tubercle as a cause. They are most common from twenty to forty. Other causes, excepting hydatids and cysts, furnish each but a small number. The small percentage of syphilitic gummata is rather surprising. Dr. Gowers states that of 637 intracranial tumors the distribution was as follows: Cerebral hemispheres (excluding the central ganglia), 297; cerebellum, 170; pons, 49; central ganglia, 48; meninges, 31; corp. quad., 18; crura cerebri, 10. Starr, in a valuable paper on 300 cases of intracranial tumors in children, found 98 in the cerebellum.

The symptoms have been so carefully studied and so fully treated by Dr. Mary Putnam Jacobi, in the first volume of this HANDBOOK (article on Brain Tumors, etc.), and by Dr. M. Allen Starr, in an article in the same volume (p. 642) on Localized Lesions of the Brain, that it would be but a repetition here for me to consider them. Three points, however, ought to be more fully noticed, viz., disturbance of language, eye symptoms, and local temperature.

The most important paper lately published in connection with disturbances of language is that by Dr. M. Allen Starr. Words in ordinary use have a complex mental substratum, made up of a number of mental pictures. These are: first, memory of the sound of a word as spoken; if this be lost we have "word deafness." Second, memory of the appearance of a word as printed or written; if this be lost we have "word blindness." Third, memory of the muscular movements made in writing a word; if this be lost the result is "agraphia," or inability to write. Fourth, memory of the muscular movements made in pronouncing a word; if this be lost, although the vocal apparatus is perfect, it is known as "motor aphasia." Fifth, the word-hearing and word-uttering processes may be perfect, and the patient can understand what is said to him, and can pronounce words well, but the connection between the word-hearing and the word-uttering processes is broken, and the patient misplaces words or uses one word for another—for instance, calling the "[illegible]" the "[illegible]." This is known as "paraphasia," or the aphasia of conduction of Wernicke. The lesion in these cases usually involves the island of Reil and severs the fibres beneath it, the great association tract uniting the temporal and frontal lobes with one another. Sixth, the mind may not recognize the use, name, color, form, etc., of any object presented to it. This general symptom is termed "apraxia." It has, of necessity, as many varieties as there are avenues by which the mind may be reached, for instance, by sight, smell, taste, hearing (not only hearing for language, but for music), either of which may be lost separately, thus producing "mind blindness," "mind deafness," etc. The patient, however, though unable to recognize any object when seen, may be able to do so when *felt*. These symptoms (according to Starr) are only found when the lesion is in the left hemisphere in a right-handed person, and in the right hemisphere in a left-handed person. Hence, in examining an aphasic thoroughly, Starr states that it is necessary to test: first, the power to recall the spoken or written name of an object seen, heard, touched, tasted, or smelt. Second, the power to understand speech, and also music. Third, the power to understand printed or written words. Fourth, the power to speak voluntarily. Does he talk clearly? Does he mispronounce words or talk jargon? Fifth, the power to repeat words when dictated. Sixth, the power to read aloud. Does he understand what he reads? Seventh, the power to write voluntarily. Can he read what he has written? Eighth, the power to write at dictation. Ninth, the power to copy. Tenth, the power to recognize the use of objects seen, felt, heard, tasted, or smelled. One illustration, and only one, so far as I know, exists of the diagnosis of a lesion by the existence of "mind blindness," and this was followed by a brilliant and successful treatment. This is recorded by Macewen, and is briefly quoted on p. 228 of this article.

Eye Symptoms.—These have been, and in fact are still being, most carefully studied by Dr. Charles A. Oliver and myself in every case of cerebral disease presented to us. The full consideration of this must necessarily be delayed until we have sufficient material to study and from which to draw more accurate conclusions. This will be done by Dr. Oliver in a future paper. At present, however, we may make the following statements, together with a short description of the methods of examination, not only in tumor but other disorders of the brain.

When it is remembered that the second, the third, the fourth, and the sixth nerves, in their entirety, are solely intended for innervation and special functions of the organ of vision, it will be readily understood how important this apparatus becomes as an index of intracranial disturbance.

The methods may be briefly given in a series of short captions, as follows:

1. Always, if possible, get central vision in each eye separately, not only for form but for color, as this practically gives the physiological power of the most highly evolutionized fibres of each retina. Types, the smallest known sizes of types or symbols, and graded areas of definite colors, such as green, red, rose, blue, and yellow, should be placed at certain distances in good light, and the results compared with the normal standards for each

distances. Should the patient be unable to designate types, symbols, or colors, then keys, coins, etc., of the same size as certain test letters can be held at the related distances, or less if necessary, and attempts made for similar selection among duplicates held in the lap.

2. *Power and range of accommodation* should be tried separately and combinedly for the smallest type visible, with or without helping lenses, at the nearest, furthest, and best points possible. Retinoscopy may be useful in quite a number of cases. Tonic and clonic spasm must be sought for.

3. *Visual fields* must be most carefully studied, not only in reference to comparative sizes and areas for white, yellow, blue, red, and green; but blind spots and points of feeble color saturation must be diligently sought for and noted.

4. More complete study of *central color perception* should now be made with graded intensities of Holmgren's wools, and the results should be recorded upon suitable blanks.

5. The *pupils* should be examined and re-examined separately and in associated action, until definite answers can be given as to their comparative sizes and shapes.

6. Monocular and binocular *action of the irides* to light stimulus thrown from all parts of the visual field; to associated action with the ciliary muscles, as in accommodative efforts; and to the combined and associated action with the ciliary muscles and internal rectus muscles, as in convergence, must be repeated over and over until unequivocal results are obtained. Spasmodic action of the irides must be carefully looked for.

7. *Extra-ocular muscle balance*, when the organs are in a state of rest, should be obtained as correctly as possible.

8. Combined and disassociated *action of the attached extra-ocular muscles* in convergence, conjugate deviation, extreme separate and combined excursions in all directions, must be gone over with special study of the varying degrees of change from the slightest loss of innervation up to total paralysis. Search for clonic and tonic spasms should also be carefully made.

9. Combined and associated *action of the muscular apparatus of the ocular appendages* should now follow, in reference both to paretic and spasmodic changes.

10. *Sensibility of the entire ocular superficies*, both to touch and pain, should be studied.

11. In cases in which a difference of temperatures is suspected, *comparative surface thermometry* should be made, although it is really best not to omit it in any instance.

12. Accurate *ophthalmoscopic study* of the media and the fundus of each eye should be repeatedly made, until adequate data as to the comparative condition of the two organs are correctly obtained.

Having thus obtained this grouping of ocular conditions in association with the history and concomitant symptoms, determinations can often be made of sufficient accuracy to point out at least not only the probable character of the lesion, but even its possible situation. Negative signs may ofttimes prove themselves of great value in the diagnosis of the position of the supposed growth; and no case can be said to be complete and ready for surgical procedure until all the ocular changes have been properly and carefully studied.

For the purposes of help in differential diagnosis the few following general observations, which for the present must necessarily remain *sub judice*, may be of use to the reader:

Optic neuritis is very usual in some stage of intracranial tumor, and indicates more rapid progress of the growth. It is of no definite value in the diagnosis of the position, the character, and the size of the mass.

If the so-called monocular type be met with in such cases, the neoplasm is most probably situated in the opposite hemisphere; and should the neuritis be double (*which is most probably always the case*), it is almost certain that the side of the lesser optic nerve swelling is the one in which to look for the growth. The occurrence of this symptom is less frequent in abscess, and may be more ordinarily found upon the same side as that of the lesion than in tumor. It seldom occurs, if at all, in cortical lesions with irritative symptoms

Primary optic nerve atrophy with or without retinal change, as shown by the ophthalmoscope, is generally found in connection with basilar disease or trunkal inflammation, from trauma, new growths, general dyscrasia, and the introduction of toxic agents into the system. In epilepsy it is seldom decidedly marked, being usually found in its incipient form, and seemingly dependent upon the number and severity of the seizures. It is not apt to occur in abscess, except in those rare cases of the encysted and slowly growing varieties.

Weakening of any single muscle, or any group of muscles, generally indicates either pressure from a coarse lesion, external to any portion of the related outgoing fibres, or true infiltration of pathogenic material into the neural meshes themselves. Unassociated with other symptoms it is of little value in questions of the position of the lesion, and must be used in conjunction with other data to be of any determining use. Being, however, more of a fixed quantity than muscle irritation, it is of greater importance in such instances than the latter, as it better shows the probable position of the lesion. Localized spasm in itself is probably more apt to be caused by lesions in the motor zones and in the centres devoted to the action of the involved group or groups of muscles. It thus often offers itself of special diagnostic value in the localization of the initial point of the epileptic spasm.

In acute and subacute meningitis, irritative symptoms of both motor and sensory varieties appear, whereas, in the chronic form, degenerative changes are more prone to occur.

Hemianopsia is of paramount importance, more so than aphasia and agraphia. Each variety, carefully considered in conjunction with ophthalmoscopic study, experiments with pupillary responses, and other motor and sensory disturbances, can hardly fail to serve as most important data for indicating the probable situation of the lesion.

It must be remembered, however, that each ocular symptom in itself, is not etiologically self-answerable. Careful study must be made of all the conditions, so that, by the process of exclusion, adequate data can be obtained upon which to base answers as to the character, the type, and the situation of the supposed intracranial lesion.

Surface Temperature of the Head.—Mills and Lloyd, in Pepper's "System of Medicine," vol. v., p. 1036, have given the record of four cases of tumor of the cerebrum and one of the cerebellum. Seguin and Weir (*loc. cit.*) have recorded the temperatures in their case, and I have done the same in the case of tumor in my first paper already referred to. The general conclusion seems to be that the average temperature of the whole head is elevated somewhat above the normal, and that the elevation of temperature is usually greatest at the station nearest to the site of the growth. But a much larger number of observations must be made in order to reach a definite conclusion as to this symptom; therefore, every case of supposed tumor, and, in fact, every other lesion in the skull, should have the surface temperatures carefully noted both before and after the operation, if any be done. In the second case in my paper the temperature certainly seemed to be elevated by the irritation of the lesion present. The elevation immediately disappeared after the operation, coincidently with the cessation of the epileptic attacks. In the third case in which the fits were relieved, but not cured, the temperature did not fall. Our surface thermometers also are as yet much lacking in accuracy, as they are used in practice.

Diagnosis.—While in many cases the diagnosis is sufficiently clear, in others we are, of necessity, in the greatest doubt, until the operation, it may be, reveals the correctness or the incorrectness of our conclusions. Hence, as already quoted with approval from von Bergmann, the great necessity of a correct diagnosis on the part of the neurologist, so that the surgeon may be sure that his attempt to remove a supposed tumor will not cause chagrin to both by finding none. This has occurred in several instances.

In the careful and elaborate paper of Seguin and Weir, already referred to. It is pointed out that the diagnosis before operation must be worked out in five lines of inquiry. 1. The existence of tumor. 2. Its exact location. 3. Whether it is cortical or subcortical. 4. Whether solitary or multiple. 5. Its nature; to which I would add: 6. If possible, its size.

1. *Diagnosis of the Existence of a Tumor.*—When the symptoms referred to by Dr. Jacobi, in his article on tumors, such as headache, gradually developing optic neuritis, convulsions, either general or localized, paralysis in varying degrees (indeed these sometimes hemianopsia), slow pulse, probably localized rise of temperature with vomiting, etc., are present, and in some cases with but little modification, it is almost certain that we have a tumor. The more difficult diagnosis is often between tumor and abscess, and for their differential diagnosis I must refer the reader to the section on abscess of the brain (p. 216).

2. *Diagnosis of the Location of the Tumor.*—This must be done chiefly by the localizing symptoms. In certain parts of the brain a tumor may exist and give rise to no localizing symptoms, but only to general headache, choked disk, convulsions, etc. This is more particularly in the anterior portion of the frontal lobes, in the temporo-sphenoidal lobes, especially on the right side, and in parts of the parietal and occipital lobes. But gradually these "latent areas" are being narrowed progressively to smaller and smaller portions of the cerebrum. It is not too much to hope that eventually there may be no "latent areas." The reader must refer to that portion of this article which treats of Topography of the Brain, and to Dr. Jacobi's and Dr. Starr's papers in the first volume of this Handbook, for the details of the methods of localization, whether in the motor or in the sensory areas. One point must be regarded in following the history of a case. If a tumor increase in size, centres adjacent to the first one involved will also be affected; hence a succession of additional spasms and of pareses will develop in different parts of the body, and they are very important to study. The first localized spasm or paresis Seguin has proposed to call the "signal symptom," a happy name for so important a symptom in diagnosis. Rapidly produced blindness, as pointed out by Zenner and others, is usually due to tumors (especially in the cerebellum) which obstruct the veins of Galen or the straight sinus, and so produce internal (ventricular) hydrocephalus and pressure on the optic tracts, followed by choked disc and hemorrhages.

3. *The Diagnosis of the Depth at which a Tumor lies, i.e., whether Cortical or Subcortical.*—Seguin, in the article already quoted, concludes that a tumor of the cortex cannot be distinguished from a subcortical tumor by the character of the convulsions or by the presence or absence of localized headache, or by the cranial temperature. But tenderness on percussion rather than pressure may very possibly be of some service. In this as in the question of local temperatures, it must be urged that more exact and detailed clinical histories may hereafter give us the means of making such a diagnosis. How near one may come to touching a tumor and yet miss it, is well shown in a case of Seeds' in which he recognized unusual resistance in two punctures by the needle, yet did not remove the growth, which was found at the autopsy just below the surface. Surgery had not then reached its present boldness and success.

4. *Is the Tumor Solitary or Multiple?*—If solitary, it may be successfully attacked by operation, but if multiple it would be clearly unadvisable in most cases, unless the multiple tumors are grouped within a limited area. If single, the localizing symptoms will probably point to one area alone if the tumor be small, or if large, several areas may be involved; but these areas will be adjacent to the primary one. If, however, localizing symptoms give two or more centres far apart, without any intervening centres being involved, then the multiplicity of the growth is probable.

5. *The Diagnosis of the Nature of the Tumor.*—In some cases this may be made with fair approach to accuracy. For example, if the patient has cancer, tubercle, or syphilis in other organs, and shows characteristic symptoms of intracranial tumor, it will most likely be of the same type as the disease in the other part of the body. Beyond these three classes of tumor I do not think it possible to make other than a guess at its nature.

Hale White and von Bergmann are both opposed to operation in case the nature of the tumor is probably syphilitic. I quite agree with Seguin, however, that, provided thorough antisyphilitic treatment has been ineffectual, including the American method of the administration of large and increasing doses of iodides, if possible up to half an ounce a day, the probable gummatous character of the tumor or syphilitic disease of the bones or membranes, is not a bar to operation. Once that a gumma has become organized and permanently developed, and has resisted vigorous specific treatment, it should be attacked precisely as any other tumor would be dealt with, surgically, unless contraindicated by special symptoms, such as multiplicity, etc.

6. *The Size of the Tumor.*—This in a few cases can be probably diagnosticated. The diagnosis of a small tumor will be based upon its involving a restricted area of representation in the brain, as shown by the limited portion of the body involved; by the non-progressive involvement of neighboring centres; and by the absence of marked pressure symptoms. A large tumor will involve a large number of neighboring centres and would show marked pressure symptoms. Until the operation, however, it is impossible to make any accurate diagnosis of the size of a tumor. It is probable, however, that a few of them will be so large (F. A. Heath) as to prohibit surgical interference, before the general symptoms will be so grave as to make such interference quite unadvisable.

Surgical Treatment of Intracranial Tumors.—I have already referred to the historical case of Bennett and Godlee, which was the first really to arouse the attention of the surgical world to the possible diagnostication and removal of a brain tumor, of which there were no external local symptoms. I have also referred to later cases which have been operated upon, and which have made such a brilliant chapter in cerebral surgery—a chapter that has only been begun, the end of which we cannot even yet see. But we know enough to be sure that the beneficent results will be much wider and more important than we now expect. Operations have been undertaken by Weir, Hammond, and Gerster, in which no tumor has been found. But in Weir's case, at least, the exploratory operation was followed by great improvement, probably in consequence of the relief obtained from intracranial pressure. In Mr. F. A. Heath's case, though a tumor was found, its adhesions were so extensive in the anterior fossa that it could not be removed; but here again the great relief, in spite of hernia cerebri, was marked. The limits of operative interference with cerebral tumor are not, of course, at all well defined. Mr. Horsley has pointed out that a tumor situated in the auditory nerve, as was discovered at the post mortem, could have been removed by incising the tentorium. Weir has pointed out that by detaching the dura, the lateral or longitudinal sinuses can be lifted out of the way, a procedure which I have found also perfectly practicable.

As to operative technique I have already taken up the various steps under that head. The only point necessary to be insisted upon here is, that in cases of tumor which are not encapsulated, it is not only important that the entire tumor shall be removed, but also the zone of apparently healthy but probably infiltrated brain tissue in its immediate vicinity, so that we may be sure, so far as it is possible, that we have removed the entire neoplasm. In doing so the surgeon must remember that he can excise with greater impunity a larger area in the antero-posterior direction than in the vertical, for reasons already given.

Prognosis.—In case the tumor is malignant, its return is only a question of time. In Weir and Seguin's case of sarcoma the patient was alive about a year after the operation, but with symptoms of beginning recurrence. In tubercular and syphilitic tumor the prognosis is, of course, a much more favorable one; while in cases of benign growths, such as my own (a fibroma), recurrence is not to be expected. It is proper to add that in my own case there have been a few recurrences of epileptic fits. What the ultimate physical and mental condition of a patient will be after the removal of a cerebral tumor, the data are as yet too small for a definite statement, but the results (especially in Macewen's and in Horsley's cases) have been most encouraging.

The prognosis as to death or recovery from such operation cannot be made in any individual case, for up to the time of the operation we cannot be certain of the size and the relations of such tumor, nor of the surgical complications that may arise during its removal.

The *percentage of recovery* in cases of operation on intracranial tumors has been, for a new operation, unexpectedly large. In general it can be stated that the mortality at present is only 35.3 per cent. Of course, in any individual case, it will depend largely on the size, position, complications, etc. Undoubtedly, in the future, we shall have much better results when we learn, first, what cases ought and what ought not to be attacked, and secondly, when we improve the technique. Thus far, seventeen operations on intracranial tumor have been reported, of which eleven have recovered and six died. The following table gives all the cases thus far recorded :

Cases.	Operators.	Reference.	Result.
I.	Macewen	Glasgow Medical Journal, 1879, vol. xii., p. 210.	Recovered.
II.	Bennett and Godlee.	Lancet, December 20, 1884.	Died twenty-sixth day, meningitis.
III.	Hirschfelder and Morse.	Pacific Medical and Surgical Journal, April, 1886.	Died seventh day, encephalitis.
IV.	Bennet May....	Lancet, April 16, 1887.	Died in three hours.
V.	Weir and Birdsall.	Medical News, April 16, 1887.	Died next day, hæmorrhage.
VI.	Horsley and Ferrier.	British Medical Journal, April 23, 1887.	Recovered.
VII.	Horsley and Ferrier.	British Medical Journal, April 23, 1887.	Recovered.
VIII.	Horsley and Bastian.	British Medical Journal, April 23, 1887.	Died in nineteen hours.
IX.	Suckling........	Lancet, October 1, 1887.	Died second day.
X.	Durante.	Lancet, October 1, 1887.	Recovered.
XI.	Markoe....	Medical News, November 5, 1887.	Recovered.
XII.	Heath..........	Lancet, April, 7, 1888.	Tumor not removed. Recovered.
XIII	Horsley, quoted by Harrison.	Liverpool Medico-Chirurgical Journal, July, 1888.	Recovered.
XIV.	Weir and Seguin.	American Journal of the Medical Sciences, July to September, 1888.	Recovered.
XV.	Macewen	British Medical Journal, August 11, 1888.	Lived eight years.
XVI.	Macewen	British Medical Journal, August 11, 1888, p. 307.	Recovered. Tumor not removed.
XVII.	Keen...........	American Journal of the Medical Sciences, October and November, 1888.	Recovered.

It is not unworthy of notice that of the 17 cases 3 have been tumors of the cerebellum, and that all three died (Nos. IV., VIII., and IX.). Whether this mortality is merely incidental, or whether operations on tumors of the cerebellum are, as is probable, more fatal *per se*, cannot as yet be definitely determined, but it is a fact not to be overlooked. The mortality of cerebral as distinguished from cerebellar tumors has only been 3 in 14 cases, or 21.4 per cent. Weir and Seguin's case has shown symptoms of recurrence after nearly a year, and will probably soon die. One of Horsley and Ferrier's cases (No. VI.) died after six months, from recurrence. Counting these as fatal cases, the ultimate mortality has been only 35.7 per cent.

Case XIII. (Horsley's) was one of ivory exostosis at the root of the orbit, giving rise to paralysis and convulsions, and though not pathologically a cerebral tumor, was equivalent to it surgically.

Two of the cases (XII., XVI.) were of such a character that the tumors were not removed.

Epilepsy.—From a surgical point of view cases of epilepsy may be sharply divided into the traumatic and the non-traumatic varieties. The cases arising from traumatism can again be subdivided into (1) those in which the scar, old depression, etc., arising from injury, lies over well recognized centres, motor or otherwise, and (2) those in which the evidences of injury lie over the so-called "latent zones" in the brain.

In those cases in which the lesion lies over well known centres, and the epileptic fits affect only the muscles corresponding to the motor centres (monospasm or hemispasm) there can be no question at present as to the propriety of surgical interference, and the excision of the epileptogenous centre so involved. In the cases where the injury lies over a portion of the "latent zones," I believe that it is also proper to operate. Accumulated experience, however, will be needed to decide these questions absolutely. While these are my present opinions, I would not assert them too emphatically.

In these traumatic cases it is always possible that the scalp may be the site of irritation, and should there at least be no evidence of depression of the skull, it would always be wise, therefore, to *excise the scar* first of all, especially if it be tender, or if pressure upon it produces pain or an epileptic fit, or if the epileptic aura starts from the scar. Even should none of these symptoms be present, and if the bone be not fractured, I should deem it right first to excise the scar and then to wait in order to see whether this would cut short the epileptic seizures. Thus Briggs reports five such cases and Mears one in which such a happy result followed mere excision of the scars. Any other source of peripheral irritation must also be eliminated, as has long since been observed. Briggs relates a case in point in the same paper (p. 115), in which a girl had both a depressed cranial fracture and necrosis of the tibia. He wisely operated on the tibia first to eliminate this as a source of irritation, and the fits had not recurred when the case was reported five years later, thus disproving their origin from the fracture of the skull, which was *prima facie* the most probable cause. It must be remembered, also, that *any* operation is apt to cause a cessation of the fits for some time ; hence, before deciding that the epilepsy has been cured by removal of the scar or other source of irritation, at least two or three years of immunity should elapse. Should excision of the scar not cure the patient, or should there be a depression of the skull, with fits corresponding in their distribution to the motor centre or centres over which the scar lies, the patient should be trephined. The operator will probably find a splintering of the inner table, with not uncommonly a fragment of bone either detached or projecting into the brain substance. Sometimes a cyst will have been developed under the site of the injury. Sometimes, as a result of laceration of the brain tissue at the time of the injury, a brain scar will be found. The dura, also, will have been ruptured in some cases, and a scar will be found in it, or mere eburnation of the bones, as a result of osteitis from the traumatism, may be the only lesion. The skull having been trephined and the dura opened, the damaged brain tissue should be removed, and if there be a scar or thickening of the dura, the dura itself should be removed. In removing the damaged brain tissue, care must be taken to see that it is *all* removed, even to the extent of trenching upon apparently healthy brain tissue, and the directions heretofore given that freer excision may be made in the antero-posterior direction than in the vertical (for reasons already mentioned) must be remembered. The bone should not be replaced in a large piece, if by its shape, or for any other reason, it would cause pressure on the brain. It may sometimes be replaced to advantage after dividing it into small pieces by the chisel or rongeur forceps.

In those cases in which the lesion lies over the "latent zones," the same rule would apply to the excision of the cutaneous scar as above given. Should this not effect a cure, then it would be proper to operate. What should be done would depend upon what was found to exist in the brain, and any damaged brain tissue or cyst should be excised as above. Occasionally, after accidents, primary trephining will have been done, yet epilepsy will develop at a longer or shorter time after healing. In such cases, no matter where situated, it is sometimes wise to raise the flap over the site of the primary trephining and round off the edges of the bone, and to excise any scar in the dura or in the brain which may have resulted from the primary traumatism or from any operation done at that time. The question, however, of secondary operation is still undecided. Our experience as yet is not wide enough to dogmatize.

The papers of Macewen and Horsley may at present be accepted to be the best illustrations of the treatment above described, as well for the traumatic as for the non-traumatic cases still to be considered.

Non-traumatic Epilepsy.—First, of the Jacksonian type. So far as our limited experience goes, it seems probable that in cases of distinct Jacksonian epilepsy it is proper to operate and to excise the centre corresponding to that portion of the body which is involved. The experience of Horsley and Macewen, as well as quite a number of other operators, at present would seem to show that such operations at least do no harm, and in not a few cases they have resulted in apparent recovery both from the epilepsy and from the operation. It is a matter of some importance also that, if we operate at all, it shall be as early as possible, before the "epileptic habit" has been established. But both in this and in the non-Jacksonian type, *it is of the utmost importance that the fits shall have been always observed by a competent, and, if possible, a trained observer.* I have already had brought to me for operation a number of cases of alleged Jacksonian epilepsy and others of ordinary epileptic type, in which the fits were said to be limited and uniform in the point of beginning. These statements have been in some cases the result of the patient's knowledge, but more commonly of members of the family only. It is very evident that persons not trained to exact observation, and especially those persons whose affections are involved, and whose first motive would be to aid the patient rather than to observe the fit, are, as a rule, incompetent observers. Several times after placing such persons in hospital under observation I have found that the fits had not been at all correctly described. Therefore it cannot be too strongly insisted upon that accurate observations shall be made the foundation of knowledge before we proceed to excise any brain centre. In making these observations not only should the observer note all the phenomena in detail, and especially the muscles involved—particularly the muscle or muscles first involved (Seguin's "signal symptom") and the "march" of the fit (that is, the progressive involvement of one muscle or set of muscles after another); but the dynamometer should be used as soon as possible after the fit to determine whether the muscles involved in the fit be paretic.

Secondly.—In cases of general epilepsy, there have been reported already several cases of excision of the centre in which apparently the convulsion starts (Seguin's "signal symptom"). The results thus far may be said to be fairly satisfactory. In a number of cases there has been no return of the fits after some weeks or months; or the fits have been diminished in number or ameliorated in type, passing from attacks of severe convulsions into slight petit mal. It is as yet, however, far too early in the history of cerebral surgery, in my opinion, to decide positively whether it will prove wise to excise such a centre or not. Several years must elapse, and the definite later history of the patients be published, and in sufficient numbers, before any definite conclusion can be reached. Meanwhile, in any suitable case where the fits have been accurately observed, it would seem to be proper at present to excise such centres for the discharging lesion, not operating indiscriminately, but only in well-selected cases. Mr. Macewen has objected seriously to such operations on the ground of subsequent paralysis. This seems to me not to be a valid objection. To exchange epilepsy for paralysis would, I think, be a choice at which few patients would hesitate. It must also be remembered that the excision of a centre for an ordinary group of muscles, though it be followed by paralysis which may even be complete, has resulted eventually in so great a restoration of power as to convert the paralysis to merely moderate paresis, probably through the compensative action of the centre on the opposite side. Thus, in the third case related in my first paper already referred to, in which excision of the wrist centre was done, the patient was entirely paralyzed from May 31, 1888, till early in July. Motion began to return at this time, and when I last saw him, in the middle of September, 1888, he had so far regained control of his hand as to be able to play base-ball. The fits, however, had persisted, though changed in type, there being now but few severe convulsions and only a moderate number of attacks of petit mal.

As to operative procedure in these cases, it is important, first of all, to obtain a view of the brain sufficiently large for the operator to be able to recognize the convolutions. Once the convolutions are exposed, no antiseptic solution should be allowed to touch them until the centre sought for shall have been well defined by the battery. Hot water, however, may be used to check the bleeding. As soon as the brain is uncovered the faradic current should be employed by means of my double electrode (Fig. 458, p. 217).

In common with Nancrede and other operators, I have been very much struck with the strength of the current required to cause muscular contraction. I have found it necessary to use a current so strong as to be painful to my hand before any muscular response was obtained from faradizing the brain. Nancrede has questioned whether this may not be a serious injury to the brain. It does not at least seem to have been, but it is sufficiently possible to make us faradize the brain as little as is possible consistent with accomplishing our purpose.

When any centre sought for has been found I have suggested that a little nick be made in it, in order that it may be recognized again without difficulty. As this nick would be in the part of the centre to be removed, it would do no harm. As above described, all the centre, and possibly even a little more, should be excised in order that we may be sure of the thoroughness of our work. As Horsley has stated, most of the reported failures are due to too limited an excision.

The remainder of the operative procedure is as described in the section on the technique.

INJURIES OF THE HEAD. *Contusion.*—In any case of serious contusion, the patient should at once be put to bed on light diet, and the bowels and general hygiene carefully looked to. The patient should then be closely watched, and if any serious symptoms arise indicating intracranial mischief, a semicircular flap of the scalp should be raised and the bone inspected. If a fracture of the bone be discovered and the symptoms are at all serious, showing that inflammation of the meninges or of the brain substance has set in or is impending, exploratory trephining must be done at once, and the dura be opened. Even if no fracture exists, if the symptoms are those of encephalitis, trephining should be done. It is possible, in such a case, either that a piece of the inner table has been separated, with or without external fracture, or that the dura has been ruptured or the brain lacerated, and that inflammation with exudation has begun. Once inflammation with its attending proliferation has set in, it is essential that a means of escape for exudation be provided for, or for the escape of pus if the inflammation shall have proceeded so far. In other words, we should treat contusions followed by serious symptoms of mischief in precisely the same manner that we would treat them in any other part of the body, always remembering that in the brain it is impossible for any exudation or hæmorrhage to find its way to the surface without surgical assistance, by reason of the bony case in which it is contained. Trephining of the skull, therefore, is only equivalent to incision through the soft parts down to the seat of injury in any other part of the body. In many cases of very severe contusion, it would be proper immediately to make a horseshoe flap in order to determine the question of fracture. The swelling of the scalp is often so thick and so dense that in some cases it is extremely difficult to ascertain whether a fracture exists or not without such an incision. It is all important to know this fact, and especially if there be depression or not, so that the proper treatment shall be adopted. *Preventive* *trephining*, in many of these cases, is not only justifiable but demanded. A simple incision through the scalp is of itself unattended with danger in these days of antiseptic surgery. It may be objected that if a simple fracture exists, by such an incision we convert it into a compound one; but the position taken by Roberts in 1885 is certainly the correct one, that such an incision, with modern surgical methods, adds nothing to the danger, and is the only method by which we can make an absolutely certain diagnosis in any serious case, and so enable us to pursue a course of treatment which will diminish or avoid the danger.

Should there be any motor paralysis without any decided loss of sensation, there is almost certainly a lesion of the cortex; but, as Ferrier has pointed out, if sensation is impaired to any extent, there is probably a lesion of the sensory tracts of the internal capsule, or of the centres to which they are distributed.

Even after recovery from a severe contusion of the head, the patient should be carefully watched for some months, as in not a few instances abscesses, cysts, or epilepsy has developed after a long time. One case in which I trephined, a month after an exploratory incision of the scalp alone had been made, was most instructive as to the intracranial effects of a very slight extracranial traumatism. In enlarging the trephine-opening, I found that the dura suddenly became remarkably adherent to the bone. Inspection showed me that the area of adhesion was precisely under the flap of the first operation. This had been simply the raising of a flap of scalp, had been conducted with the utmost antiseptic care, and had healed without incident in a few days; yet the simple lifting of this flap had been felt instantly within the cranium, and exhibited itself by the strong adhesion between the dura and the bone. A severe contusion, therefore, it can easily be understood, even without fracture of the bone, might set up such inflammation as would ultimately lead to suppuration, to the formation of a cyst or a tumor, or to such organic changes as would be followed by epilepsy. Williams[65] has reported an unusual case in which a blow on the forehead produced an abscess which discharged through the nose.

Compression of the Brain.—In 1885, in a paper read before the American Surgical Association, Roberts insisted that the complexus of symptoms passing under the title of "compression of the brain" was due not so much to compression as to brain injury and inflammation. In cases of encephalic hæmorrhage, we certainly have an example of compression. Apart from this cause, and probably from tumor and from effusion, in both of which, however, inflammation has a large share, I certainly would agree with the position taken by him. A blow which is followed by symptoms of compression, when it is sufficiently serious to produce violence to the membranes, or laceration of the brain tissues, is, as a rule, one which has been followed by inflammation; and it is this inflammation with its exudation and swelling that causes the mischief. We are apt to think of increased intracranial pressure as a result to be looked for only from tumor, abscess, or effusion into the ventricles. But it is certainly reasonable to believe that mere inflammation of the cranial contents will be attended by swelling as in other tissues, and that thereby the intracranial pressure will be increased.

An experiment by Felizet is full of instruction. He filled a skull with melted paraffine, and after this had cooled, he let the skull fall from a moderate height to the floor. The calvaria was then removed. No fracture existed but the surface of the paraffine was flattened at the point corresponding to the blow. The skull had been momentarily depressed, and had returned again to its former shape by its elastic resiliency. Undoubtedly the same occurs in the brain, and no such momentary changes of form from violence, even though followed by its restoration to its original place, can have been produced without more or less laceration of the brain tissue. What is to be feared is that inflammation will take place, and that the products of inflammation will produce symptoms of pressure. Hence, in such cases I would trephine for the same reasons as are given under the last heading, if similar symptoms arise.

Scalp Wounds and Injuries of the Head.—In every case of scalp wound, the head should be shaved over a large area, and scrubbed with a nail brush and soap and water, followed by ether, and then with a sublimate solution It should, of course, by this process be thoroughly cleansed from all dirt and foreign substances, and if need be the edges of the wound should be trimmed in order to get entirely rid of the dust and dirt. The wound may now, and not until now, be examined by a probe and the finger, both of which must be entirely aseptic Should the injury be limited to the scalp and the periosteum, after providing for drainage by horse hair the wound should be closed and dressed antiseptically. But should the skull be fractured, it should be treated as described below. In wounds which produce a crushing or sloughing of the scalp, Dr. William Hunt has called my attention to the fact that the depressed scar resulting from loss of scalp tissue only, not seldom may be mistaken for an old depressed fracture of the skull—an error he has known to be made by more than one good surgeon.

Simple Fracture of the Skull without Depression.—This is often exceedingly difficult to diagnosticate. One of my patients, a bright, intelligent fellow, experimented on his own head the morning after a fall of nine feet, by tapping on his head on the injured side. He elicited a "cracked-pot" sound which did not exist on the uninjured side. It is possible that this may be hereafter of great value in diagnosticating simple fracture without depression. Whether this can only be heard by the patient, or whether it can be heard by the surgeon as well, with or without the aid of a stethoscope, I have as yet had no opportunity of determining; but it should be a matter of careful investigation, and be reported upon, with a view of utilizing it hereafter. If the fracture be simple and without depression, and without cerebral symptoms, it should be treated expectantly, but the moment that there are any symptoms of encephalitis the trephine should be used for the reasons previously stated. Two most instructive cases of such trephining are reported by Heusner.[66]

Simple Fracture with Depression.—In simple fracture with depression I should certainly advise immediate preventive trephining, even if there be no sign of encephalic mischief present, although I am quite aware that many conservative surgeons are opposed to such radical treatment. As already stated, the conversion of a simple fracture into a compound one is at present attended with no serious risk. It must be remembered that any violence, sufficient to break a bone and to depress it, will unquestionably have produced some laceration of the brain substance, and possibly of the dura. In addition to this, as the inner table is so much more easily fractured than the outer, it is always possible that a fragment may have been detached and driven into the brain. The immediate dangers arising from such a fragment of bone and laceration of the cerebral tissues and membranes are those of serious inflammation, and if the products of inflammation are confined within the skull, without possibility of escape by drainage, the danger is a serious one. Even should the patient recover, as is undoubtedly often the case, the numerous instances of epilepsy arising from irritation of a scar, from a cyst, or from secondary degeneration, are so great, and the danger of trephining so small, that but little choice would seem to exist.

The last four years have certainly remodelled our views as to intracranial surgery, and have shown that lesions of the brain should have the same opportunity for drainage and for the escape of wound products that the soft parts have. The harmlessness of trephining, with modern methods, is so marked that no patient should be allowed to take his chances in the hope that neither the immediate nor the remote consequences will follow. Trephining in this case, to be of use, must be done early. Nancrede[67] has insisted on the great advantages that accrue from early operation, and Bryant (*Lancet*, 1888) has re-enforced the same views. An investigation of most of the cases which have been operated on by Macewen and Horsley and others, will show clearly the mischief that arises from neglect.

Compound Fractures of the Skull.—The rule in such cases should be always to explore by a large incision in the scalp. Should there be no depression, no strong probability either of separation of the inner table or of serious laceration of the brain, or of hemorrhage, the wound should be most scrupulously disinfected, and, after careful antiseptic dressing, the expectant plan should be pursued. Should the fracture be a mere linear fissure, after careful disinfection, if the fissure be at all impregnated with hair, dirt, etc., the soiled edges should be carefully chiselled away so as to make sure that we have cleansed them of all infective material; for it is in the probable infection more than in the mere fissured fracture (apart from the violence of the accident) that the danger of complication resides lies. In doing this only the outer table need be cut away. An antiseptic dressing should be then applied.

But if depression exists and there are symptoms which lead us to believe that serious injury to the brain, or fracture of the inner table, or hemorrhage exists, preventive trephining should be done at once. It goes without saying that a large area of the scalp should be shaved and most rigidly disinfected in all these cases.

Mr. Mayo Robson[33] has reported an excellent illustration of the value of comparatively early trephining in such cases. A man received a blow on the left side of the head directly over the arm centre, the scalp showing a small lacerated wound. The right arm was paralyzed, which a surgeon who first saw him attributed only to bruising. Later rhythmic epileptiform spasms began in this limb, followed by facial paresis, oedema of the left optic disk, and exaggerated reflexes on the right side. Exploration showed a depressed fracture, and trephining saved his life. The twitchings disappeared in six days after the operation. Even had he recovered without operation he would probably have suffered from a Jacksonian epilepsy.

The very first case in Horsley's table, again, is a most instructive one as to the value even of late operation. In this he removed a scar in the brain (the result of an old depressed compound comminuted fracture, with loss of brain tissue) which caused two thousand eight hundred and seventy fits in the first thirteen days of his stay in the hospital! The operation was followed by improvement in his mental condition (though not of his paralysis), and no fits had occurred fourteen months after the operation.

In a case of extensive compound fracture of the occiput, so early as 1810, Hutchison[34] boldly anticipated modern surgery with the happiest results. The patient had fallen thirty feet and fractured the occiput, into the foramen magnum, as proved at the operation. He was trephined at once and, to the embarrassment of the surgeon, the dura bulged beyond the outer surface of the bone, and by its elasticity showed that there was an extravasation of blood beneath it. The next day this was incised, the blood evacuated, and, after a tedious illness from a suppuration that would now happily be conspicuous by its absence, the patient recovered.

In *punctured wounds of the brain*, which are of course always compound fractures of the most dangerous character, the rule should be *absolute* to trephine at once, whether there be brain symptoms or not. The almost certain danger of severe inflammation, and the need both for immediate provision for drainage and for antiseptic cleansing of the wound, render immediate trephining imperative, just as incision, cleansing, and drainage of a similar wound in the soft tissues is the rule. No better illustration could be given than a case reported by Bull[35] in which a man was struck on the left temple with a penknife. The wound was not considered serious enough to warrant his admission to the hospital where he first applied. Ten days later aphasia, word-blindness, and word-deafness set in, without paralysis. Five days later he was trephined. The knife-blade had penetrated the dura and wounded the brain. A clot was removed and drainage provided for. The next day his aphasia recurred, but disappeared after the blocked drainage-tube was made pervious and further clots removed. An excellent recovery followed.

Wagner[36] states that in eighty-one cases of complicated vault fractures of the skull *freshly* treated as above advocated, the death-rate was only 1.23 per cent.; whereas in twenty such, treated secondarily, the mortality was 60 per cent. No better commentary could be made.

GUNSHOT WOUNDS.—Recent experience in cerebral surgery will undoubtedly, in the near future, entirely revolutionize the treatment of gunshot wounds of the brain. The application of antiseptic methods to the treatment of brain injuries, the consequent boldness with which we can operate on the brain and its membranes, the introduction of the gravity probe and the making of counter-openings by the trephine, both to search for the bullet and for drainage, are the chief points in which recent practice differs from the old.

FIG. 4875.—Fluhrer's Aluminium Probe. [illegible]

The cardinal principles to be applied to gunshot wounds may be stated as follows: First, the scalp should be shaven over a large area around the wound or wounds, or, better still, over the whole head.

Next, the entire wound should be disinfected, from the wound of entrance all the way to the wound of exit, or to the site of the ball, if the missile has not escaped.

Thirdly, If hemorrhage has taken place, either the wound of entrance or the wound of exit, or both, should be freely enlarged by the bone-forceps or by the trephine, and the vessels secured by catgut ligatures, or, in rare cases, be controlled by pressure or by haemostatic forceps.

Fourthly, The bullet or other missile should, if possible, be removed, if need be, by a second trephine opening.

Fifthly, Absolute free drainage should be secured, again, if need be, by a counter-trephine opening, even if the drainage-tube should have to traverse the entire brain.

Sixthly, Antiseptic dressings should be applied, and the subsequent treatment of the case be conducted on general principles.

The admirable cases of Fenger and Lee,[37] Fluhrer,[38] Nancrede,[39] Bryant,[40] and others have proved conclusively the truth of the above maxims, and the next war will tell as different a story in cases of penetrating wounds of the head as it will in penetrating wounds of the abdomen.

Of the above points several have already been considered. The *removal of the ball* has always been one of the chief difficulties in cases of gunshot wounds. Fluhrer, in the brilliant article alluded to, has shown, however, a new method which is of the greatest importance. The wound having been suitably disinfected, together with, of course, the hands of the operator and the instruments, etc., the head of the patient is so placed that the probable direction of the ball will be vertical. The gravity probe of Fluhrer, made of aluminium, with large rounded ends, is now introduced by its larger end. This probe is so light that it will not force its large end into the brain substance and so produce a false passage, but by its own weight will follow the track of the ball, if this be vertical. If the ball be within easy reach it may be extracted by the ordinary methods; if, however, as shown by the probe, it has penetrated so far as to be more accessible from the opposite side of the skull, unless important centres lie in the way a counter-opening should be made on the opposite side of the skull at the point at which the probe would emerge if pushed through. The proper point for the counter-opening can be best located by the point of intersection of the lines determined in various planes by the method described by Bryant.[40] Figs. 4876 and 4877 show the method plainly. Before the probe has been

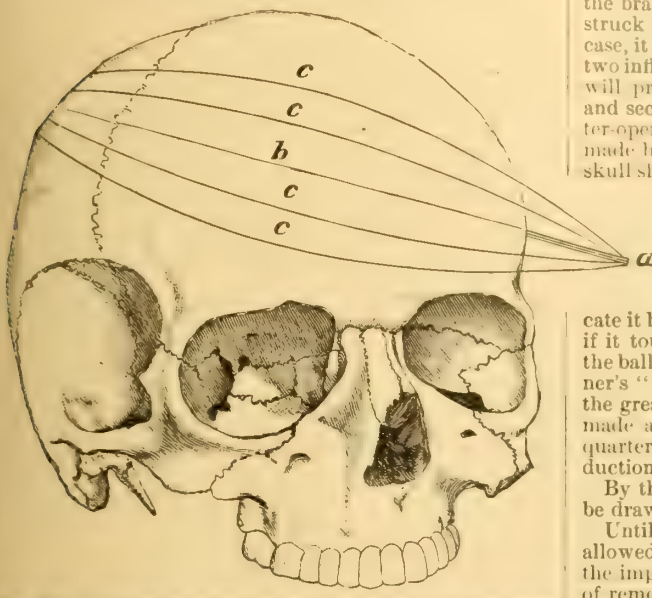

FIG. 4876.—*a*, The extra-cerebral portion of the probe ; *b*, the line taken by the probe through the brain ; *c*, *c*, *c*, *c*, lines placed in the direction of the probe with the aid of a string.

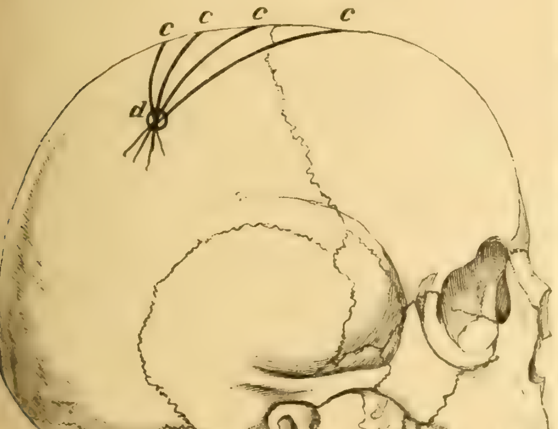

FIG. 4877.—*c*, *c*, *c*, *c*, Lines converging on the opposite side of the head ; *d*, point at which to trephine.

introduced in the search for the ball its length should be measured. If, then, it impinges against the ball, by measuring the protruding part of the probe the difference in the two measurements will give the depth at which the ball lies. Pushing the probe through to the counter-opening, and again measuring the part protruding from the original opening, we ascertain the depth at which the ball lies from the counter-opening. The probe is now to be carried entirely through the counter-opening and two strands of antiseptic silk are attached to its extremity, and on withdrawal of the probe the strands of silk will lie in the track of the wound. To one of these is now attached a No. 9 (French) gum catheter, which should be new and carefully disinfected, especially in its interior, and within it should be a disinfected straight stylet in order to give it rigidity. The stylet being ensheathed by the catheter will not mislead by its metallic sound or feel in the search for the metal ball. A pair of forceps is now tethered to the catheter by a loop of silk round one of its arms, and the ball is searched for at its known depth, above, then below, then to the right, and lastly, to the left of the catheter-guide. Between searching in any one direction and the following one the forceps should be entirely withdrawn and reintroduced so as not to swing around the catheter and thereby, perhaps, injure the brain substance unnecessarily. In case the ball has struck the opposite side of the cranium, as in Fluhrer's case, it will have rebounded in the direction determined by two influences : first, the natural angle of reflection, which will probably be about equal to the angle of incidence ; and secondly, the influence exerted by gravity. A counter-opening having been made, the wound in the meninges made by the ball in impinging on the opposite wall of the skull should be sought for, and from this, as a new point of departure, a new search may be made in the same manner as above with the gravity probe. Two other instruments may be used, also, in determining the site of the ball. They are the very ingenious invention of Dr. Girdner.[76] The "telephonic probe" if it touch the ball, will indicate it by a grating sound, a sound which is not produced if it touch any other than a metallic substance. Should the ball be but a short distance below the surface, Dr. Girdner's "induction balance" will indicate its position with the greatest accuracy, and the counter-opening should be made at the nearest point to the missile. Two and a quarter inches is the maximum depth at which the induction balance will locate it.

By the second strand of silk a drainage-tube may now be drawn entirely through the wound.

Until recently missiles that lodged in the brain were allowed to remain there unless easily accessible, under the impression that meddling with the brain with a view of removing anything that may have lodged there was entirely unwarrantable. This we now know is an error. The missile should in all cases be removed if accessible. Dr. Wharton[77] has presented the analyses of 316 cases in which foreign bodies were lodged in the brain. As a result of this investigation in 106 cases in which removal was effected, 34 (32 per cent.) died. Of the much larger number, 210, in which the missile was not removed, 122 (58.1 per cent.) died, and of those who lived 10 died from the ultimate effects of the ball, and many of the others suffered from epilepsy and physical and mental deterioration.

Arnold, at the request of Bryant (*loc. cit.*), investigated very carefully 140 cases and found that of the 85 cases in which the missiles escaped primarily, or were removed, 38 (44.7 per cent.) died. Of the 55 in which the missile was not removed, 32 (58.2 per cent.) died, giving nearly the same result as Wharton's tables.

If the bullet has not escaped, and cannot be found or removed directly, or by a counter-opening, the wound should be carefully disinfected and thorough drainage should be secured by a rubber tube carried to the entire depth of the wound. If, however, a second opening has been made, the drainage-tube should be carried entirely through the track of the wound.

Drainage should be kept free and thorough, and antisepsis secured by a gentle syringing with some suitable antiseptic solution, but it should be done with care and with a weak solution.

FRACTURE OF THE BASE OF THE SKULL.—Besides the ordinary dangers from fracture of the vault of the skull, we have at the base another danger of great importance, that does not at first glance seem to be present, viz., probable and insidious communication with the external air, and, as a result of it, septic infection that is apt to be overlooked. This communication with the outer air may take place either through the ear, the nose, or the roof of the orbit.

Fracture of the occipital bone, involving the base of the skull, should be dealt with, of course, as in the case of fracture of the vault.

Heretofore fracture of the base has been excessively fatal, and it is a remarkable fact in cerebral surgery that Wagner, in the lecture already referred to (p. 89), states that in twenty three cases of fracture of the base that survived the first forty-eight hours (that is to say, those which did not die from the severe primary violence) every one of them recovered.*

If the communication with the air be through the ear, as shown by escape of the cerebro-spinal fluid, the first thing to do is most carefully to disinfect the ear, after having removed all of the wax, hair, etc., within it. This disinfection should extend to all the hollows in the external ear and the surrounding scalp, which last should be shaved. The ear should next be filled with boric acid, and the ear and scalp should then be covered with sublimate gauze. I have no confidence in iodoform, but [illegible] vastly superior.†

Should the fracture of the base involve the roof of the orbit and not communicate with the external air, of course it should be treated as a simple fracture without operative measures, unless the subsequent history should demand it. But should such a fracture be caused by an umbrella-tip, a splinter of wood, a pair of scissors, or other such penetrating body, then the eyebrow should be shaved off, and the whole region about it be carefully disinfected (special precautions being taken to keep the solution from injuring the eye, as, for example, by closing the lids with rubber plaster). After disinfection by bichloride solution (1 to 1,000) a solution of boric acid (1 to 100) or hydronaphthol (1 to 500) should be used. An incision should then be made in the line of the eyebrow, in order to hide the subsequent scar, the lid drawn down, the track of the wound carefully disinfected, and a considerable opening made in the roof of the orbit by a gouge or chisel, rather than by a trephine. If the brain itself has been injured, the dura should be opened, and the track of the wound again disinfected. Thorough free drainage should be provided for, and the wound treated as usual.

Should the fracture involve the nose, the same principle would apply, viz., thorough disinfection and free drainage. Trephining here should be through the track of the exterior wound, if it involve the base of the nose or lower forehead. If the penetrating body has passed through one nostril, of course the nostril should be first washed clean and then disinfected with boric acid or hydronaphthol, and, after trephining, the same acid should be thoroughly instilled into the nostril, both from below and by way of the trephine opening. The trephining would probably be done best just above the root of the nose, and would, unfortunately, involve the frontal sinus, which should always be avoided if possible. But the great danger from want of drainage must overcome every objection of a minor character. The frontal sinus, as well as the wound, should be disinfected, therefore, with great care, and the same drainage and dressing be applied as heretofore recommended. In order to prevent the passage of infective air through the nose, both from without and from the lungs, it would be well, perhaps, to plug up both anterior nares with a moderate tampon of soft sublimate gauze for the first three days at least. A tampon in the anterior nares would nearly prevent any current of air through the nose, even from behind. In children it is to be remembered that the frontal sinus is very small and ill developed.

INTRACRANIAL HÆMORRHAGE, ESPECIALLY FROM THE MIDDLE MENINGEAL ARTERY.—Three papers recently published have practically settled the question of the treatment of hæmorrhage from the middle meningeal (Wiesmann in the *Deutsche Zeitschr. f. Chir.*, Bd. 21 and 22, 1885; Jacobson in "Guy's Hospital Reports," 1886, vol. xliii.; and Krönlein in the first journal, Bd. 23, Hft. 3 and 4, 1886).

The violence that may rupture the middle meningeal is but slight in some cases, so slight, indeed, as even to leave no mark. A fracture may exist, but it may be so small as not to be recognizable by the touch, and barely by sight. In a number of cases there will be no fracture whatever. Stokes [illegible] reports a case which is a model of diagnosis and treatment, in which, after only a bruise, trephining evacuated a clot one and one-half inch thick, followed by immediate relief to the paralysis, and speedy recovery. Jacobson (loc. cit.) reports four cases out of seventy, of such hæmorrhage, in which no fracture existed. In some, of course, the fracture will be both visible and palpable, not only over the vault but also at the base of the skull. Either the trunk or the branches may be ruptured. Of the seventy cases tabulated by Jacobson, in two certainly, and in four others probably, the trunk was injured; but the divisions beyond the trunk are the site of the lesion more commonly than the main trunk itself.

The adhesions of the dura to the skull, it should be remembered, while in general very strong, are very slight in the area of the middle meningeal, as pointed out by Tillaux, and so favor hæmorrhage.

The symptoms of the greatest value are: First, An interval of consciousness between the accident and the appearance of serious symptoms. This interval of consciousness is of the greatest importance, and probably is worth all of the other symptoms put together. It is due to the fact that it takes a certain amount of time for sufficient blood to escape to produce unconsciousness from pressure. It was present in two-thirds of Jacobson's cases. If the main trunk be injured, or one of its larger branches, and the blood poured out rapidly, this interval will be very brief, and coma and death will quickly supervene. But not uncommonly it will be some hours long, or occasionally even days. But even if brief, its possible existence should always be inquired into, and if present the other signs of intracranial hæmorrhage should be looked for with care. Secondly, Hemiplegia on the side opposite to the hæmorrhage. This may be progressive, the hemiplegia extending from one portion of the body to another, as the extending clot presses upon one cortical centre after another; as, for example, if the clot be effused over the face centre, the face muscles will be paralyzed first, and as the blood clot extends upward over the arm centre, paralysis of the arm will follow. Such extension is extremely significant. The paralysis, however, may exist on the same side as the injury, if the artery has been ruptured on the side opposite to the injury, as has not infrequently happened. Clark [illegible] in just such a case trephined on the same side as the injury and the paralysis, and lost his patient, who had a clot in the side opposite to that of the injury. Sometimes, though rarely, both arteries may be ruptured, as in the remarkable cases of Hill (Cases 18 and 19, Jacobson's paper). If there be no paralysis, the dilated and immobile pupil on the side of the clot may assist the diagnosis. Thirdly, The pulse becomes frequent. Fourthly, The respiration becomes slow and stertorous. Fifthly, If the clot extends toward the base, the pupil on the side of the clot will be dilated and immobile; and if the clot be on the left side, aphasia also will take place. Sixthly, The temperature will probably rise; it may be quite suddenly, and up to 101°, 102°, or even 104° F., especially on the side opposite to that of the clot, according to Hersey.

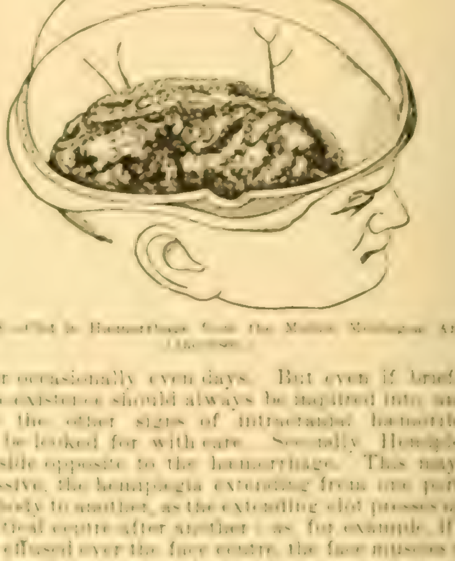

FIG. 1575.—Clot in Hæmorrhage from the Middle Meningeal Artery. (Jacobson.)

---

* It is interesting, however, as the most [illegible] of [illegible], to [illegible] the [illegible] of all these cases [illegible] the [illegible].

† [illegible] the experiments of [illegible], Medical News, December [illegible], 1888, and [illegible] in the journal of [illegible] for March, 1889.

The importance of operative treatment is best shown by Wiesmann. Of 147 cases treated expectantly, 131 died (89.1 per cent.); of 110 cases treated actively, only 36 died (32.7 per cent.)! Besides this, in the majority of these cases ending fatally after operation, the *extravasation was not reached, and the clot therefore was not removed.* When, therefore, any of the above symptoms are present in a case showing a reasonable ground for believing that the middle meningeal, or its branches, have been ruptured, even though some doubt exist, the skull should be trephined.

As to which side of the skull should be operated upon, we should be guided by the localizing symptoms rather than by the site of the injury. Krönlein, in the last three years, has trephined four cases of rupture of the middle meningeal, and in two of them removed the clot, and the patients recovered. In the other two he failed to find it, and both patients died. He states that in by far the greatest number of cases the clot will be best reached by trephining at a point one inch behind the external angular process of the frontal bone, at the level of the upper border of the orbit. Should this not reach the clot, he strongly urges that another trephine opening be made just below the parietal boss on the same level as the former. By not making this last opening he lost the two patients alluded to. By the anterior opening access is had to the main trunk and the anterior branch of the middle meningeal, and by the posterior to its posterior branch. As in not a few cases there will be doubt as to whether the rupture is in the anterior branch or trunk, or, on the other hand, in the posterior branch, the need for the second opening, in case the first does not disclose the clot, is apparent. Having made one or both of these openings, the clot should be removed, and either opening, if necessary, enlarged by the rongeur forceps in order to obtain access to it. If the pupil be widely dilated, showing that the clot has extended downward toward the base, the trephine should be applied about half an inch below the level of the upper border of the orbit, rather than at its level.

Should the middle cerebral artery be wounded, it must be secured by ligature. No diagnosis can be made at present between hæmorrhage from the middle meningeal and the middle cerebral; hence the discovery that the middle cerebral is wounded would follow a trephining at the point already indicated for the meningeal, viz.: an inch behind the external angular process. If the bleeding-point on the middle cerebral be not accessible here, as the artery lies in the fissure of Sylvius, the trephine opening should be enlarged by the rongeur forceps, upward and backward, in the line of the fissure, *i.e.*, in the direction of the parietal eminence. The case reported just below is an excellent instance of ligature of one of its branches.

The clot-cavity should be washed out, after the hæmorrhage has been controlled, by a weak antiseptic solution or cooled boiled water. Drainage should be carefully provided for, and the wound dressed in the usual way. Weir, in May, 1885, was the first, I believe, to propose that in case the first trephine opening would not answer well for drainage, a second one should immediately be made. In doing so, not only must the position of the clot be remembered, but the second trephine opening should be made also in such a position as to favor drainage in the recumbent posture. As a secondary measure, it was done by Noyes as early as 1882, and later by many others.

The following case, furnished me by Dr. Dench, by the kind permission of Dr. W. T. Bull, of New York, illustrates well several points above mentioned. A man, aged twenty-one, was brought into hospital in August, 1887. He had been shot at a distance of twenty feet, the ball entering at a point two and a half inches to the left of the middle line, just behind the biauricular line. When first seen his right arm was paralyzed, but shortly afterward when admitted to the hospital, this paralysis had extended to the leg, with ptosis and left external strabismus. The pupils were equal and dilated. The pulse was slow and the patient unconscious. A probe was passed directly into the cranial cavity, but the ball could not be found. Intracranial hæmorrhage was diagnosticated from the progressive paralysis. The wound, therefore, was exposed by a crucial incision, several fragments of bone were removed, and considerable arterial blood gushed from within the skull. Motion immediately returned in the right leg. The patient was then trephined a quarter of an inch below, and in front of the wound, and the dura, which bulged into the wound, was incised. The original wound and the trephine opening were then made into one by forceps, and the bleeding meningeal artery was exposed and tied with catgut. A large branch of the middle cerebral, which had been severed, was likewise tied. There was no evidence whatever as to the location of the ball. The wound was disinfected, and drainage and antiseptic dressing were applied. A hernia cerebri followed. The wound healed in a little over two months, no rise in temperature having taken place and no pus having appeared. He could speak perfectly well and could use his arm, but not his hand. He was, however, subject to ungovernable attacks of temper.

Another admirably managed case is reported by Owen.[60] Under the head of hæmorrhage should be mentioned, also, a remarkable and instructive case, reported by Dr. T. Grainger Stewart and Mr. Annandale,[61] of traumatic pachymeningitis interna, accompanied by hæmorrhage. In consequence of a fall on the occiput, without visible lesion of the skull or scalp, in two months there was gradually developing vertigo and frontal pain, increasing optic neuritis, gradually developing stupor, right hemiplegia and aphasia, with subsequent normal temperature. Annandale trephined over Broca's convolution, and found under the dura a space extending three inches behind and two inches in front of the trephine opening, which was filled with brownish-red fluid. Temporary improvement occurred, but he died five days later. The post-mortem showed inflammation of the cerebellum, diffused lepto- and pachymeningitis, with hæmorrhage of the cerebrum on both sides, with red softening on the left side. This was evidently of inflammatory origin, and it is not improbable that in such a case as this, and in those of serous apoplexy, very early trephining might result very differently.

Ceci (quoted by v. Bergmann, *loc. cit.*, p. 112) also has reported a case of chronic hæmorrhagic pachymeningitis, the result of a blow, in which palsy, incontinence, and coma were present. He trephined over two months after the accident, evacuated the blood, and his patient recovered and regained all the motor functions except those of the left hand (slight paresis).

In the *British Medical Journal*, March 2, 1889, Spencer and Horsley report some remarkable experiments on the possibility of controlling hæmorrhage from the middle cerebral artery and its branches by pressure on the carotid. The ingravescent form of apoplexy from such a rupture, impending apoplexy from intense cerebral congestion, and some of the severer congestive headaches may possibly prove capable of relief by this means. The reader must consult the original paper for the grounds upon which their conclusions are based.

INVETERATE HEADACHE.—Horsley (Case 7 of his table) and von Bergman (*loc. cit.*, p. 113) have published two cases of relief of fixed and excessively severe localized headache by operative interference. In Horsley's case he trephined at the seat of pain and removed a piece of the parietal bone, the inner table of which had been perforated and was being eroded by a Pacchionian body. Relief from pain had continued for five months after the operation.

In von Bergman's case, after all ordinary means had been exhausted, the bone was exposed. Its color was dark and purplish, as if extravasated blood were seen through it. It was greatly thinned, so that he was able to cut it with his scalpel. A quantity of tea-like dark blood escaped, and the pulsating dura was seen beneath. Six months before the operation a stone had struck him on the head, without, however, wounding the skin. This had been followed by considerable localized swelling, and the headaches began some weeks after the injury. As soon as he recovered from the effects of the anæsthetic his headache was gone, and the relief had continued for certainly three years.

A somewhat similar case presented itself to me a few months ago. A man had fallen on his occiput and had suffered from such severe headaches as to be entirely incapacitated for business. In addition to the headaches there had been repeated paralysis of the face and extremities. These, however, were of a temporary character. Furthermore, the patient gave a very probable history of syphilis. These considerations, coupled with the fact that the site of the cerebral lesion seemed to be so doubtful, led me, after consultation with Drs. Mills and Osler, to advise against an operation. The patient afterward consulted Dr. Weir, of New York, who, disregarding the medical aspect of the case, trephined with a view of relieving the headaches. Whether from altered intracranial pressure or from other reasons I do not know, but certain it is that for three months after the operation, when last heard from, the patient was entirely cured of his headaches. I should add that vigorous anti-syphilitic treatment had been without effect. As Dr. Weir informs me, the dura was not opened, nor was the button of bone replaced.

Such operations seem, therefore, to be entirely justifiable in view of the very small risk to life from trephining; provided, of course, that the headache be really so constant and severe as to justify a reasonable risk, and that all suitable medical means have been faithfully and ineffectually tried. Very probably, as in the first and last cases, simple trephining without opening the dura may be all that is necessary to effect the cure. In cases of suspected syphilis the iodides should be pushed, on the American plan, if necessary, up to half an ounce a day before a decision in favor of operation can properly be made. Just such a persistent, severe headache (of syphilitic origin) has recently been under my care, and has in this way been cured, and an operation avoided; less than three drachms a day, it was found, did absolutely no good.

Cole reports an obscure case of such pain existing for a year and so severe that the patient tore all the hair off the right side of his face. He had paralysis and atrophy of the muscles of mastication, with loss of taste and unilateral deafness. The teeth of the same side all dropped out, and the cornea sloughed. The diagnosis was a syphilitic neoplasm between the pons and medulla, and the basilar process. Though this diagnosis seems to have been a very questionable one, yet his treatment, after all anti-syphilitic remedies had failed, was most successful. He trephined behind the base of the mastoid and punctured with a fine trocar, but only evacuated some cerebro-spinal fluid. The patient rapidly recovered from the operation, lost his pain after two days, and was recovering power in the muscles of mastication.

MENTAL DISTURBANCES.—So far as I know there has been only one case, and that a notable one, in which a psychical disturbance has suggested the true diagnosis, which in turn was followed by a successful operation. This was reported by Macewen. The man had received an injury a year previously, and was suffering from melancholia, with homicidal tendencies. These were relieved by paroxysms of pain, which were not well located. There were no motor phenomena, but it was discovered that immediately after the accident, for two weeks, he had suffered from psychical blindness. He could see, but what he saw conveyed no impression to him. He recognized his New Testament by touching its smooth leather cover with the deep indented letters on the back, but on opening it the printed words were unknown symbols to him. At the operation the angular gyrus was exposed, and it was found that a portion of the inner table had been detached and had exercised pressure on the posterior portion of the supra-marginal convolution, while a corner of it lay imbedded in the anterior portion of the angular gyrus. The bone was removed from the brain and replaced in its proper position. He was greatly relieved from his mental state, though still excitable. He was at work when the case was reported, and had made no further attempts to his homicidal tendencies. This localization of a single mental process is of great importance, and leads us to hope that before long, by a more accurate observation of the mental processes in cases of injury, of disease, and of the lesions found at operation or at the post-mortem, we may be able to locate other mental processes in different parts of the brain. The fact that Macewen was able, by a careful and shrewd examination, to elicit so important a localizing symptom from a case which was obscure both in its history and in its visible lesion, is a matter of great encouragement. It is not perhaps too much to hope (as Ferrier and Horsley have also indicated) that hereafter we may be able to locate and deal surgically with lesions of mentality, as we do with those of the motor area.

Besides the case just alluded to, in which psychical symptoms led to the localization of the lesion, there are a number of cases on record in which insanity has followed injury and has been cured by operation involving the brain. One is reported by Hoffman. A man fifty years of age was made unconscious by a blow on the head which, however, produced neither fracture, convulsion, nor paralysis, but was followed by pain in the head and aphasia, and a tender spot above and in front of the right ear. Insanity developed after healing. The cranium was opened by a chisel over the tender spot. The dura bulged but did not pulsate. An incision evacuated a half ounce of cerebro-spinal fluid. The brain tissue had been lacerated by the blow. He recovered both from the operation and from his mental alienation.

McDonald reports a case of insanity following a pistol wound. The wound was three-eighths of an inch to the right of the middle line, and at the junction of the anterior and middle thirds of the first frontal convolution. The skull was opened eighteen months after the injury. There was no bone, but only fibrous tissue, at the point of injury. At the fourth puncture by a hypodermic needle, two drachms of serum were removed. On recovery from the anæsthetic the patient had recovered his mental condition.

Bennett and Gould report a case of a man, who received a severe blow 2¼ inches behind the meatus and 2½ inches to the right of the middle line. Six weeks afterward epilepsy developed, followed by mania, so that he was placed in an asylum. Trephining was done and the brain explored, in three or four different directions, to the depth of one inch, but nothing was found. The patient recovered both from his epilepsy and from his insanity.

Rannie reports the case of a woman who had tertiary syphilis. For eighteen months she had suffered with frontal and parietal pain on the right side, with tenderness of the scalp and discharge from the right ear, all of an intermittent character. There was no evidence of disease of the middle ear. She also suffered from visual hallucinations and melancholia. Her disease finally culminated in epilepsy affecting chiefly the left side, including the face. The attacks were followed by marked paresis on the left side. She was trephined over the right pre-Rolandic convolution. The skull and the dura were thickened. On opening the dura a small quantity of purulent fluid ran out which was found to come from a small degenerating gumma in the dura. Very slight opacity of the membranes existed. Three weeks later she was walking without any limp, and the motor power of the left arm was steadily improving. The headache and tenderness of the scalp had disappeared, and her mental condition was very much improved.

On November 30, 1888, I myself trephined a boy of eighteen, who had a thickened frontal bone just at the border of the hairy scalp, just to the right of the middle line, with obliteration of the diploë and eburnation of the internal table, the result of a fall from a wagon at five years of age. No fracture existed. At thirteen he developed epilepsy, and four months before I operated very marked delusional insanity began. No gross lesion was found in the brain, which was punctured four times by a director to a depth of 2 and 2½ inches. He recovered in a few days, and excepting two momentary delusions, he has had no further mental trouble, and only three fits in the next four weeks. The case will be fully reported later.

Briggs, Byrd, Garmany, and not a few other surgeons, have reported cases of mere trephining for insanity, but I have only referred to cases in which there has been interference with the brain itself by puncture, incision, etc.

Trephining for Arrested Development.—A case reported by Dr. Felkin and Mr. Hare[88] raises a very novel question as to whether, in some cases of arrested development, especially if it be the result of trauma, surgery may not be able to do something toward effecting rerecovery. The patient was a girl, seventeen years of age, who, when ten months old, had sustained a fracture of the skull, and as a result of it, the right arm and leg were completely paralyzed and shortened, badly developed, and with loss of function. The temperature of this side was two degrees lower than that of the other, the reflexes were exaggerated, and the sense of located tactile sensation was absent. Mr. Hare operated by trephining at a slight depression over the left motor area. The operation revealed a cyst two inches in depth, and an internal osteophyte half an inch long. The dura was not opened. The fragments of bone were replaced and healing took place without any rise in temperature. When the case was reported, about a month after the operation, the patient could walk better and also move the arm to a considerable extent. The condition of the reflexes and the temperature were alike on both sides. The case has not yet been reported in full, but when it is, it will give most important indications as to what we might possibly do in future cases.

Tapping of the Lateral Ventricles as a Definite Surgical Procedure in Meningitis with Effusion, and especially in Tubercular Meningitis.—In a brief address at the Washington Congress of American Physicians and Surgeons, held in September, 1888, I used the following language: "We distinguish in the body three cavities, the cavity of the head, the cavity of the chest, and the cavity common to the abdomen and pelvis. In the chest, and in the abdomen and pelvis, we recognize a large number of distinct viscera with separate and distinct functions. We can investigate the diseases of each viscus and locate them according to the physical signs and the symptoms presented by the history of the case. Until very lately the head was regarded as a cavity containing but one viscus, acting in its entirety like the liver, spleen, or kidney. If it were affected, we were not able to distinguish one part from another. But in my opinion we ought to regard the brain cavity precisely as we regard the chest cavity or the abdominal, as a cavity containing a number of viscera, fused physically, but separate physiologically and pathologically." In a later paper,[89] read before the College of Physicians of Philadelphia, November 7, 1888, I said: "I would go further now, and draw a similar analogy between the serous membrane of the abdomen and that of the brain, and plead for a similar treatment for both in case of similar disease. Since we now open the belly and drain for tubercular peritonitis with such remarkable success, I would propose that we do precisely the same for the brain. That it may be done without serious injury to the cerebral tissue, the history of the case here related I think abundantly shows, and also that it is *more* urgent and necessary in the brain than in the belly or chest. In the belly and chest the walls are more or less yielding, and the viscera to a large extent spongy. They can bear a great deal of pressure with little damage to their integrity or to life itself, if the pressure be relieved within a reasonable time. Not so in the cranium. The walls are rigid and will undergo but little pressure (unless it is very gradual, as in chronic hydrocephalus) without producing death. The fatal issue is so uniform that any means which holds out a reasonable hope of relief, even if it involve great risk of life, should be tried. The proposal in the present paper seems to involve but moderate damage to life, and to offer possibly high hopes of success."

The proposition made in this paper was, that in the case of meningitis with effusion, and especially in tubercular meningitis (and the same would be true in the so-called serous apoplexy), trephining should be done and the lateral ventricle tapped as a definite surgical operation.

It may be objected that much draining of the cerebro-spinal fluid would be dangerous. I answer, firstly, we do not know until we try. Secondly, in my brain tumor case there was probably a very slight wall between the cavity occupied by the tumor and the lateral ventricle. This wall subsequently ruptured and gave exit to a quantity of cerebro-spinal fluid sufficient to wet an ample sublimate dressing continuously for three weeks. In Horsley's case of spinal tumor very abundant drainage continued for a long time. In the Comptes Rendus, 1888, cvi., 1693, Championnière reports a case in which no ill results followed such an abundant flow of the cerebro-spinal fluid as to wet the pillow, the dressings, and the bed. Such abundant and long continued drainage does not, therefore, seem to be dangerous. Thirdly, experience may show us that possibly, in the head as in the abdomen, simple evacuation of the fluid without its continuous drainage may not only be feasible, but best. Of course, for pus in the ventricles the drainage should be prolonged, if, indeed, so fatal a lesion allow of any treatment. Possibly even this may not be necessarily mortal, for Professor Joseph Pancoast[90] reported a case of abscess communicating with the lateral ventricle, in which death resulted on the sixteenth day, apparently from obstruction to the escape of the pus. See also the case referred to on p. 216.

I have not yet had an opportunity of performing the operation in any case, although in the case related in the paper referred to, my drainage-tube was within *a quarter of an inch* of the lateral ventricle; but I am so thoroughly convinced of the feasibility and the possibility of success that I offer it, at least, for the earnest consideration of the profession, in the hope that it may bear good fruit in the near future.

Baldwin[91] has recorded a remarkable case of brain injury opening the lateral ventricle. A hernia cerebri followed, and when this sunk in, the bottom of the cavity opened into the ventricle by a slit half an inch long and one-eighth of an inch wide. A fracture of the base as well as of the vault probably existed, yet the patient made a good recovery with hemianopsia. In the famous tamping-iron case the ventricles were also undoubtedly penetrated, yet the patient recovered. These cases, therefore, show that a wound involving the ventricles is not necessarily fatal. How much less, then, is an aseptic puncture likely to do serious injury!

In the *American Journal of the Medical Sciences* for January, 1850, Detmold has reported a case in which he opened the lateral ventricles and evacuated an abscess; but tapping the ventricles has never been proposed heretofore, I believe, as a definite and deliberate surgical procedure. The improvement in my case, from even the slight relief of intracranial pressure, leads me to believe that a more thorough relief from pressure might possibly result in cure. How incising and draining the peritoneal cavity in cases of tubercular peritonitis cures, I do not know, but certainly it is a fact, and why the same measures may not be followed by the same result in the serous membrane of the brain as in that of the abdomen, I do not see. Inasmuch as all cases of tubercular meningitis with effusion die, this uniform mortality seems to me to be the strongest possible argument for, at least, a trial of such an operation.

Operative Technique.—In doing the operation it is clear that we must avoid the motor zone, Broca's centre for speech, and any other well-defined centres for the special senses, and also the regions of the large blood-vessels of the brain, the middle meningeal, and the middle cerebral arteries. A number of experiments on the cadaver have led me to point out three practicable routes for the purpose. They are all, of course, only provisional, until experience shall show us a better one.

First, from a point from one-half to three-fourths of an inch on either side of the median line, and one-third of the distance from the glabella to the upper end of the Rolandic fissure. This is high enough to avoid the frontal sinuses, and is in advance of the motor area. A three-quarter-inch trephine opening having been made and the dura having been incised crucially, a grooved director should be thrust slowly into the brain tissue in the direction of the [illegible]. The director will traverse the first frontal convolution. At a depth of two to two and one-fourth inches the normal ventricle will be reached. Should it be distended, it would be reached at a less depth.

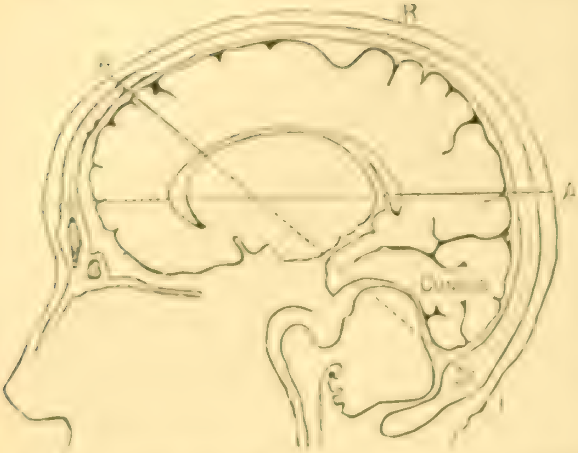

FIG. [illegible].—(Drawn by Dr. John M. Taylor.) Antero-posterior Section of the Head [illegible] R, Rolandic fissure. A and B [illegible] director [illegible] the dotted line showing [illegible] temporal convolution to the opposite [illegible] point.

Secondly. Trephine, etc., as before, midway between the inion and the upper end of the Rolandic fissure, one-half or three-fourths of an inch from the median line. This is high enough to avoid the cuneus, the wounding of which would produce hemianopsia. The director should now be slowly thrust into the brain toward the inner end of the supraorbital ridge on the same side. The director will traverse the precuneus, and the normal lateral ventricle will be reached at a depth of two and one-fourth to two and three-fourths inches from the scalp. A distended ventricle will, of course, be reached at a shorter distance.

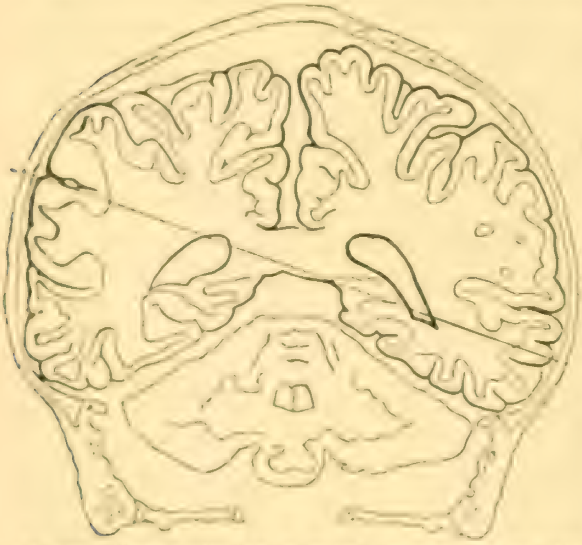

FIG. [illegible].—(Drawn by Dr. John M. Taylor.) Transverse Section of the Head [illegible] behind the meatus. The [illegible] line through the line of puncture; the dotted line [illegible] temporal convolution to the opposite side of the skull.

Thirdly. Trephine, etc., as before, one and one-fourth inch behind the external auditory meatus and one and one-fourth inch above "Reid's base line." This will expose the second temporal convolution. It is possible that this may be the site for hearing of the opposite ear, but it has been penetrated in a number of cases of abscess in the temporo-sphenoidal lobe without apparent injury to hearing. The director should be carefully thrust into the brain in the direction of a point vertically over the opposite meatus, and two and one-half or three inches above it. When at a depth of two to two and one-fourth inches the normal lateral ventricle would be reached, either at the beginning or in the course of the descending cornu. I have advised the use of the director rather than the hypodermic needle for the reasons already stated in the section on abscess of the brain. The fluid having been found, a bundle of horse hairs or a drainage-tube should be inserted for a suitable length of time. In order to prevent possible loss of the drainage-tube in the cranial cavity it may be passed through a button-hole opening in the flap and, if necessary, be secured to the flap by a stitch. To regulate the amount of drainage through the tube it may be closed by a disinfected wooden plug. In this a V-shaped slot may be cut, and the size of the slot will regulate the rapidity of the drainage. Whether the drainage shall be continued over twenty-four hours, a longer experience must decide.

Of the three proposed routes my preference would be for the present for the lateral opening. This route has a great advantage in that by it we can explore for abscess of the temporo-sphenoidal lobe, and also for effusion into the ventricles by the same trephine opening. The drainage could be either favored or hindered by the patient lying with the operated side down or up. Should prolonged drainage prove to be wisest, the posterior route might be the best one. The anterior route would hinder drainage, and as an additional disadvantage there would be a visible scar. As to a choice of which side to operate on, we should select the side of the diseased ear, if there be such disease, or if not, then that side which is tender either to pressure or percussion, or both.

Since the above was written my attention has been called to the fact that Wernicke[?] so long ago as 1881 proposed to tap the ventricles, and that Zenner[?] renewed the proposal. At the time of writing my paper I was wholly unaware of their propositions, and in referring to them I find that, while I must resign priority for the suggestion, I may claim that I have established exact rules for the operation and described its precise technique.

January 11, 1889, in my clinic at the Woman's Hospital, I first performed the operation. I found it easy and the rules I laid down proved to be correct. The patient was a fat and hearty boy, of four, suffering, it was thought probable, either from tumor or chronic meningitis with effusion, most likely a tumor of the cerebellum pressing on the straight sinus or the veins of Galen. There were no symptoms by which it could be more accurately located. His head had begun to enlarge about the early part of December, 1888, and measured 21¼ inches in circumference (exactly the measurement of my own head), with a biparietal diameter of 6¾ inches. At Christmas he became blind. For this he was brought to Professor George Strawbridge, to whose courtesy I owe the case. There was great choking of both disks and threatened blindness. The general health was good, and the temperature was normal. As the approaching blindness from the increased intracranial pressure was the immediate danger, I decided, with Dr. Strawbridge's assent, to tap the ventricles, and selected the lateral route. I removed a one-half inch button of bone, one and one-fourth inch behind the left meatus and one and one-fourth inch above Reid's base line. The dura pulsated and bulged. In the dura as in the skin, I made a small crucial incision. I then slowly introduced a hollow needle (of the size of No. 5 of the French catheter scale), into which I had already packed three doubled horse hairs nearly to the end. I introduced it toward a point two and one-half inches above the right meatus. At one and three-fourths inch from the dura suddenly I felt a marked diminution of the pressure and said to the class that I believed I had entered the ventricle, and in a moment the fluid began to escape. This fluid was found to contain sugar and albumen. It was slightly turbid, with small flakes in it.

The horse hairs were now pushed in as the tube was pulled out. About ℥ iij. of fluid escaped during the operation. An ample sublimate dressing was applied. During the first week from ℥ ij. to iv. escaped daily, and the choking of the disks diminished from 2.30 mm., to 1.09 mm., in each eye, the decrease being *measurable from day to day.* At the end of the first week I explored for a possible tumor by thrusting a probe in two directions into the left occipital lobe to the depth of three and a half inches. Finding no tumor I made a small opening, by a simple gouge, in the occipital bone, below and to the left of the inion. Through this I probed the left lobe of the cerebellum to a depth of two inches, and then obliquely across into the right lobe two and a half inches, but found no tumor. There was no reaction from these procedures, and the wound healed promptly. At the end of the second week the choking was reduced to 0.96 mm. As in spite of the drainage the swelling was subsiding very slowly, and Dr. Amy S. Barton, who kindly examined the eyes for me, reported that there was beginning atrophy of the nerves, I removed the horse hairs and introduced a small rubber tube into the ventricles. For a week this gave vent to from iv. to viij. ounces of fluid daily. Except a temporary rise of temperature, no reaction followed. At the end of four weeks, as the boy's general condition had deteriorated, especially when from choking of the tube the drainage was poor, I trephined another similar half-inch button at a corresponding point above and behind the right ear. I then explored the right occipital lobe as far as to the tentorium and falx, but found no tumor. I therefore tapped the ventricles from the right side by a drainage-tube. Following this, there was a brief but sharp rise of temperature to 104 F., which, however, quickly subsided. Four days later I washed out the ventricles from side to side by ℥ viij. of a warm boric acid solution (gr. iv. to ℥ j.), evidently to the boy's comfort, and with no results of a deleterious character. The boy died fifty-two days after the first operation. The post-mortem showed that at the site of the drainage-tubes, even after so long a time, there was not the slightest trace of inflammation either on the cortex or in the ventricular cavities, and the cerebro-spinal fluid evacuated at the autopsy was less turbid than that evacuated at the operation. There was not any perceptible trace of the various punctures. The cause of death was a tumor of the cerebellum. The probe had penetrated it, but as its density was about the same as that of the brain its presence could not be appreciated. Its nature has not yet been determined.

The case has shown clearly that the rules I formulated for the operation are exact; that the procedure is easy and safe; and that the ventricles may not only be drained, but even irrigated, without at least any deleterious results.

BRAIN, VESSELS OF THE. All the larger intracranial vessels and most of their easily visible branches lie in the enveloping membranes—dura, pia, and their processes. Over the convexity only minute branches enter or leave the brain proper. The largest arterial twigs directly entering the cerebrum are those of the (basal) pre- and post-perforated spaces. The largest venous rootlets directly from the organ are the corresponding perforants and some in the cœles. Hence the vessels of the meninges have to be included in any account of the encephalic circulation; and the vascular distribution—especially the arterial—can be best mapped out on the surface. From studies published within the last twenty years our knowledge of this subject has been greatly developed. Our aim is to reclassify and harmonize the often puzzling independent and rediscoveries.

Nomenclature.—In this article the simplified terms of Wilder (*v.* amended list in *New York Medical Journal*, November 25, 1885) will be employed. These are extended—with his approval—also to the veins, sinuses, and so-called meningeal vessels. As these last lie wholly in one of the membranes, the dura, the general term *meningeal* does not accurately define them; for this the unequivocal *dural* is substituted.

[illegible]

Internal Veins of the Brain.

[illegible]

ARTERIES.—The encranial arteries present two distinct systems of vessels:

I. The dural, commonly called meningeal.

II. The cerebral, or those of the brain proper.

These latter do not anastomose with any other arteries. Rarely there are marked exceptions to this rule, and perhaps always slight anastomoses about the sella turcica.

Heubner (1874), from injections in adults, says: "The territories of the meningeal and of the cerebral arteries must be considered as absolutely independent of one another." Langer (1877), speaking of infantile and young subjects, states: *a*, that one or two dural branches of the pericephalic anastomose by the falx with terminal twigs of the dural artery; *b*, also that pia branches of the pericerebral may reach minute dural arteries accompanying the supercerebral veins as they spring over to the dura near the longitudinal sinus.

I. THE DURAL VESSELS ramify in the exterior of the dura. In a general way it is true that the pre-, meso- and post-dural arteries are branches respectively of the internal and external carotid and vertebral arteries. These various branches intercommunicate freely, so that dural infarction does not occur. They are distributed not simply to the dura, but also to the diploë cranial bones; small twigs may also pass to extracranial parts.

a. The branches from the External Carotid supply the middle belt, and, in fact, nearly the whole of the dura. They are:

1. The *mesodural*, the largest and most constant of all the dural arteries, arising from the internal maxillary and entering through the spinous foramen. Its branches pass up the divergent small meningeal (or arteries and accompanying veins) of the lateral cranial wall, connecting at the top with those from the opposite side. Of its two main divisions, the larger anterior is often for a short distance arched over in a canal.

Besides many minute branches to the sinus walls, outgoing nerves, and orbit (*e. lacrimal*), it may send to, or receive from, the deep temporal region minute rami perforating the interposed wall; in young subjects (Hyrtl) cerebral also branches may pass through the anterior fontanelle and the sagittal suture to the soft cranial coverings.

2. The *paradural*, an inconstant accessory meningeal, arising close to the latter, or even directly from it, and entering by the oval foramen. It goes to the Gasserian ganglion and adjacent dura.

3. The *mastoid* branch of the occipital (or external carotid 15 in 120 times, Wyeth, 1878), entering by the mastoid foramen, within which it always sends a branch to the diploë. It is small, variable, and destined for the wall of the lateral sinus and adjacent dura. Here again a reverse course has been observed, where the postauricular arose from a dural artery by emerging through a foramen in the mastoid (Bankart).

4. Separated branch of *ramus parietalis* also from the occipital, accompanying the emissary through the parietal foramen. It is usually insignificant, and often absent.

5. The *subdural* branches are very small and variable. They include twigs from the ascending pharyngeal, occipital, and stylomastoid arteries, enter by the pre- and post-lacerated, precondyloid and stylomastoid foramina, and partly supply the dura of the posterior fossa and basilar sinuses.

b. Branches from the Internal Carotid.—1. The cavernous carotid yields several small rami to the sinus wall, the pituitary body, Gasserian ganglion, and dura about the sella turcica. These are variously styled receptacular and [illegible] arteries, even precentral in case of any prominent single branch. Their field of distribution and that of the paradural are obviously complementary.

2. The *predural* usually refers to the one or more slight branches of the ethmoidal arteries supplying the adjacent dura of the precranial fossa.

c. Branch from the Vertebral.—The postdural artery arises opposite or just below the occipital foramen, passes with the vertebral into the cranial cavity, and supplies the dura of the postcranial fossa, especially the posterior portions, as the cerebellar falx, etc.

[illegible]

The only anastomoses of special interest, between dural and extradural arteries, are with those of the orbit. Such connections always exist. Often a medidural branch enters, through either the sphenoidal foramen or some special opening, and supplies the external wall, even substituting partly or wholly the lachrymal artery. Or a branch of the lachrymal may take the reverse course. Very rarely the medidural arises directly from the ophthalmic (Zuckerkandl, 4 cases, Hulston, 1), and then passes by the sphenoidal fissure to its usual distribution. This possible origin should be borne in mind in the rare operation of tying the medidural at the base of the skull.

II. INTRINSIC ARTERIES, or those of the Pia and Brain-substance.—In removing the brain from the skull we sever at its base the four arteries which suffice for its entire blood-supply. These are, anteriorly the two carotids entering through the carotid foramen and canal, posteriorly the two vertebrals entering beside the foramen magnum. By means of communicating branches at the base of the brain—the vertebrals having first united, and their common basilar trunk having divided into the two postcerebrals—the primary vessels combine to form the circle of Willis. From this practically all and only the *cerebral* arteries emanate. Previously, however, several branches are given off by the vertebrals and basilar; while the carotid yields only the ophthalmic. The latter is said always to originate before any of the cerebral branches, and some millimetres before the bifurcation of the carotid.

The vertebrals and basilar supply in their course the organs of the posterior fossa, viz., cerebellum, pons, oblongata, and their adnexa. In approaching the distal border of the pons the vertebrals unite to form the mesal basilar. This is occasionally divided within by a septum, or separates into two vessels which soon reunite. The basilar lies in the median sulcus of the pons, directly on the basilar process of the occipital bone; opposite the central border of the pons it ends in the two postcerebrals.

The lateral branches are:

1. *Postcerebellar*, the largest offshoot of the vertebral. It passes around the oblongata, beside the pneumogastric nerve, to supply the extremity of the cerebellar lobe as far as the median line, the subvermis and adjacent surface, and the plexus of the metepicœle.

2. *Recurrent spinal twigs*, also from the vertebral.

3. *Medicerebellar*, usually from the basilar trunk. This passes along the middle cerebellar crus to the preventrad surface of the respective cerebellar hemisphere, including the flocculus.

4. *Transverse* branches, three or four in number. These are parallel and accessory to the preceding.

5. *Auditiva interna.*—Starts like the last, but passes to the internal auditory meatus and structures of the inner ear.

6. *Ponticular* branches.—These immediately enter the pons perpendicularly, and supply its substance. They represent true terminal arteries (Heubner), quite comparable to the perforants of the cerebrum. From the importance of the tracts supplied they have likewise great interest to the pathologist.

7. *Supercerebellar.*—This starts near the end of the basilar, passes outward along the front border of the pons, winds around the crus cerebri near the optic lobes, and is distributed to the supervermis and general dorsal surface of the cerebellum. It also supplies the postoptic arteries.

The basilar branches all emanate at practically a right angle to the mother trunk. Those going to the surface anastomose much more freely than do the cerebral arteries. Accordingly Heubner found the pia-districts of single arteries much less definite over the cerebellum than over the cerebrum. Moreover, the branches of the two sides communicate dorsad across the median line; this is explained by the development of the cerebellum from a single median vesicle. The only communication between this system of vessels and the cerebral—except through the basilar trunk—is by small branches of the precerebellars and postcerebrals across the crura cerebri.

CIRCLE OF WILLIS.—The carotid ends at the outer angle of the chiasma in two main branches, the pre- and medicerebral arteries. At about 1 ctm. in front of the chiasma the two precerebrals are connected by the precommunicant. From either the medicerebral or the carotid passes the postcommunicant to the corresponding postcerebral. Hence the circle (or polygon) of Willis is made up by 1 precommunicant, 2 precerebrals, 2 medicerebrals (or 2 carotids), 2 postcommunicants, and 2 postcerebrals. This is the classical arrangement; from it, however, there are frequent and important deviations. Professor Windle found that it held in only 76, or, overlooking any disproportion in the postcommunicants, in 119 out of 200 cases. Only in the apes do the vertebrals nearly equal the carotids. In man, Ehrmann, from 157 measurements, found that very constantly the basilar trunk was equal to one carotid (*i.e.*, furnished one-third of the brain-supply). The communicants are not simply to re-establish a circulation in case of obliteration, but they normally act to equalize pressure in the local vessels. When this circle is complete and of normal structure, an adequate collateral circulation is established after occlusion of any one part. From this circle and the first few centimetres of its branches, originate a multitude of arterioles passing to the basal ganglia and adjacent structures.

The components of this circle and their branches:

The Precommunicant.—This is a transverse branch beneath the rostrum, from 1 to 2 mm. in size, connecting the two precerebrals, and forming the anterior side of the circle. Windle found it normal in 159, double in 14, incompletely so (forked at one extremity) in 6, triple in 1, absent in 8, and associated with union of the precerebrals in 2. Wilder notes the latter condition in 6 out of 7 cases, and Starr in 2 of 14. Duret says that when double, one is of normal size, the other very small. Its place is sometimes supplied by a fasciculus of small twigs. Its branches—more numerous when the communicant is unusually long—are:

1. The *termatica*, a mesal vessel at its origin. Wilder found this present in all the 7 brains examined. "It usually divides soon into a right and left portion, which supply respectively the cinerea forming the surface of the triangular area ventrad of the genu and rostrum, and then extend around the genu to the dorsal aspect of the callosum." Windle notes it in 9 of his cases. It passed along the longitudinal fissure for two-thirds of the length of the callosum, and divided into branches supplying the opposed surfaces of the hemispheres. When the communicant is wanting, this vessel may start from the junction of the precerebrals.

2. Small retrograde rami to the gray lamina of the chiasm.

3. Arterioles which plunge into the callosal rostrum, and very often one or two considerable branches completely perforating the rostrum and ramifying on the crura of the fornix, the anterior commissure, and the septum.

The Precerebral.—This at its origin is almost perpendicular to the carotid. Often the artery of one side is larger than, and partly substitutes, that of the other side. Windle found it normal in 181 of 200 cases. In 2 the right was absent, its place being partly supplied in one by twigs from the right medicerebral, in the other by a small branch from the carotid. In 1 the right was double the size of the left; in 1 the two united to a single trunk; and in 8 they united for a short distance, six times replacing and twice accompanying the precommunicant.

The short oblique portion, dorsad of the optic nerve, between carotid and precommunicant, represents part of the circle of Willis. This portion may give off the following branches: 1. Arterioles to the optic nerve of the same side. 2. Lateral arterioles to the neighboring convolution and the callosal rostrum. 3. When, from premature division of the carotid, the precerebral goes over a longer course, it much oftener gives large twigs to the cephalon (perperforatus). Duret separated these branches into two of two courses. In one they penetrate almost within the expansion of the olfactory nerve, perforate the callosum at its junction with the lower part of the caudate head, and divide into five or six almost subequally and ramifications not extending beyond the first two rods of the constant. In the other, one or two arterioles, of about 1 mm. diameter, form a retrograde course of 3–4 mm. to the preperforated space beneath the caudate, to which latter exclusively they are distributed.

From the precommunicant on, the precerebrals run side by side around the genu and caudal in the bottom of the longitudinal fissure. After giving off the first few twigs then the main trunk may divide into three branches as noted by Duret, whose description is largely followed, or several successive branches are given off as in the accompanying plate. Together they supply the lower two-thirds of the ventral surface of the frontal lobe, the anterior four-fifths of the opposed surface of the hemisphere, the callosum (largely), and a portion of the septum. (See Plate XXXII.)

1. *Subfrontal* twigs, to the olfactory gyrus and region as far as subfrontal sulcus. 2. *Prefrontal* branch, to mesal surface of superfrontal and convex surface of superfrontal and part of medifrontal convolutions. 3. *Medifrontal* branch, to the callosal convolution and paracentral lobule. After doubling the crest of the hemisphere it terminates about the dorsal extremity of the central fissure. 4. *Postfrontal* branch, to precuneus and the adjacent portion of the convexity, rarely or quite reaching the occipital fissure. 5. *Callosal* artery. This may pass around the splenium to terminate in the pineal gland and even posterior commissure. It runs in the callosal convolution and runs along, perforating the latter and ramifying over the whole extent of the roof of the paracoeles.

The Cerebral Carotid.—As a rule the postcommunicant is a direct branch of the carotid, though it often starts from the medicerebral. In the former case the carotid, from this branch to its termination at the commencement of the Sylvian fissure in the perforated space, forms part of the circle of Willis. In this short course a few lateral branches are given off.

1. Arterioles to the external angle of the chiasm. Either these or the *chiasmal* arterioles from the precerebral supply minute twigs to the first portion of the optic nerve. 2. Frequently, one or more of the *perforantes* to the caudate. 3. *Postchoroid.* This may come from the medicerebral or even from the postcommunicant; in any case its origin is peripheral to that of the last named. It is directed obliquely caudad along the outer side of the optic tract to attain the choroid plexus in the lateral horn (through the extremity of the transverse of Bichat's fissure). It gives off *a*, internal and slightly recurrent branches to the optic tract; *b*, internal branches for the central part of the outer aspect of the crus cerebri; *c*, external branches to the uncus (a terminal arteriole, Heubner); *d*, extremely fine twigs to the two tubes of the choroid plexus, that it is stated to traverse.

The Medicerebral.—The vessel represents the most direct continuation of the cerebral carotid. It lies at the bottom of the Sylvian fissure, as do also the primitive portions of its larger branches as they spread out over the insula. When the postcommunicant starts from the medicerebral, the previous short (4–6 mm. long) portion of the latter participates in the circle of Willis. No branches are assigned to this part.

The medicerebral in its further course yields two classes of branches: *a*, direct, perforating, or nutrient arterioles; *b*, large and small pia arteries.

a. A few perforantes from the earlier part of this artery may pass directly to the caudate head, with those described under precerebral and mentioned under carotid. But the main group from this source take a somewhat different course, and, as stated by Heubner, are often detached from the trunk farther out in the fissure. These have been divided into two sets. The first to leave the trunk—*lenticular arteries*—are the finer, and are similar in department to the preceding, except that they go to the first and second segments (apex) of the lenticular nucleus. The second, coarser set runs along the base of the lenticular nucleus on the inner of the external capsule. A portion of these pass caudad and dorsad to the thalamic extremity of the lenticular nucleus and terminate in the thalamus—*lenticulo-thalamic arteries*. One arteriole, uniformly larger than any of the others, and the frequent source of hæmorrhage in this region, passes dorsad and mesad to the third segment of the lenticular, where it gives off many side twigs, and finally divides into four or five terminal branches, supplying also the adjacent internal capsule, etc. Two or three accompanying arterioles extend toward the third segment, and may attain the tail of the caudate. Collectively these are termed *lenticulo-striate arteries*.

A further group might be made of the small direct vessels traversing the insula to gain and supply the claustrum; as this is, however, a derivative of the external gray layer, these twigs more nearly correspond to the general cortical and allied arterioles.

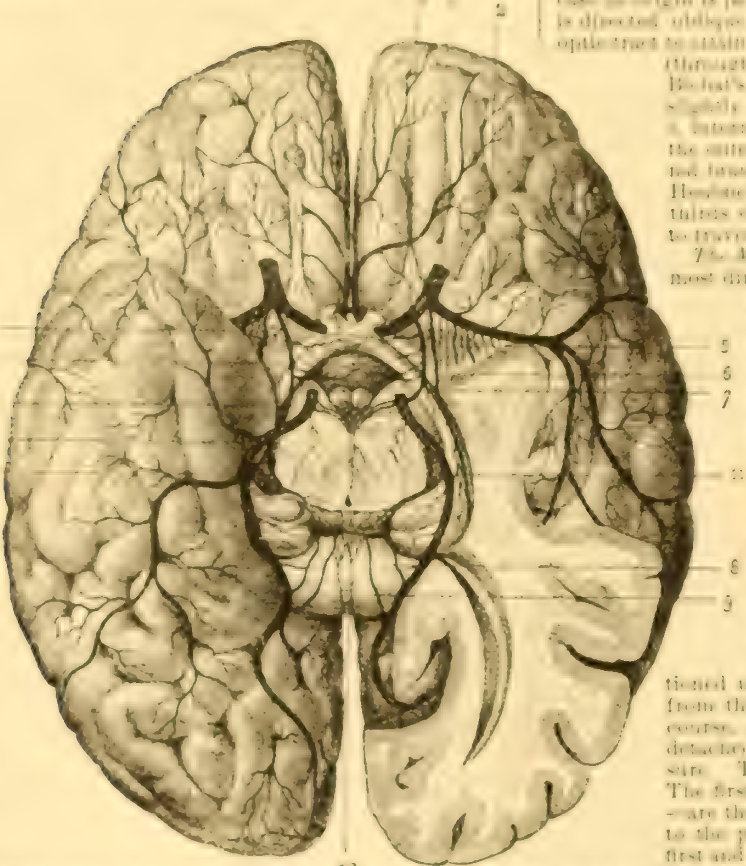

FIG. 889.—Arteries of the Base. (After Duret.) 1, Carotid; 2, medicerebral; 3, precerebral; 4, postcerebral; 5, [illegible]; 6, [illegible]; 7, precommunicant; [illegible]

Of the perforantes as a whole, it may be said that they all emanate at right angles from the inner side of the mother vessel. Their size varies from ½ to 1½ mm. They immediately enter the brain substance, only occasionally dividing, and never anastomosing before doing so. They usually run a further short course before branching. The ultimate distribution of each is pencil-shaped. They are destined to supply the central gray nuclei and the capsules, notably the inner. They are all true terminal arteries, without any anastomoses either between themselves or with other arteries. According to the French school, even their finest capillaries do not connect, but on this point the Germans teach otherwise.

b. Pia-branches of the Medicerebral.—After a course of 1 to 2½ ctm. the main trunk, either at one stroke or successively, divides into several large branches. 1. Previously, however, there are usually a few small rami for the adjacent borders of the frontal, and especially the temporal, lobes. (See Plate XXXII.)

2. *Frontal* branch. This is generally the first large ramus. Like the succeeding, it runs some distance deep in the sulcus and subdivides often, at least before appearing externally. It is especially destined for the subfrontal convolution. It supplies the orbital surface of the frontal lobe external to the orbital fissure, and the convexity dorsad to the middle of the medifrontal gyrus, caudad to the precentral sulcus. Duret found a very constant corresponding artery in several species of animals.

3. *Preparietal.* This nourishes the precentral and adjacent extremity of medifrontal convolutions, and may by an early branch include the postcentral also.

4. *Mediparietal.* This may gain the fissure of Rolando to supply not only the postcentral convolution, but dorsad a portion also of the precentral. It may also reach the adjacent parietal region.

5. *Postparietal.* This is a large branch in the horizontal Sylvian fissure. Its ramifications do not extend beyond the parietal or occipital fissure, but may pass beyond the supertemporal.

6. *Temporal.* This is included under the last by many, but it is often an early and large branch of the medicerebral. By its numerous considerable subdivisions it then covers practically the whole external temporal surface. At least the supertemporal convolution and much of the meditemporal are regularly supplied. Its distribution extends nearly to the suboccipital convolution.

There is no special artery for the insula, but it receives several small branches from the preceding as they cross it.

The Postcommunicant.—Connecting the pre- and post- (carotid and vertebral) systems. They start from the carotid or medicerebral, and run directly caudad to inosculate with the corresponding postcerebral at 5-12 mm. from the latter's origin. They pass ventrad of the optic tracts and also encounter the crura cerebri. In size and occurrence these vessels are variable, and frequently unsymmetrical. The left is more often the smaller or even absent, though some filiform anastomosis from a corresponding branch of the carotid usually does exist. As a very large branch from the carotid, especially the right, it may replace the corresponding postcerebral wholly or in part, or conversely; a large left communicant has been observed to arise from the postcerebral and supply the same medicerebral. Aside from disparity in size (43 times) the postcommunicants were normal in 175 of Windle's cases. Excepting slight anastomosis, both were absent in 3 cases, the right in 9, the left in 13. In 7 both were very small; in 28 the right was much larger than the left; in 15 the reverse.

This vessel gives off laterally pia-branches, (*a*) internal, (*b*) external, and (*c*) inconstant penetrating rami.

a. 1. Chiasmic branches to the caudad side of the chiasm. 2. Twigs to the tuber cinereum and infundibulum, a descending ramus supplying the pituitary body. 3. Two to the mammillary bodies.

b. 1. To the optic tract. 2. To the cerebral crura. 3. Often considerable branches to adjacent temporal gyri.

c. 1. *Prethalamic artery* (internal and anterior optic of Duret). It penetrates between the tuber cinereum and mammillary bodies, and ramifies in the more anterior part of the aula, on the walls of the infundibulum, etc. 2. Medithalamic artery (posterior internal optic). At times large, it enters the postperforated space and passes directly dorsad near the inner thalamic wall, to which and the gray commissure it is distributed. This vessel comes as often from the postcerebral as from the postcommunicant. The prethalamic may also have the same origin.

The Postcerebrals, from the end of the basilar to the postcommunicants, complete the circle of Willis. This part furnishes: 1, three or four arterioles to the internal aspect of the crura cerebri, supplying its basal layer, the locus niger, etc.; 2, little branches entering the thalamus through the postperforated space. These accompany, and often include, the above-described medithalamic artery.

Windle found the postcerebral arteries normal in 173 cases. The vessel was derived from the carotid instead of the basilar in 11 cases on the right, 9 on the left, and 4 on both sides. There were 2 postcerebrals on the same side—the smaller from the basilar, the larger from the carotid—in 3 cases, 1 on the right and 2 on the left.

This trunk, in passing around the crus, describes a kind of semicircle, directed toward the transverse fissure. Dorsad of the crus, at about 1 ctm. from the optic lobes, it turns latero-caudad to gain the calcarine fissure, where it breaks up to supply the basilar postcerebral region. From its crural portions it supplies, besides other branches, nearly all the nutrient arteries of the cœlian walls.

1. Little twigs to the outer part of the crus, penetrating almost immediately. Instead of several in the thalamo-crural sulcus, there may be a single larger one, parallel to the main stem.

2. The fairly constant *medioptic* (median quadrigeminal), giving fine offshoots in its course to the crus, and terminating in a bunch of fine vessels in the interval of the optic lobes.

3. *Postthalamic* (so-called posterior and external), two or three, or a single larger one, starting midway from this portion of the postcerebral, and following the crus to enter the thalamus between the geniculate bodies.

4. *Geniculate*, emanating directly, or from the thalamic.

5. *Postchoroid* (posterior and lateral), starting near the optic lobes, and entering between the layers of the velum. It always divides into two principal rami: a lateral one for the third of the choroid plexus not supplied by the prechoroid artery, *i.e.*, for the plexus over the thalamus; the other more median one for the velum (*ramus velaris*).

6. *Medichoroid* (posterior and median choroidal), from the postcerebral at its nearest approach to the median line. It courses beside the conarium, to which it yields some rami, and immediately divides into two branches, one to the velum of the aula, the other exclusively to the choroid plexus of the same cavity.

The choroid plexi and velum represent a double layer (fold) of the pia, within which the cœlian arteries and veins course. Duret states that in all the cœles the arteries to the velum are distinct from those to the plexus, often even from their origin at the postcerebral, and always at their entrance into the corresponding cavity, and that they never mingle in their distribution. From the velar arteries are detached a multitude of little arterioles, which penetrate the thalamus 1 to 1½ ctm. They have the arrangement of cortical arterioles, and are penicillated. The two velar branches terminate in the head of the caudate, either simply subependymal or passing deeply into its substance. The velar branches to the aula emit little arterioles laterally at intervals of about a millimetre. These penetrate perpendicularly the adjacent wall. They supply also the posterior and gray commissures, and terminate in a fine pencil in the anterior commissure. The plexus arteries, on the contrary, do not usually participate in the nutrition of the cœlian walls. They divide into four or five long parallel branches from which little arte-

[illegible] pass into the plexuses, properly speaking. They enter the villi, by their base, and form very sharp-bent and continuous capillary meshes. It has been suggested that they are the remains of former branches ramifying in the embryonic surface pia, and that they became coiled as [illegible] this [illegible] [illegible].

7. *Posterior anterior quadrigeminal*, very short, coming from the most median part of the postcerebral, or from some branch of the latter. It forms a very delicate plexus over the geniculate body. This makes the third possibly [illegible] part of [illegible] arteries, as these latter are very [illegible]. They have some anastomoses across the median line.

8. Artery of the [illegible]. Sometimes offered from some branch of the postcerebral than arising directly. It does not ramify on the median surface, but passes between the hippocampus and the [illegible] convolution to the [illegible] in the manner of external arteries.

9. Variable branches to adjacent temporal gyri.

Three Branches of Postcerebral.—[illegible], be brought under three general heads (see Plate XXXII.):

1. *Temporal* branches to the uncus in part, and the basal surface of the temporal lobe as far as the border of the convexity, except the third nearest the apex of the lobe, which is supplied from the medicerebral.

2. *Post-temporal* to the basal surface of the occipital lobe, including a variable amount of the adjacent temporal region, and climbing the border of the convexity to supply a little of the external occipital region. The hippocampus may be supplied from the parent stem, or from either 1 or 2.

3. *Occipital artery.*—This runs along the calcarine fissure, sending a large branch through the occipital fissure. It supplies the cuneus and general median surface of the postcerebral lobe, and a considerable strip of the adjacent occipital convexity. Spitzka says that an artery large enough to cause fatal hæmorrhage enters the gray and white of the right occipital lobe.

General Features of the Arterial Supply.—The distribution of each primary trunk includes: *a*, basilar or nuclear branches; and *b*, pia or cortical branches. *a*. These are the pre- and post-perforating and median arteries, arising in part from the circle of Willis. They supply the central ganglia, median structures, and in part the centrum semiovale. To the same class belong the direct arterioles from the basilar to the nuclei in the pons. Excepting occasional and unimportant anastomoses these are all true terminal vessels. They divide within the brain-substance at an acute and not a right angle. *b*. The pia branches or divisions as described are only averages, complementary variations therefrom always being present, though it is claimed that while "their origin is often very variable, their distribution is constant." The larger arterial trunks correspond to the main fissures. To a marked extent it is true that the same branch does not supply both sides of a sulcus. Branches usually leave the parent stem at almost or quite a right angle. Some writers try to show a freer supply to the left hemisphere. Duret's attempted correlation of arterial distribution and physiological function was at least premature (1874) and faulty.

Anastomoses.—The basal circle of Willis comprises all the communications readily demonstrable on the uninjected pia arteries of the cerebrum. Only within this circle and over the outer lobes are there any minute connections across the median line of the hemispheres.

There has been a dispute as to the extent to which the ramifications of adjacent branches on either hemisphere are connected. Duret, after numerous, varied, and evidently careful examinations, says: "Never have we found an anastomotic network in the pia." He also notes the frequent superposition in the pia of the arterial ramifications. Nevertheless he found considerable individual differences, and regularly found fine (1/4 to 1/2 mm.) communications, especially at the periphery, i.e., between adjacent territories of distribution. On p. 317 he expressly states that in the great majority of cases, owing to anastomoses, "extremely fine and unimportant," softening from occlusion of any of the large basilar trunks spares the peripheral parts of the artery's territory. In the four-months fœtus he found abundant fine anastomoses. Heubner (p. 170), on the contrary, says: "The chief (pia) branches end in a kind of communicating canal system or passage, which is spread out in the shape of a tubular net over the whole surface of the brain." By injecting "under weak fluid-pressure" he found plentiful anastomoses up to 1 mm. in diameter. Heubner's description harmonizes with that of older writers, and is corroborated by Lucas, who by sufficiently penetrating injections was able to demonstrate an abundance of communicating arterioles up to 1/2 mm. It remains true, however, that when the communicants of the circle of Willis are poorly developed, the peripheral anastomoses are in a large majority of cases incapable of substituting them.

Brain-Nutrient Arterioles of the Convolutions.—These emanate at right angles from the pia branches of all sizes. They penetrate the crests of the convolutions perpendicularly, the inclined surfaces obliquely. They are innumerable, scarcely more than a mm. apart. According to size and distribution there are two classes:

1. *Cortical*, 0.05 to 0.08 mm. in diameter. The finer stop in the cortex proper; the others go to the boundary of gray and white. The capillary net-work from these rami has been divided into three somewhat differently characterized layers, each parallel to the outlying surface.

2. *Albal* (arteriolæ longæ), 0.08 to 0.14 mm. in diameter. These are almost rectilinear, can be followed a distance of from 3 to 4 cm., and branch at an acute angle. They supply a considerable portion of the centrum semiovale. One often passes down along the axis of the convolution. A group of five or six at the bottom of a fissure (in section) converge on entering. The capillary net-work of the albals is more elongated than that of the corticals and accompanies the fasciculi of nerve-fibres.

Both classes anastomose freely in their finer branches though in general penicillate.

From the anatomical arrangement it is believed that the intravascular pressure is less in the gray than in the white substance.

It has been claimed by many that the thyroid gland acts as a safety diverticulum to the cerebral supply; and, furthermore, that the lack of this regulator explained the occurrence of so-called cachexia strumipriva after removal of that gland; but any such special function of the thyroid is at least not proven.

Veins.—The venous passages of the brain and its membranes include:

I. The dural veins.
II. The intrinsic veins, or those of the brain proper.
III. The sinuses.
IV. The venous exits from the skull.

All the intrinsic and most of the dural veins discharge into the sinuses, or [illegible] spaces, which in turn convey the blood to the exits. Otherwise these two sets of veins are separate systems, not intercommunicating, unless occasionally near their mouths. The intrinsic veins without exception have thin, readily collapsing walls, while the sinuses are held open by the firm enclosing dura. In general it may be stated that *the walls of all these vessels are devoid of muscular elements*, though occasional unstriped fibres have been observed in the intrinsic veins. From this absence of actively contracting fibres it follows that these vessels play a merely passive rôle in the encephalic circulation. The encranial veins, like the external veins of the head, are devoid of true valves. However, at the orifices of the diploic veins (Dupuytren, Langer, doubted by Trolard) and in the ophthalmo-facial vein, valves may occur. It has also been claimed that the superficial veins in part present a valve-like arrangement at their discharge into the longitudinal sinus. The general impression that valves do not occur in any of the veins above the common jugular is, therefore, correct.

I. Veins of the Dura, including those of the diploë.—These are many in number, but all of small size. They anastomose so freely that they might almost be denominated a plexus. In position they are comparable to the plexus venosus existing between dura and periosteum of

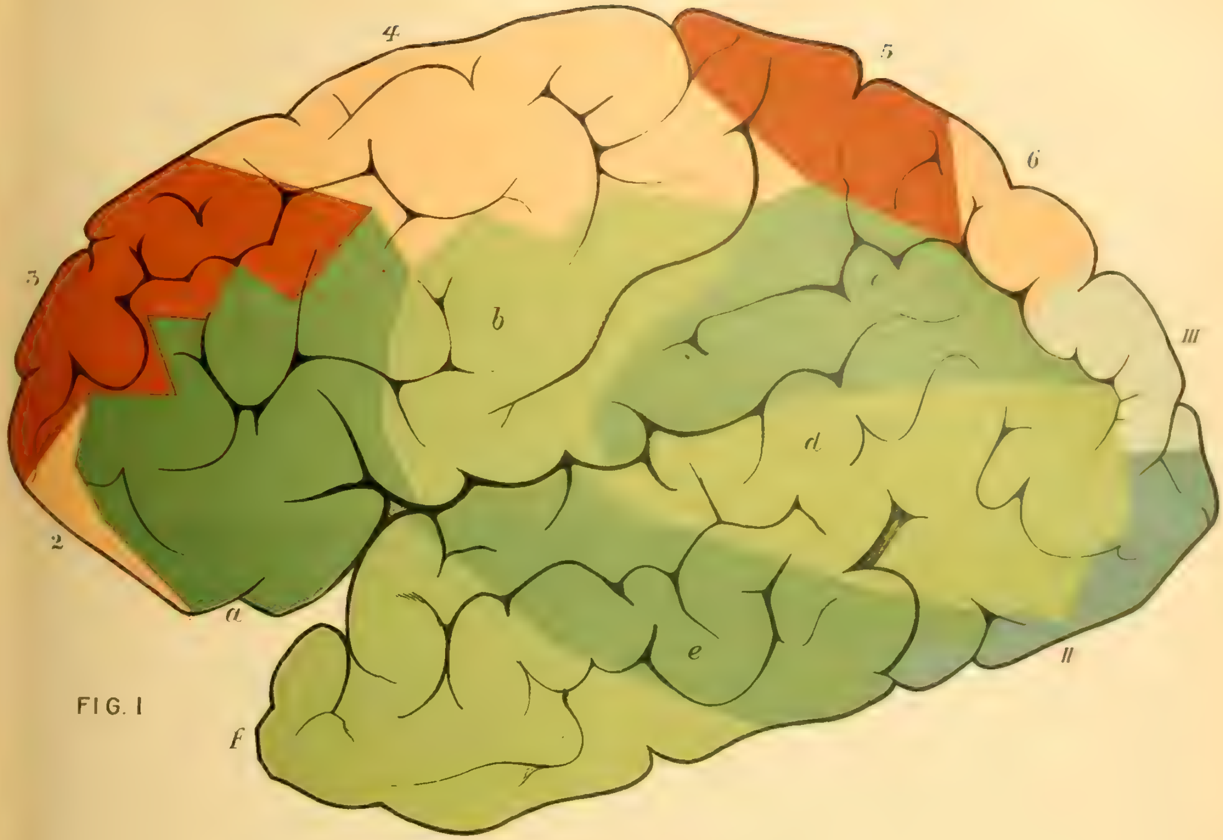

FIG. I

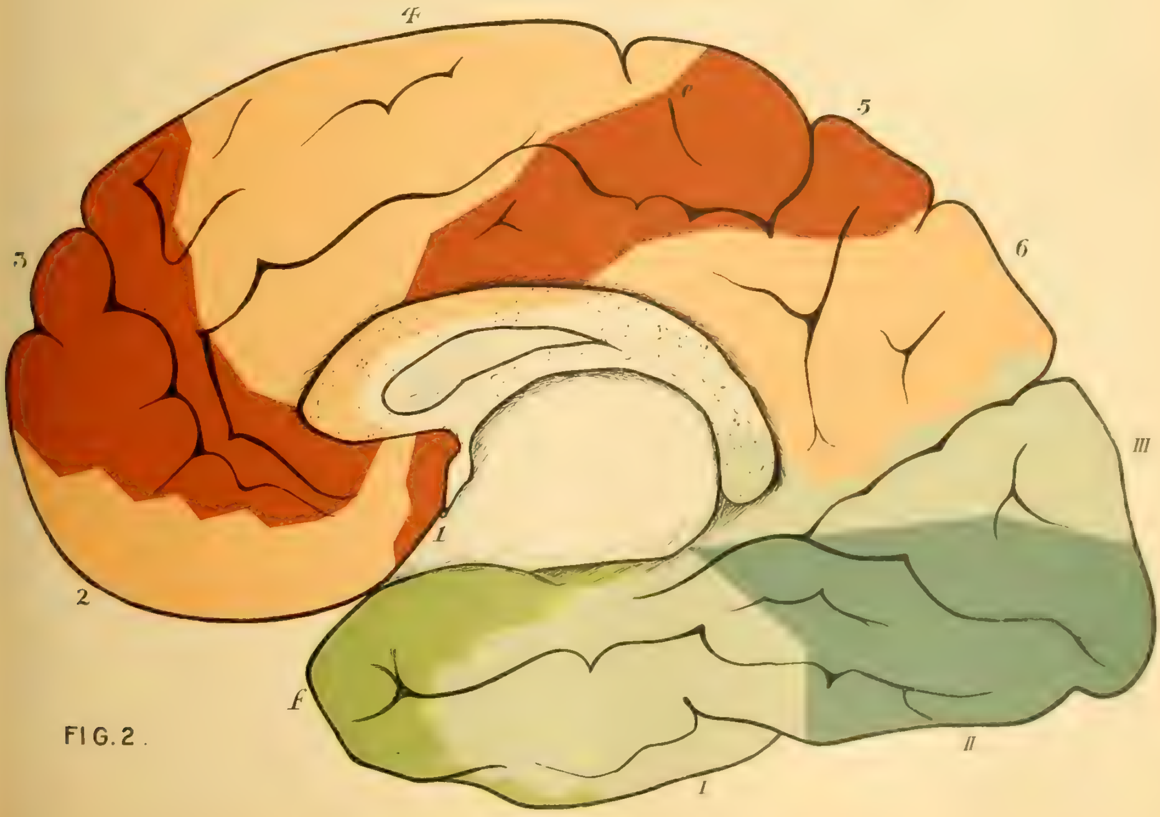

FIG. 2.

Arterial Distribution over Convexity (Fig. 1), and Mesial Surface (Fig. 2): Precerebral in Brown: Medicerebral in Green: Post Cerebral in Blue. Branches indicated by Shades of the Primary

the spinal canal. In their ultimate distribution they form two vascular nets, according to Langer, one in the outer, the other in the inner, layer of the dura. The beautiful, almost regular, interlacing of the former, figured by Langer from the fœtus, the writer is able to corroborate. By means of small veinlets penetrating the inner plate of the skull, the dural veins communicate extensively with those of the diploë. They include:

1. *Medidural*, or *Venæ comites*, accompanying the medidural artery and its branches. The two on either side of an artery repeatedly connect with each other and with neighboring veinlets. The largest pair is about the common trunk of the artery. One of these passes externally through a basal foramen to the pterygoid veins. The other ends in the medicerebral vein or its temporal sinus, or directly in the sphenoidal or cavernous sinus, with which latter it usually at least connects. The diploic canals have some special openings into the larger medidural veins.

2. *Superdurals.* These appear in part as direct continuations of the preceding, and then are double. They pass to the longitudinal sinus, largely through the intermediation of its lateral spaces. Labbé suggests that the supra- and medi-dural veins may constitute a small collateral path between the long sinus and basal conducts.

3. *Falcial trunklets* (Fig. 4882, *k*), running to the longitudinal sinus and to the falcial sinus when present, otherwise to the tentorial. The tentorials go to the lateral and tentorial sinuses, also in part by way of the parasinual spaces.

4. The numerous veinlets for the other dural arteries, *e.g.*, in the occipital fossa, have a more independent course and end in adjacent sinuses.

Venous canals of the diploë, even less yielding than the sinuses. Breschet's description is somewhat modified by Trolard. The diploë is made up of little areolæ. These canalize in any direction, though in general ventrad to discharge near the base. These canals are quite unsymmetrical, and do not increase in size in their course, excepting where there are casual enlargements; areolæ, conduits, and lacunæ are lined with a smooth membrane. Generally the diploë begins to appear about the tenth year, though small straight veins are evident earlier. Resorption of the cancelli goes on continuously, and after fusion of the sutures they may pass from one bone to another. In the aged we find a sort of wide-spaced venous plexus, no longer canals. There are several exterior outlets and numerous interior ones. Even the one through the supraorbital notch passes to the ophthalmic vein and so to the cavernous sinus. Casual mention will be made of most of the special terminations.

II. VEINS OF THE PIA AND BRAIN SUBSTANCE.—From their derivation and discharge, these vessels naturally fall into three classes:

A. The supercerebrals, passing to the longitudinal sinus. B. The internal or Galen's system, tributary to the tentorial sinus. C. Basal veins, ending in the various sinuses of the base.

A. The *supercerebral* veins return the blood from the convexity as far as the Sylvian fissure, and from the median surface of the hemispheres as far as the supercallosal fissure. There may be a slight interval between the frontal set and the others, or a smaller vein may here occur; otherwise they are all fairly equidistant. There are usually six to eight large trunks on each side. These veins tend to empty into the sinus in pairs. This is less marked in the frontal set. It is most easily demonstrable in the fœtus, owing to the absence of Pacchionian bodies, or thickening, adhesions, etc., at the border of the convexity. The last pair ends in the sinus some three to five centimetres before the torcular. The second or third pair from the last may be somewhat larger than the others, and then represent the so-called anastomotic vein, though its size is quite as much due to the greater width of the brain in this part. Although Labbé says this vein runs along the postcentral fissure, it is probably identical with Krause's fœtal *vena sulci centralis.* Moreover, each supercerebral vein is double, also best seen in the fœtus. The two constituent veins are of unequal size, the larger external one coming from the convexity, the smaller inner one coming from the median surface (of hemisphere). They may soon unite to one trunk, but generally, in their further course to the sinus they lie side by side within a common sheath, and do not lose their integrity as independent conduits until about to open into the sinus. Commonly some of the paired, as well as their constituent double veins, are wanting to complete the diagram.

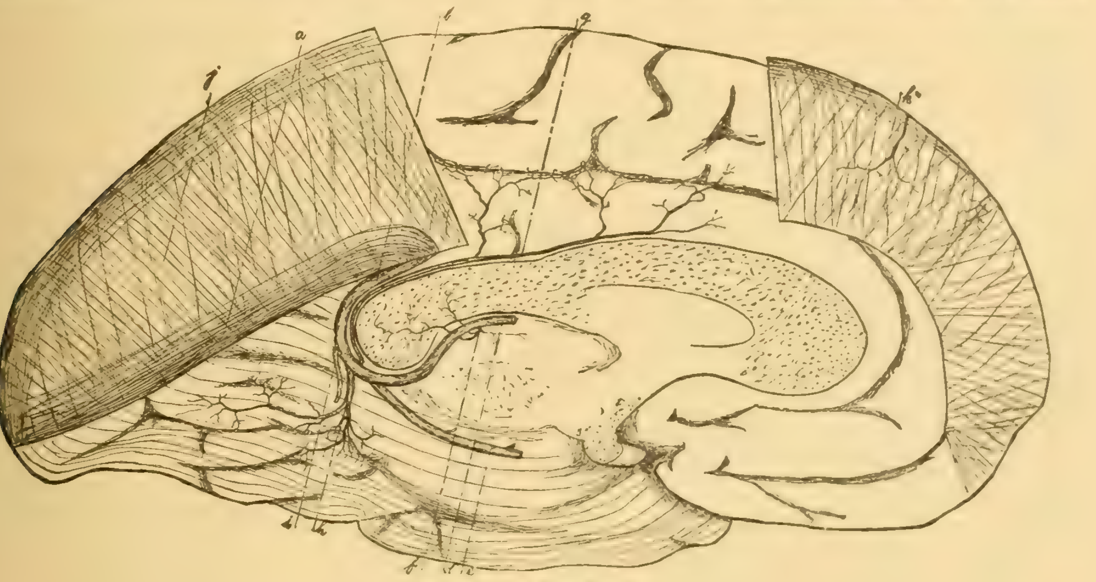

FIG. 4882.—The Vena Galeni.

The frontal set take a course very nearly at right angles to the sinus, or the first of them may even run caudad along the sinus before discharging. They usually spring over to the dura a couple of centimetres away from the sinus. Farther along the sinus the veins take a more and more oblique course until they at last run forward a distance of three or four centimetres, to discharge against the current. At the border of the convexity, or farther out in the pia, the vein makes the necessary bend to approach the sinus as described. It then runs a short distance in the pia, becoming in the cortex a free trunk, for a further short length, and finishes its course in the sinus.

Again, the frontal are open at the lateral angle of the sinus, while the others open more and more at the side, and the last quite at the bottom of the sinus, even coming up a distance towards the face.

Toward their field of derivation these trunks pursue an insufficiently grouped course. In general, over the cortical area the finer radicles are fairly distributed everywhere, from the bottom of the fissures to the crest of the convolutions.

II. *The Internal System, Tributary to the Tentorial Sinus.*—Along its course this small sinus receives only unimportant, mostly dural, venules. At its commencement there may be two affluents: *a*, the basal sinus; *b*, the vena Galeni.

a. The important *basal sinus* also receives only dural twigs in its course, but at its commencement, opposite the frontal border of middle third of callosum, could take up a small vein or veins coming from the frontal third of the callosum, and from the bordering convolutions. Labbé calls this the interhemispheric vein, and says that the case is the continuation of a venule bifurcating, sending a branch to either side. A parallel term, precallosal, was given by Breschet to the precerebral vein.

b. *Vena Galeni.*—This discharges through a slit in the basal wall of the sinus, just caudad of the free border of the tentorium. The name is now limited to the short (1 cm. long, 6 mm. broad) trunk from the union of the velar veins to the sinus. Within, it is often divided by a longitudinal septum.

The course of Galen's vein and the adjacent portion of the velars is very peculiar. The vessels sink a little after crossing the optic lobes, then encircle the splenium, and become subtentorial before ending in the sinus. The latter bears the relation thereto of a tangent to a circle (cf. Fig. 4882).

Galen's vein does not usually receive any lateral affluents. It arises from the union of the right and left velar veins. Each of these consists of two portions, a terminal bent part (*portio curvata*, Fig. 4883, *c-e*) from the entrance to the vena Galeni, and a peripheral, or caudad straight part (*portio recta*) from the origin of these veins opposite the foramen of Monro. The two curved portions start and end together, but midway diverge 0.5 cm.; they receive laterally many large branches. The straight portions run parallel and adjacent, but receive only few and small additions.

The affluents to the portio curvata are largely of cortical origin: 1, v. suboccipitalis; 2, v. supercerebellaris; 3, v. callosalis; 4, v. subcerebralis; 5, vv. optici et conarii; 6, v. postcornualis.

1. The *suboccipital vein* (Fig. 4882, *h*) comes from the collateral fissure and median portion of the suboccipital surface of the cerebrum.

2. The *supercerebellar vein* (Fig. 4882, *k*), oftener a single trunk, but occasionally bilateral, empties into the main vein near its termination, or even directly into the sinus tentorialis. It starts from many little branches over the dorsal surface of the cerebellum, the supervermis, and in its further course takes up small veins from the crura cerebri, and at times also from the optic lobes.

3. The *callosal vein* (Figs. 4882 and 4883, *g*) (first mentioned by Labbé, 1879, then independently described by the writer in 1884) may be either single or bilateral. It is a small but long vessel, and the only one emptying on the concave side of the portio curvata. Its origin is near the middle of the callosum, and dorsad as far as the callosal fissure. It runs caudad at the bottom of the longitudinal fissure, and curves around the splenium close to Galen's vein. In animals (sheep) its size almost equals that of Galen's vein.

4. The *subcerebral* (Fig. 4882, *e*) is a large vein, though its derivate territory is very variable. It forms by the union of many branches—collectively termed *prebasal veins*—opposite the preperforated space. The prebasals include the first five next following:

1. The *precerebral* vein takes nearly the same path, but is too small and uncertain to be well compared to the precerebral artery. Its derivative area is very small, less. It comes around the genu to the base, where it passes before the chiasm to the subcerebral vein. The right and left are usually of unequal size, but communicate, though by an insignificant branch compared to the arterial precommunicant. The two veins may anastomose before the chiasm and pass to one of the subcerebrals, in which case there are one or more slight connections in front of the chiasm with the other subcerebral vein. This vein receives branches from the genu and adjacent median frontal surface.

2. The *olfactory* is a tiny venule, very constant, and demonstrable as far as the olfactory bulb.

3. *Suprafrontals.* One of these is frequently more developed, and may empty instead caudally into the Sylvian or the mediocerebral vein.

4. The Sylvian vein is a variable complement of the mediocerebral venous system. *It lies at the bottom of the basi-Sylvian fissure*, covered up, except near its termination, by the tip of the temporal lobe. It arises in the region of the insula from a great number of radicles. When the mediocerebral is poorly represented the Sylvian may take up twigs from the surface of the temporal and frontal lobes. Around the venae perforantes pass, as a rule, to this vein. There is here often a group of perforantes separated from the others and coming from the lenticular substance caudad of the vessel.

5. The *venae perforantes* are small, very variable in number, and take a straight course for a short distance before splitting up. They come from the striate body and adjacent frontal alba. Their radicles approximate those of the precentral veins, yet without observable anastomoses.

6. The subcerebral vein receives, in its course obliquely across the optic tracts and crura cerebri, several small venules from the chiasm, infundibulum, mammillary bodies, crura, etc. These anastomose freely with each other, and with those of the other side, thus making an outstretched network over these parts which connects on the one hand with a small network before the chiasm, and on the other with that across the pons. This corresponds in general to what Labbé terms the inferior interhemispheric veins. Frequently there are accessory venules from the basal temporal surface.

7. The *subcornual* vein, in that it comes from the end of the middle horn, is comparable to the prechoroid artery. It is very constant in occurrence, but not in size. Though connected with the choroid plexus of the medicornu, it originates in the cerebral substance, sometimes even from the lateral wall of the postcornu, almost opposite the caudal border of the thalamus, where branches are received from the alba lateral to the thalamus or from other directions. In its course along the lateral wall of the horn it receives many accessories, notably from the cornu Ammonis, and as it curves around the end of the horn several twigs from the alba of the temporal apex.

8. *Postperforants*, at least one considerable venule.

9. *Crural* branches, one in particular, can be followed along the crus to the cerebellum.

5. The *bigeminal* vein and variable *optic* twigs often end in the supercerebellar vein instead of directly in the velar. They originate in a fine venous plexus over the optic lobes and conarium, which appears to be connected across the crura cerebri with the basal network described above.

6. The *postcornual* vein is variable, complementary in derivation to the subcornual. It may arise in the alba near the tip of the occipital lobe, and then runs subependymal along the cornual wall. The parathalamic branches above ascribed to the subcornual, and some from the Ammon's horn, pass often in part to the postcornual. The radiate radicles of this vein are traceable through the alba nearly to the cortex (Fig. 4884, *q q*).

There is frequently another vein intermediary between 7 and 6, emptying into either the subcornual or the postcornual.

The straight portion of the velar vein in its course through the velum receives the following, all at right angles:

1. The *splenial* veins (Fig. 4882, *f.*) are very small, and but two or three in number as they come out through the fornix. They often combine with thalamic radicles and empty as one trunk into the velar.

2. The *thalamo-crural* vein, usually one on each side, but sometimes multiple (Fig. 4883, *m.*, *m.*). This begins about the cerebral crus, makes its way dorsad and mesad through the thalamus, and joins the portio recta at about its middle point. It approaches the ventrad side of the velar, and hence is but too easily overseen. Neither 1 nor 2 runs any length in the velum.

3. The *thalamic* veinules are very variable in size, number, and position. They may even be entirely wanting, or run to neighboring veins, *e.g.*, the postcornual. These only arise to a limited extent in the thalamus; they come chiefly from the albalis beyond, running across or a trifle embedded in it. Where one of these is specially large it might be termed the *transthalamic.*

Opposite or toward the apex of the thalamus, the velar vein is formed by the immediate or mediate union of several small trunks. Most of these are in a cluster coming in laterally between thalamus and striatum; the latter nucleus appears much richer in veins than the former. Of all but the first, the intracœlial course of these veins is subependymal.

1. The *medicornual* vein (Fig. 4883, *l.*) takes a sinuous course in the outer edge of the choroid plexus, of about double the actual distance. Its membranous envelopment makes it a counterpart of the pia-veins, and hence the actual continuation of the velar, as held by Bell. It begins in the middle horn, where it is said to anastomose with the subcornual. It comes out of the horn with the plexus, bends to follow the lateral thalamic border, and ends in any one of the veins near the commencement of the velar. Meanwhile it receives a multitude of radicles from the plexus, and some that seem to come from the surface of the thalamus.

2. The *tænial* vein comes from the thalamo-striatal groove, beneath the tænia. Nevertheless it has few tributaries from the thalamus. This short trunk is made up by three sets of veinules: (*a*) *Striatal.* Of these there are usually two or three larger and several smaller branches, coming from the substance and surface of the caudate, and passing to the tænial trunk or to either of the following: (*b*) A prealbal trend of veinules, passing along the outer cœlian border toward the precornu, and thence largely to the albalis of the frontal lobe. (*c*) An opposite trend, directly caudad, a short distance along the outer cœlian wall, and coming from the lenticular nucleus, the internal and external capsules, and the superimposed portion of the centrum semiovale. Many of these various albal radicles can be followed almost to the cortex; their angles of union are acute.

3. The *paraseptal* trunk (Fig. 4883, *o*, *o*). This short vessel, with its two constituent *precornual* veins, is the most direct continuation of the velar. Laterally it receives small *septal* and *genual* accessions. There are usually two parallel precornuals (*pp*). They come from the extremity of the horn and follow its contour around to the septum, or run in the adjacent border of the caudate, though they take up no important radicles from that nucleus. Their multitude of radicles come from the albalis in the basal portion of the frontal lobe, also demonstrable nearly to the cortex.

4. The *superalbals* (Fig. 4883, *nn*) are commonly two small trunks that appear at the outer border of the cœle, opposite the body of the caudate, cross the latter, and empty through the tænial or paraseptal trunk. They come from the cœlian roof, and the frontal and parietal albalis dorsad of those previously described.

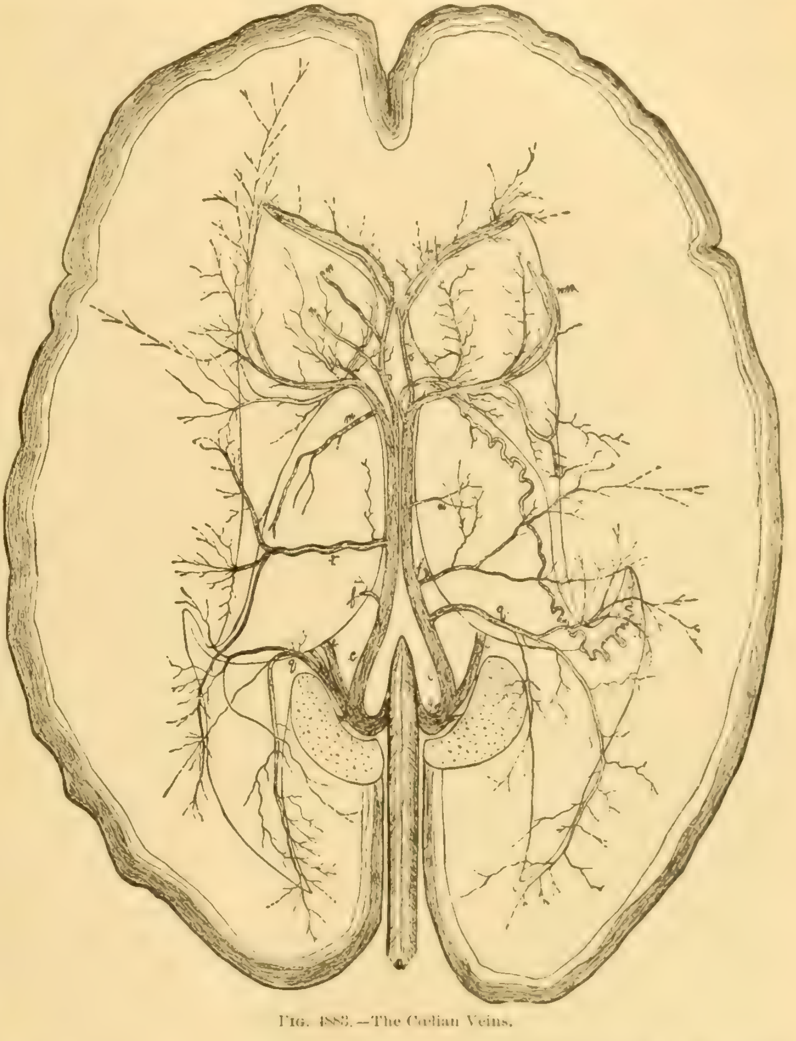

FIG. 4883.—The Cœlian Veins.

C. *Basal Veins.*—These do not constitute a system in the sense of having a common point of discharge—in fact, they have already been described in part under Subcerebral Vein. Although they are quite irregular in termination—small veins seem occasionally to end at any point in the basal sinuses—still there are four frequent points of discharge: 1, Cavernous (and sphenoidal) sinus; 2, superpetrosal sinus; 3, middle of lateral sinus; 4, some sinus about the foramen magnum.

1. Some small veins from the pituitary body and other structures about the sella turcica have been described as tributary to the vene-circle of Ridley. But the largest vein discharging at this point is the *medicerebral*, a superficial vessel following the Sylvian fissure. This should be distinguished from the smaller though complementary

Sylvian vein running at the bottom of the fissure. The medisagittal is inclined to be double, i.e., there are sometimes parallel adjacent veins, one taking up frontal branches, the other only temporal. In this case one vein may receive some of the branches above described and empty into the sphenoidal or the cavernous sinus, while the other vein, accompanied by the dura across the temporal fossa, to the middle of the superpetrosal sinus. This latter is the course that the Sylvian medicerebral vein takes in many cases, as Trolard rightly says; the deep portion may be termed the temporal sinus; by one or two lateral affluents it communicates with the meningeal veins which it crosses.

2. The discharge of the subcerebral vein through the vein of Galen, as given above, holds for about one-half the cases, not always alike on the two sides. The main trunk may be diminished by the termination of some of its usual proximal constituents in the cavernous sinus or medipeduncular vein. Whether larger or smaller, the trunk in others passes to a basal sinus (superpetrosal) by turning ventrad instead of dorsad on reaching the cerebral crus.

One or more precerebellar veins from the flocculus region pass to the superpetrosal sinus, with the subcerebral vein, when this terminates at the base; otherwise they seem to connect with this by venules along the lateral surface of the cerebral crus.

3. The postcerebral veins usually unite into one trunk just at the point where, turning caudad, they form an ampulla in the dura and enter the sinus. This is at the lateral border of the occipital fossa, opposite the exoccipital fissure. These veins come in part from the convexity, in part from the basal surface of the occipital lobe. The latter may be single or multiple; their derivative area is lateral to that of the suboccipital vein. The former is represented by one large trunk from the direction of the Sylvian fissure; it receives varying temporal branches and large ones from the external occipital surface. The postcerebellar veins are smaller than the postcerebrals, but often empty opposite them, though, of course, subtentorial to them. They come from the lateral portion of the cerebellum. The very inconstant postcerebellar veins, one or more in number, terminate in the lateral sinus near the torcular, or even in the tentorium.

4. The subcerebellar veins include only small vessels at the bottom of the posterior fossa discharging into the occipital sinus.

The cerebellar veins—supra, pre-, post-, and sub—are but partially distinct from the cerebral veins.

GENERAL FEATURES OF THE INTRINSIC VEINS.—*Communications.*—In this regard the pia veins must be distinguished from those of the brain substance. In contrast to the arteries, the pia veins communicate freely, not only indirectly through the sinuses, but everywhere on the surface by a network of small vessels, as well as frequently by anastomoses between larger trunks. The veins of the convexity might almost be said to radiate from the Sylvian fissure (horizontal Sylvian). At least several of the larger ones connect toward the middle of the convexity. Of these four may be specified: 1. One of the frontal supercerebrals (fronto-dorsal); 2, the second or third from the last supercerebral (caudo-dorsal); 3, the external trunk of the postcerebral (caudo-ventral); 4, the medicerebral (fronto-ventral). Or any two of these trunks may communicate independently, e.g., the ninth and postcerebral veins by a large anastomosis directly across the temporal lobe (oblique), of course. There are some other connecting veins, not so markedly bridging the fissures, however. The great anastomotic vein of Trolard is No. 4 (most commonly) when continuous with No. 2. Labbé's illustration includes also No. 3. Trolard says it "sometimes takes origin at the side of the longitudinal sinus, but almost always by the confluence of other anastomoses at the middle part of the convexity." He encountered it twenty-five times in thirty subjects. According to Labbé this anastomosis, instead of being with the medicerebral vein, is in common with the deeper Sylvian vein. Practically these various anastomoses present a collateral path in the pia between longitudinal, lateral, and cavernous (sphenoidal or superpetrosal) sinuses. The proximal veins, excepting the perforants and the cerebellar, have ample though smaller anastomoses, including an imperfect counterpart of the circle of Willis. It is evident that the derivative area of the pia veins can never be exactly defined.

The internal system must be separated into those veins uniting in the curved portion of the vein and those tributary to the straight portion. The former, as the writer has elsewhere shown, have the following sets of anastomoses: 1, between the callosal vein—including practically the rare interhemispheric vein—and the median branches of the supercerebrals, across the callosal fissure; 2, between the subcerebral vein and the basal branches of the postcerebral; 3, between the supercerebellar and other cerebellar veins; 4, between the subcerebral vein, when, as in about one-half the cases, this discharges into the Galen, and the many veins adjacent to its derivative area. These communications are all in the pia; from clinical cases we know that these may suffice to compensate fairly when only the terminal sinus and the short common vein of Galen are closed. They do not suffice, however, when there is any impediment to this collateral discharge, and possibly not when the subcerebral vein ends elsewhere. Of the veins passing to the portio recta of the vena Galeni, only one, the mesocoelian, has superficial anastomoses. As this is a long, tortuous vessel, and connects with the subcerebral only by small and questionable anastomoses, it is of itself entirely unable to compensate when the portio curvata becomes occluded. We have remaining the various callosal veins coming directly from the brain substance, to which the postcommissural may also be added. Neither between these nor between their subdivisions short of the ultimate capillaries did the writer succeed in finding any anastomoses. The same holds true for the perforating veins of the base. There still might be intra-cerebral connections between these vessels and the cortical venules. However, the apparently positive results of injections by Duret, and especially by Labbé, are all explicable by the surface anastomoses above described. There may be such occasional but inadequate connections paralleled by the rare ones between the otherwise terminal perforating and cortical arterioles. Hédon (1888) says that a few do exist. Clinical evidence also goes to show that the veins emanating from the central walls are all true terminal vessels, and that closure of the great vein—unless just at its mouth—cannot be compensated.

Cortical Venules.—Duret found only six or eight in the section of a medium-sized convolution, one or two emanating perpendicularly at the crown of the gyrus, and from four to six by the sides. However, they have a diameter triple that of the arterioles. They start principally from the capillary transition plexus—between gray and white—and from the deeper strata.

GENERAL RELATIONS OF THE VEINS AND ARTERIES.—In the pia, over the convexity and on the median surface, the arteries lie beneath the veins (dorsad) as generally as the body elsewhere. But over the insula, and evidently in the sulci generally, the writer has observed the reverse, while of the finer pial arterioles Labbé asserts that the venules lie beneath the arterial. Though the larger veins often jump across from one gyrus to the next, the arteries go down with the pia more or less deeply into the fissures, to come up near or distant over the next gyrus.

Only by a forced comparison can any of these veins be said to accompany the arteries. By contrast, the dural vessels conform in most general features to those elsewhere; they have abundant collateral anastomoses, most of the arterial branches are accompanied by two veins, etc.

Dwight quotes the suggestion that, as the blood in the internal jugular and carotid flows in opposite directions, the arterial pulsations might interfere with the venous discharge, if both lay in a common canal. Trolard drew a strong analogy between the vertebral artery, surrounded by the vertebral vein and plexus, and the carotid through the cavernous sinus. "The supply arteries of the encephalon bathe in venous blood; the carotids from the moment they enter the carotid canal; the vertebrals from the moment they penetrate the vertebral canal." This point has recently been elaborated by Rudinger (*vide* abstract in *Boston Medical and Surgical Journal*, 1888, ii., 323). He shows that by this cushioning the pulsatory movements of the arteries are not abolished as they would be if they filled the bony canals. The diameter of the carotid canal he gives as 5–7 mm. ; that of the artery, 3–4.3 mm. In the cavernous sinus the artery, though situated at one side of the cavity, is not in contact with either the bone or the dura.

The various retarding bends and angles in both classes of vessels can only be referred to. They affect very unequally the circulation in the different parts. The existence in the pia of vessels larger than capillaries, connecting the arteries with the veins, has been many times asserted and denied—the last investigator, Labbé, contriving to do both. This point still awaits final settlement.

III. THE DURAL SINUSES.—The encranial sinuses are all intradural, and all except the tentorial (with the falcial) lie against the cranial wall. They do not collapse on being slit open, nor do they admit of much distention—the falcial and the parasinual spaces excepted. They are lined by a continuation of the inner membrane of the jugular. Allen counts 16 sinuses ; 10 paired (symmetrical), and 6 unpaired (azygous). But their number depends so much on the way they are divided as to cause the remark that the easiest piece of anatomical work was to describe a new sinus.

They have been variously classified : (a) In two reciprocally perpendicular planes, the vertical plane including the longitudinal and tentorial (plus falcial), the horizontal including the remaining ; or, (b) in three horizontal planes ; or, (c) as connecting at three points, viz., the torcular and the two cavernous sinuses (to which Trolard sought to add a precondyloid confluens) ; or, (d) according to the area drained.

The Longitudinal Sinus.—This, the longest sinus, runs parallel to the sagittal suture, slightly grooving the bone in a curved line from near the crista galli to the internal occipital protuberance. It lies between the folds of the falx, as they diverge to continue as the parietal dura. Its section presents a rounded triangle, increasing in size from the accession of large veins. Its lumen toward the bottom is crossed by numerous irregular strands (trabeculæ, chordæ Willisii). The openings from the supercerebral veins are usually larger than those from the parasinual spaces (and dural veins). The sini subalterni of Malacarne are often seen in the falx just beneath the sinus, and present more or less developed parallel narrow passages freely connecting with the main vessel. At the torcular this sinus more often turns into the right lateral. Rarely it, or its tributaries, drops down through the falx to the falcial sinus, or just before the torcular to the tentorial, or even divides, following the lambda sutures to each lateral sinus. The whole longitudinal sinus may be occluded without causing disastrous results.

Falcial Sinus.—This may run along about two-thirds of the free border of the falx or near the border, and then represents the continuation of the tentorial sinus. It is rather a large dural vein than a sinus. At its commencement, the occasional interhemispheric veins empty. Its only lateral tributaries are usually small dural veinules, though part of the supercerebral veins or of the longitudinal sinus have in rare instances been seen to turn this way. On the contrary, Knott once saw the falcial pass to the longitudinal, and some connection between the two is not uncommon.

But, as stated by Luschka, this sinus is very variable in size and occurrence. In a series of adult subjects the writer found that its average occurrence was only one in six ; in the fœtus it was never present. Trolard's attempt at presenting this as an important anastomosis between the dorsal and internal systems, or as a safety-diverticle of the latter, was quite overdrawn.

Tentorial Sinus.—This lies at the junction of the falx and tentorium (Figs. 4882 and 4883, *a*). It extends in full size from the torcular to the intersection of the free falcial and tentorial borders opposite the point where it receives its main tributary, the vein of Galen. Its section is a triangle with narrow base resting on the tentorium. Laterally it takes up small dural radicles, and often a supercerebellar vein. It is straight, lies in the median line, and is directed caudad. "It opens into the lateral sinus by an oval mouth formed by strong pillars of fibres."

Torcular.—A *confluens sinuum* in the sense of the old writers does not exist. "The right lateral sinus for the most part begins higher than the left, and may be considered as the continuation of the longitudinal. In some subjects the right or left lateral sinus begins from the longitudinal one, while that of the other side is continuous from the tentorial ; and then the lateral sinuses are separated at their origin by a membranous isthmus" (Charles Bell, 1827). Rüdinger speaks of a "valvular arrangement" separating the two currents. In 26 out of Knott's 44 cases, the tentorial opened into the left lateral sinus, in 6 into the right, in 12 mesially. The statistics given below, on the larger jugular canal, bear on this question. This peculiarity of the paths at the torcular tends to prevent a reflux of blood from one into the other, or any interference of the currents.

However, in a considerable minority of cases the currents must intermingle. From the arrangements of the sinuses at the torcular, thrombosis of the longitudinal and right lateral is more often associated than of the longitudinal and left. A comparison of the few casual cases at hand shows 6 of the former to 2 (or possibly 3) of the latter. Of course, much more frequently—in 12—all three sinuses were involved.

Lateral Sinus.—This runs from the torcular, at first in the attached tentorial border, then curves (*flexura sigmoidea*) to follow the groove in the mastoid and gain the jugular canal. It has been seen to take a more basal course, running first in the cerebellar falx, then beside the foramen magnum to its usual exit. From the extensive investigations of Hartmann, Rüdinger, Bezold, and Politzer, it appears that frequently the sigmoid portion approaches within a few millimetres of the posterior wall of the auditory meatus. The one into which the longitudinal sinus turns, usually the right, is double the size of the other, and also a trifle longer. Rarely, one lateral is minimal in size or even absent. It receives laterally the postcerebral and paracerebellar veins and superpetrosal sinus, and gives off two inconstant emissaries.

Cavernous sinus, distinguished by its irregular outline and cellular or reticulated appearance from intercrossing fibrous bands. It represents a colossal perivascular structure about the carotid, in a way similar to that established by Braune and his school, for certain lymphatics accompanying veins. The late Von Langer, in one of his last publications, based on corrosion and other preparations from infantile subjects, showed that the cavernous sinus is originally a plexiform net-work of veins, which, by fusion of its channels, takes on its later characteristics. The wall-resorption goes on to old age, when villous offshoots of the remaining trabeculæ are often seen to project into its cavity. It is traversed by the carotid (cavernous portion). All the orbital nerves except the optic pass near or through its outer wall. Besides veins and emissaries, it is the communicating centre for all the prebasal sinuses. Frontad it tapers to the ophthalmic vein—the swollen end of which has been dubbed *sinus ophthalmicus.*

Laterally, the cavernous receives the *sphenoidal sinus*. This runs out along the dependent side of the lesser sphenoidal wing. Knott notes great variability in its size, though never complete absence, a small vein at least being found. Peripherally it receives or connects with a medidural vein, and also a diploic canal, and may take up the medicerebral and connect with ophthalmo-dural veins.

The *subsphenoidal sinus*, on the great wing of the bone, was found by Knott 14 times on the right and 9 on the left side.

Mesad, the cavernosi connect by the two *transverse sinuses*—which alone deserve to be called transverse. These follow the walls of the sella turcica, curve slightly to enclose the pituitary body, and complete the so called vene-circle of Ridley.

Sinus præpetrosus (jugularis spurius of Luschka, pe-

(squamo-squamosus of Hyrtl, petrosus anterior of Bell). This occasional sinus, at the bottom of the temporal fossa, describes a curve along the petro-squamous suture, from the spinous foramen—connecting with the meningeal veins and also with the cavernous sinus—to either (or both) the contiguous transverse or the petrous portion of the lateral sinus (often by perforating the prominent petrous ridge). Its physiological interest arises from the prominent part which it plays in the fœtus. Zuckerkandl (1873) found this sinus 22 times in 280 skulls. Knott, [illegible] in [illegible], found what appears to have been a continuation of this sinus to the sphenoidal; in 7 of 44 subjects he found the [illegible] on both sides, in 19 on one side only.

Caudad, the cavernous empties into the oblique superior and inferior petrosal sinuses, but principally the former. The superior petrosal sinus starts from the cavernous, runs in the prolonged attached border of the tentorium along the dorsal ridge of the petrous bone, and enters the lateral sinus against the current at the beginning of its sigmoid flexure. It alone offers a direct intracranial connection between the petrosal and lateral sinuses. The temporal sinus (superior cerebral or anastomotic vein) and the [illegible] vein, the larger (into this in nearly one half the cases, the [illegible] vein more constantly). As a consequence, its size varies considerably, though it is usually small. The vestibular and even tympanic veins of the ear pass to the superior petrosal sinus, either directly or by a dural vein. In his forty-four subjects, Knott notes its absence twice on the right and once on the left.

The inferior petrosal sinus runs in the petro-occipital groove, from the cavernous sinus to the subpetrosal vein, which, by bending before its discharge into the jugular vein, secures an unimpeded outlet for this sinus (for comparison, see Vena Subpetrosa).

Occipito-basilar plexus.—In the occipital fossa are several small sinuses that vary much in size and distribution. The *occipital sinus*, usually bilateral, runs along the cerebellar falx and connects with the lateral sinuses by small mouths beside the torcular. Pre-, trans-, and post-occipitals have been made out. The so-called circular sinus of the foramen magnum is more often incomplete, [illegible] of the hole. The basilar sinuses over the like-named process connect with the preceding and with the petrosal sinuses. Langer has shown that, like the cavernous sinus, all of these are the persistent channels of what originally, in the fœtus, was a vein-plexus; and he has also corroborated Virchow's description of their enlargement in the aged.

Parasinoidal Spaces.—These are the venous pockets or derivative reservoirs (lacunæ, *venous laterales*), though described with increasing definiteness by a long series of observers, find but little mention in the text-books. Their principal development is opposite the middle of the longitudinal sinus (bilateral). As numerous minute spaces they further occur along nearly the whole length of the said sinus, and also (Langer) beneath it in the falx, beside the lateral sinuses, on both sides of the tentorial sinus, and it is said even about the cavernous. The dilated intradural termination of the postcentral and parietal veins has also been thus classed. They all occupy the interstitial space between the dural layers lateral to the sinuses, and hence are very shallow and of irregular outline. They have a lining membrane, also many intersecting fibrous trabeculæ, and are injectable from or with the sinuses. In position and characteristics they are intermediaries between dural veins and sinuses. Where present they receive most, if not all, the dural veins. The larger spaces are traversed by ascending pia-veins, with which they connect by one or more openings. They increase in size as life advances and then have intimate relations with the Pacchionian granulations—so much so that they have even been termed Pacchionian blood-cavities. The circulation in their interior is not believed to be very active, and the spaces have repeatedly been found thrombosed.

On opening a sinus or the mastoid canal, blood usually flows out in a more or less pulsatory stream, showing that the [illegible] interior pressure is positive. In the cases of operative perforation of a lateral sinus (Jacoby, Knapp, [illegible], [illegible], Owen, Reeve, and Von Bergmann), all ending in recovery, there is no record of air being aspirated. But in one case of opening of the longitudinal (Genzmer, 1877) so much air was aspirated as to prove quickly fatal, and François-Franck (1881) has endeavored by experiments to show that aspiration can be communicated through the vertebral veins to the diploic canals of the occiput.

Blocking of any single sinus is not necessarily dangerous, though occlusion of a cavernous or the torcular is always a serious matter.

IV. VENOUS OPENINGS THROUGH THE SKULL (EMISSARIA, ETC.).—From their number and pathological importance, and for clearness of description, these passages ought to constitute a separate class. Each of the cranial bones (unless the ethmoid) has a foramen permitting direct communication between the dural sinuses and veins and the exterior veins; still these are of very unequal size, and in part disappear in the adult. There is not [illegible] topographical correspondence between the position of these exits and the area drained through them, nor is the area in any case closely definable. They may all act as efferent vessels, although the ophthalmic veins are usually afferent—partially so, says Sesemann (1869), largely so, Gurwitsch (1883), and Merkel—and certain of the others may conduct either way according to circumstances. Only Nos. 2, 6, 7, and 8 are superficial, while 7, 8, 11, and perhaps 4 belong rather to the dural and diploic system. Nearly all the blood normally passes out through the two posterolateral foramina with their four canals. But any one of the exits and, so far as known, any two—or, in case of the smaller emissaria, several—may be permanently closed, without causing serious harm. Both internal jugulars have been tied in the same subject (Pilger, 1880) without other evil consequences than a temporary headache.

1. *Jugular Canal.*—In the lateral part of the posterolateral foramen. This, by far the largest of all the exits, leads from the sigmoid flexure of the lateral sinus to the bulb or gulf of the internal jugular vein. Its path through the foramen is often more or less separated from the passing nerves, etc., by a bony septum, thus forming a true jugular foramen. Rarely it is very small on one side, or even absent (4 or 5 known cases).

By adding the series of 159 skulls examined by Dwight to the 100 by Rüdinger, we have 259. In 173 of these the right jugular foramen was larger than the left (i.e., about ⅔), in 65 the reverse (¼), and in 21 the two were equal ($\frac{1}{12}$). This harmonizes with what was said above (see Torcular).

2. *Emissarium mastoideum*, of most importance in fœtal life. It arises directly from the lateral sinus and empties usually into the occipital vein (extracranial), sometimes into the posterior auricular, or even directly into the external jugular. In the 36 perfect skulls examined by Green (*American Journal of Otology*, vol. iii.), it was absent on both sides in 1 and on one side in 1. It was always just behind the posterior limit of the mastoid process. The external opening was opposite the middle (at about the middle of the perpendicular height of the mastoid) in 20, above this in 2, below in 6, and directly on the base of the skull in 1. Its diameter measured 5 mm. in 1, 4 mm. in 4, 3 mm. in 10, 2 mm. in 10, and 0.5 mm. in 4.

3. *Emissarium postcondyloideum* (postjugular vein), passing from the lateral sinus near its termination to the upper cervical or vertebral veins. In 44 skulls, Knott found this on both sides in only 15, on the right in [illegible], and on the left in 10. In Dwight's series of 142 skulls, with unequal jugular foramina, the postcondyloid foramen was larger on the same side as the larger jugular in 34, on the other side in 57, and equal or absent in 52 (the foramen being wholly for the transit of the emissary).

4. *Emissarium precondyloideum*, connecting with the occipital sinus or its basal prolongation, taking up a diploic vein, and passing in part to the subpetrosal vein, in part to the plexus about the vertebral. As pars venosa hypoglossi, Luschka described a cluster of veins

about the hypoglossal bundles as they unite in the inner portion of the foramen, from which two veins passed down the canal. Trolard says that externally the precondyloid foramen presents a deep cavity in which is lodged a true venous confluens. Ventrad its wall is hidden by the external part of the atlo-occipital ligament. He says that this confluens receives five veins: 1, Ventrad and mesad, the medilacerate; 2, latero-ventrad, a connection with the subpetrosal vein; 3, dorsad, a precondyloid vein; 4, latero-dorsad, an inconstant vertebral vein (passing between atlas and occiput, behind the internal jugular, sometimes in a bony canal); 5, a little vein on the pre-atlo-occipital ligament, communicating across with the intraspinal sinuses.

Dwight, in the same series of 142 skulls, found the precondyloid foramen larger on the same side as the jugular in 16, on the other side in 11, the two sides equal in 115. "There does not appear to be any definite relation between their size and that of the postcondyloids."

5. Small uncertain veins through the *foramen magnum* or beside the vertebral arteries, connecting some marginal sinus or vein with the vertebral and spinal vessels. The fine veins in the spinal cord also connect with intrasubstantial ones above.

6. *Emissarium occipitale*, a small mesal conduit from the torcular through the occipital protuberance to the external veins of the occiput. It is often, but not always sinuous, and takes up an azygoid diploic trunk. Knott found it as a small but traceable vein in six of his forty-four cases. In most of the others there was a small vein piercing one of the bone-plates and anastomosing with the diploë veins.

7. *Emissarium Parietale.*—In 100 skulls Gruber found the parietal foramen on both sides in 29, on the right in 19, on the left in 12; average distance from angle of occipital squama, 3–5 ctm.; distance from sagittal suture, 2–17 mm. Their size varies ordinarily from ⅛ to 1 mm. They do not terminate internally directly in the long sinus, but in the parasinual spaces or dural veins.

8. *Diploic Connections.*—Innumerable small openings through the inner plate of the skull connect the dural veins and spaces with the diploë canals. These are largest and most numerous along the longitudinal sinus (corrosion preparation).

9. *Orbital Connections.*—(*a*) The ophthalmic vein is, next to the jugular, the largest and most constant of all the passages. It empties largely into the cavernous sinus (through the orbital fissure, where it bears a constant constriction), but has free anastomosis with the prefacial vein at the inner canthus. Allen says that formerly the trunk of the facial was opened at this point to relieve cerebral congestion. (*b*) The central retinal vein has full anastomoses with the ophthalmic, but goes as a rule to the cavernous sinus, or frequently to a fine venous plexus around the optic nerve, and then by several veinules in part to the subophthalmic vein, in part to the said sinus. (*c*) The smaller subophthalmic vein or veins connect doubly with the larger into which, or oftener into the sinus cavernosus, they discharge (always afferent, say Sesemann and H. Meyer). Peripherally, they anastomose with facial and even pterygoid veins. (*d*) The ophthalmo-dural vein of Hyrtl (1859) is practically included under the more or less constant connection of the medicerebral vein and the sphenoid sinus. Occasionally this sinus or vein has a small anastomosis, through the lateral part of the orbital foramen, with the ophthalmic or other orbital vein. Evidently, the vena aberrans of Verga (1856) should be classed here. As a passage from the ophthalmic vein or cavernous sinus to the lateral sinus, Knott mentions one case (on right); or between ophthalmic vein and superpetrosal sinus, three instances (on left).

10. *The emissary of the foramen rotundum* from the cavernous sinus, and accompanying the superior maxillary nerve as described by Nuhn, was twice seen by Knott (on right).

11. The medidural vein discharges largely through the *oval*, or *spinous*, *foramen.* Nuhn described a pair of veins which, after traversing the oval foramen, formed a plexus about the inferior maxillary nerve and terminated in the infratemporal veins. Knott found these veins on both sides in 18; two veins on right and one on left in 6; the reverse in 4; a single vein on each side in 11; no vein on one side in 5. Luschka and Trolard describe a vein, from the cavernous sinus, that receives dural veins from the anterior petrous surface and departs through the oval foramen; in this case the medidural emerges through the spinous foramen.

12. *Plexus s. Sinus Caroticus.*—Bell (1827) mentions a *vena sodalis arteriæ carotidis*, as an emissary from a petrous sinus, descending through the carotid canal. Rektorzik (1858) seems to have rediscovered this. A prolongation of the cavernous sinus into the carotid canal constitutes the sinus caroticus. This breaks up into a plexus of small veins about the artery, converging to one or more small trunks below, that may pass to the internal jugular. It may connect with 11 and 13. Knott was always able to find this communication, though the vessels varied much in size and number.

13. *Vena Medilacerata.*—Englisch is credited with having described (1863) a constant communication, outside the skull, between the cavernous sinus and the subpetrosal vein. As *inferior petro-occipital sinus*, Trolard independently describes the same. "On the exterior base of the cranium a small vein occupies a groove extending between the two lacerated foramina. Its direction is latero-caudad. It inosculates with cavernous sinus or carotid plexus, and with the precondyloid confluens" (*v. supra, sub* 4). Knott found this in fourteen out of thirty-three cases.

14. *Vena subpetrosa*, from the subpetrosal sinus, through the premedian portion of the foramen postlacerum, to the jugular vein. Here it is separated—not rarely by bony lamina, thus forming the foramen anomalum of Gruber, 1869—by three nerve-trunks from the jugular canal. From numerous investigations Gruber found that only rarely did this vein pass quite through the foramen before entering the jugular, and that then it first connected with the termination of the lateral sinus. However, in 8 out of 22 times Knott found that the vena subpetrosa ended at about the level of the lower margin of the jugular foramen; in 9 a little above; and in 5 a little below. It connects also with the precondyloid vein or confluens, and commonly receives the internal auditory veins.

To these may be added the following, of rare occurrence in the adult:

15. *Emissarium temporale* (foramen jugulare spurium). This is held to be a relic of the primary jugular vein. Where present, it proceeds from the prepetrosal sinus, perforates the temporal bone beneath the root of the zygomatic arch, emerges just behind the glenoid fossa at the edge of the porus acusticus externus, and ends in the external jugular system.

16. *Foramen cæcum*, in fœtal life a communication between the longitudinal sinus and the veins of the frontal sinus, ethmoid bone, and nose. Rarely, if ever, observed in the adult.

17. The very rare, pathological venous blood tumors of the cranium (*v.* Mastin, *Journal of the American Medical Association*, 1886), arterio-venous aneurisms of the scalp, etc., occasionally communicate on the one hand with external veins of the head, on the other through openings in the bone usually with the long sinus.

LYMPHATIC SYSTEM IN THE BRAIN.—There are no lymphatic glands in the cranial cavity; nor does the brain possess a system of independent lymphatics. Within the brain-substance all the larger lymph-passages accompany the blood-vessels as cylindrical enveloping spaces. These are at least twofold: (*a*) *Adventitial* spaces between media and adventitia, which latter are not closely bound together in the vessels of the central nervous system as in the remainder of the body; (*b*) *perivascular* spaces of His and Robin, connecting with the subpial or so-called epicerebral space. Their existence in normal tissues has been repeatedly disputed, and unquestionably their size is artificially much increased by the usual methods of preparation. The latest investigators, Rossbach and Sehrwald, assert very positively the tral extension of these spaces. They verified by Golgi's method, claiming that this traces the lymph, and thus the lymph-spaces rather than the ganglion-cell and its processes.

The beginning of the lymph passages is to be sought in the very narrow spaces surrounding the ganglion-cells—pericellular spaces (Obersteiner). In each of these latter spaces end, according to Rossbach and Sehrwald, many fine canaliculi, often running a long distance through the tissue, and starting [illegible] from cells lymph-spaces. These surround the protoplasmic cell processes. The efferents from these cell-spaces pass along the axis process, inward, and empty into perivascular and superficial glial spaces, or directly into the epicerebral space. The lymph-system of each ganglion-cell has no direct anastomoses with that about any other such cell. They also describe a lymphatic plexus about the glia cells (perivital spaces), especially in the external cortical layer and in the first subcortical [illegible]. These are often intermediary between the pericellular spaces and the perivascular spaces, into which latter and the epicerebral space they empty.

The lymphatics of the choroid plexus in the paracele course (Arnold) to one trunk following Galen's vein. In the parenchyma lymphatic net-works have occasionally been observed.

The lymph passages collect in the pia to larger trunks, follow the course of the veins, and pass out, in part through the jugular foramen to superjugular glands, in part through the carotid canal to the deep cervical glands, in part beside the vertebral vessels to the infrajugular glands.

SEROUS CAVITIES, CEREBRO-SPINAL FLUID, ETC.—Between dura and arachnoid is the *subdural space*. In the normal condition this contains only a capillary layer of fluid. The dura has a system of lymphatics accompanying the blood-capillaries within their adventitia. Besides, in the endothelium of the dura independent lymphatic plexi and stomata have been described, presenting a communication with the subdural space, and conducting off the subdural fluid. Through the oval and spinous foramina pass (Arnold) lymphatics to the deep facial glands, probably coming from the dura.

The interspaces of the pia, i.e., the somewhat broken room between arachnoid and pia proper, constitute the subarachnoidal space (*cavum subarachnoideale*). This is the reservoir of the cerebro-spinal (cephalo-rachidian) fluid. Although this fluid can pass back and forth between the supratentorial cephalic and spinal spaces, it is no longer held that there is a continuous ebb and flow from one to the other at each respiratory movement and every pulsation. This space is exceedingly attenuated wherever the brain lies close to the skull, as over the convexity. At other points it forms lacuna-like pockets, termed by Key and Retzius cisternæ. Among these may be mentioned: *Cisterna magna cerebello-medullaris*, where the arachnoid spreads across from the caudad border of the cerebellum to the oblongata; *cisterna fossæ lateralis* (*cisterna Sylvii*); and over the optic lobes the *cisterna ambiens*. The cavæ connect with these cavities (the cerebral fluid comes from the choroid plexuses), the metacele with the cisterna magna through the foramen Magendie and the aperturæ laterales; the paracele with the cisterna of the base, by the lower horn, over the great hippocampus. There is no canalis Bichati, formerly supposed to connect the paracele with the subdural space. Hence, while the cœlian and subarachnoidal cavities are united, neither has any direct connection with the subdural space. An indirect connection may be effected by the nasal lymph-net, as this may be injected from the subdural as well as subarachnoidal space by way of perineural lymph-passages about olfactory nerves. Another assumed indirect connection is by the Pacchionian bodies and the sinuses. The experiments of Key and Retzius, confirmed by Kollmann (1880), seem to show that the perforations of the dura—opposite venous sinuses—by these bodies furnish one of the principal drainage paths for both subarachnoidal and subdural spaces. Probably, however, their injections produced artificial openings not existing intra vitam. Certainly they do not usually attain any development until long after youth has passed. Further reasons in opposition are given by Adamkiewicz in his polemic ("Eulenburg's Real-Encyclopädie," 1886, Art. Gehirndruck) against Bergmann's theory of brain-compression, and in favor of his own somewhat novel views. Material injected into the subarachnoidal space in animals traverses the superior cervical and submaxillary glands. In man it can pass out in the optic sheath to the bulb, in the sheath of the facial and the acoustic as far as the internal auditory meatus—whence fracture of the petrous with tearing of the nerve sheath leads to escaping out of cerebro-spinal fluid—and finally to the lymph-tubes in the nasal mucous membrane, the supposed path of meningeal infection from nasal sources.

The subarachnoidal cisternæ protect the large basal vessels from compression, and in like manner the pericellular spaces shield the ganglion-cell and its process from shock and pressure. Further, the perivascular cisterns protect the brain-substance (His) in a more general way.

CEPHALOCELE (encephalocele, hydrencephalocele, hydrencephalocele, cephalhydrocele, meningocele, hydromeningocele, craniocele, hernia seu fungus seu ectopia cerebri).* Hernia of the brain or meninges is a name given to a protrusion of a portion of the contents of the cranial cavity through an opening in the skull beneath the scalp. There is need of greater simplicity in what is now a rather confusing terminology, and it would seem that the best designation for all of these tumors as a class is cephalocele. There is a correspondence in application between this word and enterocele, because of the similarity of their constituents. There is a hernial canal or opening in the skull, a hernial sac consisting of the dura mater, the hernial contents composed of whatever substance or fluid may be forced out from the cranial cavity, and, finally, the various coverings of the hernia, such as the pericranium, fascia, and skin. It is necessary, in a true cephalocele, that the dura mater form the hernial sac. The tumors formed beneath the scalp in traumatic lesions of the skull and dura, by the pouring out of cerebro-spinal fluid, are not true cephaloceles, and are more properly termed *pseudo-meningoceles.* Protrusion of brain-substance in compound fractures of the skull is not considered here, though sometimes improperly called a hernia cerebri; the correct designation is *prolapsus cerebri.*

---

* See Editor's Note at end of article.

The varieties of cephalocele depend upon the contents of the tumor. Hence we have a *meningocele* where the hernial contents are cerebro-spinal fluid alone pressing out the dura mater; a *hydrocephalocele,* where the tumor consists of an internal hydrocephalus expanding and forcing outward the ventricular walls; and, finally, an *encephalocele,* composed wholly of brain-substance with more or less fluid usually surrounding it.

These tumors are mostly of congenital origin, but there are certain rare cases in which they are acquired after birth, through disease of the cranial bones or traumatism. It is usual, therefore, to distinguish two forms of cephalocele, the congenital and acquired. In describing the latter it will be best to use the prefix *pseudo.*

Congenital Cephalocele.—These tumors almost always have their pedicles at or in the immediate neighborhood of some cranial suture. The great majority are in the antero-posterior median line, as a rule either in the frontal or occipital region. According to Giovanni Reale, who collected 68 cases of cephalocele, 10 were at the nasal root, 9 in the frontal suture, 5 at the posterior fontanelle, and 22 in the occipital bone, the rest arising from some of the lateral sutures. Larger tabulated 85 cases, 44 of which were occipital, and 41 frontal or sincipital. The favorite location of the sincipital tumors is at the root of the nose, either at the inferior part of the frontal suture or at the junction of the ethmoid and frontal bones. The hernial canal or opening is generally bounded by the separated or more or less malformed ethmoid, frontal, nasal, or lachrymal bones, and sometimes even the nasal process of the superior maxilla. The occipital cephaloceles are the most frequent of all. They are situated either in or near the posterior fontanelle, or lower down under the occipital protuberance, where the hernial opening may be conjoined with the foramen magnum. Hernial protrusions from other sutures are much more rare, although they do occur in the greater fontanelle, in the squamous suture, or between the ethmoid and sphenoid bones at the base of the skull.

Cephalocele is uncommon, Trélat finding but 3 in 12,000 births, and Vines 1 in 5,000. It is said to be more common in females than in males, though Z. Lawrence (quoted by Erichsen, "Surgery," vol. ii., page 378) collected 39 cases, 21 of which were males.

The tumors vary in size from that of a pea to that of a child's head. The occipital are always the largest, and are usually hydrocephaloceles. The sincipital tumors are, as a rule, small and simple encephaloceles. Meningoceles may exist in either place, but are more common behind. Hydrocephaloceles are rarely sincipital, owing to the positions and conformations of the ventricles, which are more apt to dilate posteriorly.

The occipital *hydrocephaloceles* are usually constricted at their base, often pedunculated, almost globular in form, and seldom attached by broad bases. They generally contain the dropsical posterior horns of the lateral ventricles or their fœtal analogues. Those in the lower occipital region enclose the cerebellum and the hydropic fourth ventricle. In some of the largest hydrocephaloceles have been found a great part of the cerebrum, the cerebellum, fourth ventricle, and quadrigeminal bodies. The protruding cephalic parts are commonly of inferior or defective development, often difficult to recognize as brain-substance, owing to cystoid degeneration and sclerosis (Huebner). Sometimes the constriction at the hernial opening is so great that there is marked stasis of blood in the pia, which may lead even to extravasations. Occasionally these tumors present longitudinal constrictions caused by the venous plexus or by the falces of the dura. The quantity of fluid contents varies, but may reach two quarts. It has been found to be rich in albumen, with a specific gravity of 1.010–1.012.

The *meningoceles* of the occipital region are quite as large as the hydrocephaloceles, and similar in shape, while those of the sincipital and lateral areas of the skull are much smaller. One very large meningocele held fluid which had a specific gravity of 1.004, and contained a small quantity of albumen, uric acid, chloride of sodium, and biliary coloring matters (Heineke).

The *encephaloceles* are usually small tumors with broad bases, having a diameter as a rule between one and three centimetres, generally occupying a position at the root of the nose, and containing often, besides cerebral substance, a small quantity of subdural fluid.

Pathology.—There are several theories advanced to account for the origin of these congenital tumors. One is, that there is a limited ventricular dropsy, which by pressure at some certain circumscribed portion of the skull expands and separates the cranial bones and thus protrudes. From a hydrocephalocele thus formed an encephalocele may be produced later, by reabsorption of the dropsical fluid; or a meningocele, by a recession of the cerebral substance into the cranial cavity. The arguments against this hypothesis are, that there would scarcely be a circumscription of the dropsy as imagined, but rather a tendency to a general hydrocephalus; and, furthermore, Ackermann and Heineke have determined that there is a diminution, and not an increase, of intracranial pressure in cases of cephalocele.

A more probable theory as to the etiology of these tumors is, that they originate in the early embryological periods, when the cerebral vesicle and its fluid contents are in process of growth, and their osseous capsule is not yet developed. There is then an arrested or defective evolution of the cranial vault, as a result of which complete closure of the skull does not take place, and a circumscribed portion of the fœtal brain-vesicle protrudes. According to this hypothesis, hydrocephalocele would belong to an earlier stage of development, and encephalocele to a later, when the protruding portion of brain no longer exhibits the configuration of the fœtal brain-vesicle as it does in the former. In like manner, meningocele may originate either by the mere extrusion of the dura mater through pressure of the subdural fluid, or by the bursting of a hydrocephalocele, or it may be the remnant of a disorganized encephalocele. Meningocele might also spring from the cerebral vesicle in the earliest stages of development, as a mere membranous cyst without brain-substance. Yet, if the defect in the skull were the only factor in the formation of these tumors, it would be difficult to understand why they are not present in every child in the open cranial spaces, the fontanelles. We are compelled, therefore, to recognize, as another factor in their causation, a general or partial hydrocephalus, either internal or external.

This conception of the embryological origin of cephaloceles is corroborated by the fact that most of them are found in front and behind the head, in the median line, which is the most marked direction of growth of the cerebral vesicle; and that other defects and malformations of the skull, face, spine, feet, etc., are often observed in connection with these cases. Thus striking departures from the normal shape of the skull are particularly noticeable in hydrocephalocele and the large meningoceles, where there is often asymmetry, thickening of the sutures, microcephalus, flattening from before backward, and sometimes hydrocephalus; while in the simpler tumors the skull presents, as a rule, a wholly normal configuration.

What may be the ultimate causes of these defects can only be surmised. Premature union of the meninges with the amnion, and injuries to the fœtal head *in utero,* may sometimes be the occasion of their development.

Clinical Features.—The cutaneous surfaces of the cephaloceles are usually smooth, more or less distended, and sometimes very vascular. Occasionally they are excoriated, or present old cicatrices. Angiomata and lipomata have been described as forming upon cephaloceles (Larger, Ried). Hydrocephalocele and meningocele exhibit a distinct sensation of fluctuation, while the encephaloceles have more of a sensation of softness and elasticity, but also show fluctuation if surrounded by a sufficient quantity of fluid. When the coverings are thin, from great tension by fluid contents, these tumors may be translucent. They frequently pulsate synchronously with the pulse and respiratory movements, and their tension is often variable, as there may be a sinking of the tumor in sleep and marked bulging out in the acts of crying or coughing. They may sometimes be diminished in size by pressure, which if moderate does no harm, but if great not infrequently produces symptoms of brain-compression, such as vomiting, retardation of the pulse, unconsciousness, and convulsions. Pulsation is, as a rule, absent in meningocele and hydrencephalocele, but this naturally depends directly upon the size of the cranial opening in the skull and the intercommunicability of the contents of the sac with those of the cranium; these tumors also show generally little variation during sleep, coughing, crying, or upon the application of pressure, unless the cranial foramen is large. Symptoms depend to a great extent, too, upon the physiological value of parts protruded; and in encephalocele such parts are often very different from their analogues in the normally developed brain. In the light of the recent discoveries in cerebral localization these cases might often afford very interesting results by careful study.

Prognosis.—Many children affected with meningocele or hydrencephalocele die before or during birth. Sometimes the tumor bursts during parturition. Those born living rarely last many years, partly on account of the imperfect condition of their brains and partly because the tumor often rapidly increases to such size by the superaddition of cerebro-spinal fluid that it bursts spontaneously, causing death either speedily, in coma or convulsions, or slowly, from a consecutive meningitis. Recovery after such evacuation of the tumor takes place but rarely. Death occurs usually in the first two or three years of life, but a few children with meningocele have attained the age of twelve, and even seventeen years.

The encephaloceles being smaller and simpler than the varieties just mentioned, still-birth and rupture are less common in cases affected with them, although they do occur. As a rule, this class either grows slowly or remains stationary. Whatever disturbance is excited is due to disorder of brain-function, but patients suffering from the frontal variety live longer and with fewer cerebral symptoms than those afflicted with the occipital variety. Children with occipital encephaloceles are generally idiots, whereas with the frontal or sincipital tumors they are more commonly of quite normal intelligence. Many have reached adult age.

Spontaneous recovery from encephalocele and meningocele has occurred, according to the observations of Wernher, Textor, v. Bruns, and Held, by closure of the cranial defect and the complete isolation of the tumor as a cyst on the outside of the skull. Operative procedures have proved successful in some instances.

Diagnosis.—Every tumor of congenital origin situated along the median line of the head, in the region of the root of the nose or in the glabellar or occipital regions, should excite suspicion of a cephalocele; and defects or malformations in other parts of the skull or body would be corroborative evidence. The fact of its being congenital must first of all be determined; then its relation to the various cranial sutures. The diagnosis is easy when the tumor is in one of the situations that have been described, when there is pulsation, a sensation of fluctuation, when there is a change in tension during sleep or in crying, and when there is a reduction of its contents into the skull upon pressure. If, at the same time with the reduction of the brain-substance or cerebro-spinal fluid, symptoms of irritation or compression of the brain develop, if there is an increase in the pulsatory or respiratory brain-movements, and particularly if the edges of the bony opening in the skull can be felt, a cephalocele is certainly present. But sometimes most of these pathognomonic symptoms are absent, and the diagnosis can be made only from the seat and history of the tumor. Although seldom necessary, a fine aseptic hypodermic needle may be introduced to determine the character of the contents and the presence or absence of an opening in the skull.

The recognition of these hernias in the occipital region is easiest, because other congenital tumors of similar form are of extreme rarity in this position; but dermoids, angiomata, and sarcomata of prenatal origin may have their seat at the nasal root, in the frontal region, or at the inner canthus of the eye, and thus lead to confusion. In the case of these latter the mode of development must be carefully studied, and note taken of variations in tension, compressibility, pulsation, and of the appearance of cerebral symptoms upon pressure. Angiomata exhibit pulsation and tension changes, and may be often completely compressed, but without brain-symptoms or the discovery of an opening in the skull. Pulsation and compressibility are lacking in dermoid tumors. Cranial sarcomata, which are congenital or which appear shortly after birth, may present brain-symptoms on pressure, and an opening in the skull, may pulsate, and may have a similarity of feel, but they grow much more rapidly than cephaloceles and usually are wanting in the more characteristic symptoms of the latter. The differentiation of the varieties of cephaloceles can be made from the peculiarities that have already been described.

Treatment.—The most difficult class to treat are the hydrencephaloceles, but measures can at least be taken to prevent sudden death by spontaneous rupture of the sac. This is still more important in meningocele and encephalocele if there be a rapid increase of fluid and tension, as a cure is possible in many of these cases. Equable pressure should be made by means of cotton batting and a bandage, care being taken not to produce brain-symptoms by too strong compression. If the distention increases puncture should be made with a hypodermic needle, with antiseptic precautions, and the fluid slowly aspirated—all of it if the tumor be small, but only a portion in large sacs. Then cover with aseptic cotton and continue the compression. Puncture may be repeated at appropriate intervals. If rupture has already taken place, the antiseptic dressing and pressure bandage should nevertheless be applied. By this procedure rupture may be prevented, the tumor may be gradually diminished in size, and occasionally even dissipated. Youths or adults who are occasionally observed with stable encephaloceles should wear protective plates properly curved, with bandages, and sometimes compression may be made use of, if it be deemed expedient to do anything, but great care is needed to avoid the production of brain-symptoms. Puncture in simple encephaloceles is only permissible in case of continual augmentation in size—no other operative procedure is advisable. This is about all that can be done without risk. In many cases where incisions have been made into these tumors through a mistaken diagnosis, the result has been death from meningitis. Puncture and the injection of iodine have been fatal.

Meningoceles are more amenable to treatment, as a rule, than the other forms of cephalocele. Occasional puncture, together with compression, have met frequently with good results. Little is to be expected from iodine injection, although Paget was successful with it in one instance. The stable meningoceles should, as a rule, be let alone, because they communicate almost always with the cranial cavity. Annandale in one case ligated the peduncle and removed the tumor, the child recovering completely in spite of an attack of measles. Thompson has also cured a case by ligation. Schatz cured a case by the gradual compression of a clamp applied to the sac. Sklifasowsky removed an occipital cephalocele from a nine months' child with a ligature, the result being successful. The procedure is permissible in proper cases, under strictly antiseptic precautions. No operations in these cases have been undertaken since the inauguration of the new era of brain-surgery, but doubtless much can now be achieved in the treatment of congenital cephaloceles guided by the light of the latest discoveries in cerebral localization and by the improved technique in cranio-cerebral operations, which was formerly impossible.

ACQUIRED, OR PSEUDOCEPHALOCELE.—Among the cephaloceles which originate subsequently to birth, through disease of the cranial bones or subcutaneous fractures, the most common is the pseudo-meningocele. This is observed almost exclusively in infancy or early youth, but, in very rare cases, sometimes in adults after healing of the superficial skull-coverings in fractures. Conner has written the best article upon pseudo-meningocele that is to be found in American literature. Under the name traumatic cephalhydrocele he describes two cases occurring in his own practice, and makes an analysis of 22 others collected from general literature ; 19 of these were due to subcutaneous fractures of the skull, 2 to old gunshot wounds of the skull and membranes where the scalp had reunited, and 1 was the result of trephining ; 17 of the cases were under three years of age. G. Vivien has collected 8 cases, and Thomas Smith ("St. Barth. Hospital Reports," vol. xx.) reported 2, and described 20 analogous cases. All of Smith's were under sixteen years of age.

The history is usually that a child falls upon its head, and that, several hours or days after, a fluctuating swelling develops under the scalp, which may at first be diffuse, but later, as a rule, assumes the form of a sharply bounded cystic tumor. It may reach the size of the fist or be larger. It is over the injured spot, fluctuates, and often pulsates. There is sometimes a hardened border to the tumor. Occasionally, by firm pressure, the fluid may be made to recede more or less completely into the skull-cavity, when the fractured bone may be felt. Where this is not possible, the break may often be felt after puncture and evacuation of the tumor. In many of these cases puncture has shown the contents to be cerebro-spinal fluid. In post-mortem examinations which have been made, the fluid has been found to lie under the pericranium, lifting it with its outer coverings like a cystic sac ; a cleft is observed in the bone, and one of the same size or smaller in the dura matter, through which the sac and subdural cavity communicate. Occasionally the cortex has been injured, and in recent cases there would be signs of softening and of laceration of the other membranes. In a case of Lucas, the pseudo-meningocele communicated with the open inferior horn of the left ventricle. Two or three cases may be mentioned in illustration of this traumatic form. Southam (*British Medical Journal*, May 12, 1888) gives the details in the case of a male infant, aged six months, that fell down-stairs and sustained a subcutaneous fracture in the right parieto-occipital region. Fourteen days later there was a swelling over the fracture, oval, soft, fluctuating, and pulsating. Moderate pressure was applied with a pad of lint and a bandage. In a month the swelling had disappeared and the child recovered. There was still a marked depression in the bone. Conner's first case was a boy twelve and a half years of age, who fell from a wagon, a wheel passing over his head. He was not unconscious, and walked into a house near by. There was a simple depressed fracture of the right half of the occipital bone, and a non-pulsating swelling over the fractured area, which he supposed due to extravasated blood. A week later serum began to ooze from the nose, and there was puffiness of the right eyebrow. He punctured and drew off four ounces of a pale straw-colored fluid. The sac rapidly refilled, and four weeks later five ounces were removed. There were four subsequent tappings, the fluid withdrawn aggregating nineteen ounces. The specific gravity was 1.007 ; no albumen ; sodium chloride, 6.6 parts per 1,000. The boy was never unconscious or delirious, but there was some insomnia and mental irritability, and the pulse ranged from 100 to 120. Conner's second case was a hydrocephalic and rachitic colored child about two years of age, that fell a distance of five feet upon its head. There was no scalp-wound, but a swelling appeared very quickly over the right parietal bone. In a few days it measured four and a half by three and a half inches, and exhibited pulsation and fluctuation. A radiating fracture could be felt through the tumor. No treatment was undertaken, and nine months after the accident the swelling had disappeared.

There are several facts which explain the almost exclusive prevalence of traumatic pseudo-meningocele in children. Possibly the flexibility of the skull gives a peculiar character to the fracture. The intracranial pressure is certainly relatively greater in children than in adults, and a more active secretion of cerebro-spinal fluid is probably another factor. The increase in subdural fluid may be due in part to the injury to the head, or in part to nutritive disturbance, rachitis, or some such thing, which does not give rise necessarily to a general hydrocephalus. The pouring out of the fluid, its augmented secretion, and the expansive power of the growing brain, all aid in preventing closure of the osseous fissure, and, indeed, may actually cause its enlargement, and even eversion of its edges. But pseudo-meningocele is not a constant result of subcutaneous fracture in childhood, and it is likely that various causes and conditions conduce to its formation.

There are not many observations as to the further course of traumatic pseudo-meningocele in children. Conner found that fifty per cent. of the cases collected by him died of meningo-encephalitis. In some patients the tumor remains unchanged in spite of frequent puncture, and in others it is cured by this means. Spontaneous retrogression may take place. The cleft in the skull generally remains open, and hence the prognosis is always relatively unfavorable. These cases are often of considerable forensic interest.

Pseudo-meningocele in adults has been observed several times after gunshot wounds of the skull, when the scalp-wound has healed, and once after recovery with defect of bone from trephining. Vivien mentions three such cases. As a result of subcutaneous fracture in adults it has apparently not been observed, and, if it occurs, must be extraordinarily rare.

Pseudo-cephalocele sometimes results from syphilitic or tubercular caries of the skull and perforation of the dura mater, and from complicated fractures accompanied with prolapsus cerebri. Such cases have been reported by Benett, Tavignot, Bryk, Podrazki, Spring, Hawkins, Talko, Bruns, and Kusmin. In one case only did the dura mater protrude.

These tumors vary from two to five inches in diameter, and are usually of a soft, elastic consistence. The skin over them is either smooth, glossy, and pale red, or inflamed, indurated, and presenting fistulous openings. Sometimes there is pulsation and fluctuation. Dizziness, retardation of the pulse, and even unconsciousness can, as a rule, be produced by pressure upon them with the finger. Partial replacement may be brought about by compression, and in one case there was complete return of the hernia by gradual pressure. Where the brain has protruded, it was doubtless due in many cases to the formation of cerebral abscess or to collections of pus in the cavity of the skull ; in some cases, probably to œdema or encephalitis with tumefaction of the brain in the neighborhood of the diseased or injured skull.

Treatment.—In pseudo-meningocele continuous and equable pressure should be employed where practicable. If the tumor is large and tends to increase in size, operative interference is allowable, but this should be restricted to the removal of a limited amount of the fluid by aspiration, and is only justifiable when severe pressure symptoms supervene. Strict antiseptic precautions should be observed, and a compress subsequently applied. Irritative injections are not advisable. If the opening in the skull remains patent it is well to keep it shielded by a bandage for the prevention of a renewal of the tumor or injury to the brain. Tonics, nutritious diet, and lime preparations are indicated.

Other forms of pseudo-cephalocele are treated according to the nature of the bone disease or injury. In suppurative processes we must be on the lookout for pus-deposits in the brain or skull cavity, and remove them if feasible, with careful asepsis. It is best not to operate on the prolapsed brain itself, but in this we must be governed by what we have recently learned with regard to the physiological value of different convolutions. Hitherto such heroic measures have been carried out usually as a result of error in diagnosis, and in these cases death has followed from meningitis, encephalitis, or hæmorrhage.

Compression should be naturally resorted to in these cases only where there are no symptoms of inflammation or suppuration. In the rare [illegible] of adults we may cautiously puncture and make use of the [illegible], but should always be on the lookout for symptoms of inflammation and abscess.

CEREBRO - SPINAL INJURIES (MEDICO-LEGAL).

So long as human nature remains what it is, expert evidence will be open to suspicion. It is possible, of course, even for a man who is paid for testifying on one side of a case in court to keep his mind absolutely free from bias, but to do so he must have qualities of a high order. An uncommon degree of honesty is essential, but it is not sufficient; there are needed besides a certain judicial temperament and some power of introspection. When, however, an expert possesses these qualities and has acquired the reputation which they naturally bring, his authority with the court is very great; and of this there have been conspicuous instances in patent litigation, where civil engineers, chemists, and others are called upon to discuss intricate pieces of mechanism and compositions of matter. In questions relating to medicine and surgery the testimony of the expert is even more important, because, as a rule, the premises upon which he reasons, as well as the conclusions that he draws from them, are supplied by himself. That is, neither his diagnosis nor his prognosis can be verified by a judge or jury; they must trust to him both as to the nature of the disease from which the patient is suffering and as to its probable course and duration. When the medical experts in a particular case disagree, there are two means of deciding between them. In the first place, it is of course open to the jury to weigh, according to such power or sufficiency of judgment as Providence may have bestowed upon them, the rival assertions and arguments that are advanced on each side; and, secondly, there is what may be called the medical presumption that arises in the whole class of cases to which this particular suit belongs. A very slight investigation is sufficient to show that, in cases of railway spine and of nervous shock, the medical presumption has played a more important part in courts of law than all the other evidence put together. In 1866 Mr. Erichsen's famous work on concussion of the spine was published, and in the two years that followed, according to good authority, seven millions of dollars were paid by English railway companies to real or pretended sufferers from accidents on their lines. There is perhaps nothing in the history of the medical profession which illustrates more clearly the powerful influence that can be exerted by a single eminent authority. Erichsen's statements were received almost without question by the great body of medical men who were contemporary with him, and his book proved, as one writer says, "a godsend to plaintiffs and prosecuting attorneys." The Medical Presumption established by Erichsen was, roughly speaking, that severe, long-continued, and in some cases fatal, disease of the spinal cord and its membranes is likely to follow such injury to the back, or even such a jar, as is often received in railway accidents. He defined the celebrated phrase, "concussion of the spine," as being "generally adopted by surgeons to indicate a certain state of the spinal cord occasioned by external violence; a state that is independent of, and not necessarily, uncomplicated by any obvious lesion of the vertebral column, such as its fracture or dislocation; a condition that is supposed to depend upon a shake or jar received by the cord, in consequence of which its intimate organic structure may be more or less deranged, and by which its functions are certainly greatly disturbed, so that various symptoms suggestive of loss or modification of innervation are immediately or remotely induced." A second, revised and much enlarged, edition of his book appeared in 1875.

The symptoms indicative of the disease described by this author becoming well known, and being easily simulated, were, and in a lesser degree still are, made the basis of many fraudulent claims against railroad companies. Mr. Erichsen himself was not unaware of this result, for in the second edition of his work he said: "An extensive experience in railway compensation cases will probably impress you more with the ingenuity than with the honesty of mankind. A history of deceptions practised upon railway companies by alleged sufferers from accidents upon their lines would form a dark spot on the morality of the present generation." A later writer states, with what would seem exaggeration, did not the facts bear him out, that "great moral courage is required to resist the temptation to magnify injuries for which pecuniary compensation may be had"; and he continues: "Too often have railway accidents had a baneful influence on the lives of men, whose greatest calamity it has been, not that they have received physical injuries which have maimed their bodies, but that their moral natures have been seared and twisted by abandonment to this temptation, the escape from which they would not see. It is not the language of sentiment, but of sober fact, when we say that whole households are sometimes made miserable by the devices to which it is needful to resort in order to gain the desired end. . . . So powerful indeed is the motive, that we find persons taking for long to their beds, abstaining from food, shutting themselves up, neglecting their business, and making themselves weak in body and wretched in mind."

Page relates the following typical case ("Injuries of the Spine and Spinal Cord," second edition, p. 272): "T. J., forty-three years of age, was in a slight accident in which he had a small bruise on one cheek and also at the back of the head. He was seen shortly after the accident, but there was no sign, either of injury, beyond the bruises named, or of constitutional disturbance. In about ten days he was 'taken worse,' but in no very definite way. He gave notice of a claim, and then began to complain indefinitely of a pain in the back, of pain in the legs, and oppression in the head. There was still, however, no evidence of illness or constitutional disturbance. He continued to get worse, and two months after the accident took to bed. He had not been in bed many days when he had a 'bilious attack' with constipation and vomiting. This pulled him down, and he made no further attempt to get up. A month elapsed, and he then was seized, so he said, with a convulsive attack in which his legs were drawn up, and he was very violent. From that time forward he professed to be troubled with 'contractions of the limbs and severe pains in the legs, aggravated by attempting to sit up.' He also complained of queer sensations all over, numbness of the tongue, for example, creeping in his legs, tenderness of the palms of the hand. Pulse and temperature alike remained perfectly normal. Five months after the accident he was still in bed, complaining of great pain in the back, of pain and tenderness in the legs, and of inability to stand if he got out of bed. He held his hands out somewhat in the position of tetany, but the contractions immediately disappeared when he ceased to direct attention to it. Although, when he first got out of bed he allowed his legs to slip away and himself to fall, he had only to be engaged in conversation to show that his legs were amply strong enough to support his whole body. There were no objective signs whatever of paralysis, nor was any illness to be discovered about him except such as might fairly be accounted for by his having been in bed for three months. Thus his muscles were somewhat flabby, his face was pale, and his tongue was furred. Temperature and pulse, however, were normal; his pupils were of healthy size; his mind was perfectly clear. So his state continued until the close of a year, when his claim was settled by compromise on the verge of litigation. We say 'on the verge of litigation,' for it was held that this man had received a very severe injury to his nervous system, that prospect of recovery was very small, and that it was wholly impossible for him to appear and give evidence as plaintiff at the action. His evidence was indeed taken by commission, the man being quite unfit to leave his bed. . . . Mark the sequel! In ten days this man was out of doors, in a fortnight he went away for change of air, and in two months he resumed his usual work. He has continued to work since that time in the enjoyment of good health."

The writer just mentioned, the first edition of whose work appeared in 1882, and many others whose observations were published about the same time or a little later, have overthrown the Medical Presumption, as I have called it, established by Mr. Erichsen. These authors, having carefully examined the evidence furnished by actual cases, show pretty clearly that "concussion of the spine," in the sense in which it was used by Mr. Erichsen, is, instead of being a common, a very rare condition; and that many of the symptoms supposed to be indicative of this condition are really signs of functional disorder, hysterical or otherwise, and in numerous cases absolutely feigned. The disrepute thus cast upon "concussion of the spine," or "railway spine," as it is called, as the effect of collisions and other accidents, has doubtless resulted in much injustice to plaintiffs; just as Mr. Erichsen's theory, which went to the opposite extreme, undoubtedly occasioned what was nothing less than robbery of defendant corporations. In fact, a new Medical Presumption was set up, as unjust as that which it succeeded; and inasmuch as both views, the Erichsen and the anti-Erichsen, have their money-getting or money-saving value in courts of law, they are still made the basis of medical opinions expressed in the witness-box. "There are some members of our profession," said a London doctor, "who have become specialists in this direction, who seem to think that everything that a man tells them of his subjective symptoms are matters of fact and of great importance; and, on the other hand, there are those who regard every plaintiff as either a knave or a fool, and most probably a combination of the two, but who never believe that any man is injured in a railway accident unless he has broken his neck, or has a compound fracture of his thigh." [1]

The present state of medical opinion upon this subject is much more reasonable than it was in Erichsen's time, or in the brief period of reaction which followed. There are still to be found, as has been said, witnesses who take one or the other of the extreme views so graphically indicated in the passage just quoted; but the profession, as a whole, has repudiated them both. In the minds of disinterested and instructed physicians there no longer exists what I have termed a Medical Presumption upon the point, and courts of law are quick to reflect the change. Each case must be judged by itself: the evils that Erichsen described might result from a railroad accident, although there is no probability that they will occur. On the other hand, the patient may be suffering only from slight and insignificant strain or bruise, the effects of which will disappear so soon as his damages are settled; but, again, the gravest psychical disorder, or hysterical condition, or neurasthenic state may have been incurred and may be lasting, although no indication whatever be discovered of structural or organic disease. As to the main injury discussed by Erichsen, namely, concussion of the spinal cord without perceptible lesion of its bony covering, the evidence in regard to it would make its existence appear probable, though perhaps not certain, to a court of law. This seems to be the conclusion of the latest and most thorough investigators. One point bearing on this question may be noticed: Page, in the work from which I have quoted already, says: "Simple concussion of the brain may give rise to a transient unconsciousness, and, if the analogy holds good, concussion of the spine should *per se* produce a transient paraplegia. We know of no case, nor can we discover the history of any case, where this has happened." On the other hand, in Pepper's "System of Surgery," where the above passage is quoted, two examples are given of transient paraplegia due to spinal shock or concussion.

Another consideration which has been much dwelt upon is thus stated by Page: "How comes it that . . . the chronic and incurable diseases produced by railway accidents should remain altogether unobserved, and that no cases have been placed on record to tell what is the pathological basis of the symptoms? How is it that these diseases of the spinal cord are, if we mistake not, rarely or never seen in the special hospitals devoted to them, and that at such a hospital as the National Hospital for Epilepsy and Paralysis, in Queen Square, with its justly distinguished staff, they should be well-nigh unknown?"

Another authority says: "I cannot now, after thirty years of hospital and private practice, call to mind a single case of concussion of the spine, arising from other accidents than on railways, which has had the terrible after-history that is so often attributed to them; and I have seen in that time many cases of spinal injuries of all kinds.

"There is another fact of personal experience. I have examined many cases of claimed irreparable or serious injury to the spine in private, both for plaintiffs and defendants in impending suits, but I cannot remember a single application of a patient for admission to the hospital to be treated for the after-effects of concussion of the spine, the original injury having been received in a railway collision."

Mr. Erichsen was not unmindful of this apparent hiatus in his argument, and he thus dealt with it:

"But, as in these cases of spinal concussion the symptoms are remarkably slow in their development and chronic in their progress; as the patient will live for years in a semi-paralyzed state, during which time the original cause of his sufferings has almost been forgotten; as he seldom becomes the inmate of a hospital—for the chronic and incurable nature of his ailments does not render him so much an object for such a charity as for some asylum or private benevolence; and as the cause of his death does not become the subject of investigation before a coroner's court, there is little opportunity, reason, or excuse for a *post-mortem* examination of that structure which is probably the one that is least frequently examined in the dead-house, viz., the spinal cord, as it is the one the correct pathological investigation of which is attended by more difficulties than that of any other organ in the body. Hence it is that, as in most other chronic diseases that are only remotely fatal—as in cases of hysteria, neuralgia, and in nine-tenths of those of epilepsy, we have no opportunity of determining in cases of concussion of the spine very remotely fatal, what the anatomy of the parts concerned would reveal of the present cause of the obscure and intricate symptoms presented during life." This explanation, though sound so far as it goes, can hardly be regarded as adequate.

Whether or not disease of the spinal cord is ever produced by mere concussion, it certainly may be caused by a severe blow upon the back. Page records a terrible case of this kind. The patient, a thin, delicate man aged twenty-nine, was thrown to the floor of the railway carriage in which he was a passenger, and a very heavy man fell on top of him, "right in the middle of his back." "He could give no clear account of the accident, saying he was dazed and could not stand. He was confined to bed for about a fortnight, suffering much from pain in his back and legs. He then improved a little, and was with to go to a hydropathic establishment in the country, where he stayed for two months. His back continued to trouble him very much (this is in his own words), but otherwise he improved. Toward the close of this two months the weakness which he had all along felt in his legs became a much more definite loss of power, and in a week or ten days he was unable to walk. Ten months after the accident there was no mistake as to his condition. Loss of power to move, and almost entire loss of sensation in his legs, paralysis of bowel, paralysis of bladder with alkaline urine, bedsores, and reflex spasm of the lower limbs, were the undoubted symptoms of softening of the spinal cord. His pulse was frequent, and his temperature above normal. He complained of pain in the lower part of the back, but there was no marked tenderness. He lingered for some months without improvement, and then died." Unfortunately, a post-mortem examination was not permitted. Mr. Page's comment on this case is that "without any visible signs of damage to the spine, there may well have been some separation of vertebræ, or some undue bending of the column, which, damaging at the same time the membranes of the cord, or causing slight intraspinal hemorrhage, was the real starting-point of the mischief which supervened." It is to be noted that in this case two months elapsed after the accident before there were indications of injury to the spinal cord.

Although investigation tends to disprove the existence, or, at least, the frequent existence, of "railway spine" in the sense in which Erichsen used the phrase, yet it shows how complex, obscure, and baffling are the injuries to the nervous system which may be sustained in accidents. Nor does the difficulty end here. Besides the injuries themselves and what may be called their legitimate results, the physician, as a practitioner or as a witness, has to deal with the superadded effect exercised by the will or by the imagination of the patient in view of his possible "damages." There are, from the medico-legal point of view, at least five classes into which cases of injury from railroad or other accidents may be divided, excluding those where some organic or structural change is apparent, namely:

(1) A general break-down of the system, ending sometimes in death, but usually in recovery more or less complete.

(2) A functional disorder, hysterical or otherwise.

(3) A real injury, but recovery is retarded intentionally by the patient.

(4) A real injury, but recovery is unconsciously retarded by the patient under the influence of prospective damages.

(5) The real injury being a trifling one, paralysis or other symptoms are feigned by the patient.

In classes 1 and 2 the prognosis is extremely uncertain, and the damages awarded in such cases must often be either more or less than the ultimate result of the injury would have justified. In the remaining classes the difficulty of discriminating between the disease which the patient really has, and that which he thinks he has or pretends to have, is very great, and even in those cases where, as Charcot said, the trouble is "hysteria, nothing but hysteria," the suffering may be none the less real, and recovery none the less uncertain. The possible gravity of the hysterical condition is a fact which may now be considered as established in medical jurisprudence. Many examples of the various classes just enumerated are given in the books. Page relates a striking case which would fall under class No. 1:

"A man forty years of age, of exceedingly delicate physique, was in a collision at night. The accident was a slight one, and he was the only passenger injured. He was said, in the official report, to be 'severely shaken,' but he was able to go on home. The next day he was delirious, and on the third day he was still talking somewhat incoherently. He complained of being much shaken and of feeling seriously injured, but there was no external appearance of bodily hurt. He improved for a time, and his condition was not thought to be serious. He never seemed, however, to make any marked progress, and four weeks after the accident he became more prostrate, and greater anxiety was felt about him. From this time he gradually got weaker and weaker, and died on the thirty-seventh day. No organic disease whatever was found on post-mortem examination in any of the viscera. The lungs were greatly congested, and the cavities of the heart were distended with blood, as if death had occurred from failure of respiration and circulation.

"The accident was regarded as the unquestionable cause of the death. Though moderate in character, it no doubt exercised a very unusual influence in depressing vital powers—never very strong naturally—and finally inducing such an amount of nervous exhaustion as to terminate fatally, even though there were no evidences before or after death of physical injury to any one part."

This case did not fall under the observation of Page himself, who states that he has seen none similar to it in the course of his practice, but he reports it on the authority of a "distinguished surgeon of vast experience in railway cases," from whom also the following instance is derived: "An apparently strong and healthy girl, nineteen years of age, in good position in life, was in a most serious collision. She received no bodily injury, but on the night following the accident she awoke screaming that the engine was rushing into the room. Her illness followed much the same course, and she died in about five weeks, no structural disease whatever being found after death. The brain and spinal cord were examined in both instances."

Usually, of course, the patient ultimately recovers from this depression of the vital forces, but the recovery is not always complete. Dr. P. C. Knapp says: "After severe concussion, or the psychical trauma of injury, the victim is thrown into a pronounced neurasthenic state, which may last for years. His nervous system is utterly shattered, or, to use the phrase of the day, he is all 'broken up.' He is nervous, emotional, irritable, perhaps hysterical; he is overcome by trifles; he is exhausted by the slightest effort. He may present no objective symptoms, but he remains an utter wreck. . . . The symptoms may be milder. . . . The patient finds himself changed; instead of being capable of continued exertion or strain, he is easily upset, trifles annoy him, he is irritable and quick-tempered; he has lost the power of rebounding after pressure, of maintaining the calm, good-tempered spirit which perhaps he had before; his sleep is not so sound, he starts when a door slams, his children annoy him, he is fretful and fault-finding. It may be that such a man is able to work as well as before, and to earn as much money, but if he be in some responsible position, perhaps his judgment is less sure, or his bearing toward his associates less agreeable; he is no longer a 'good fellow,' but nervous and disagreeable. These things, of course, are trifles for which no jury would award damages, but they are trifles which mark an enfeebled nervous system, and it is these very trifles which are like sand in the bearings of the carriage; they decide whether life is agreeable or disagreeable, and they are trifles which may continue for years; in fact, the man may never recover his old buoyancy, his consideration for others, and his good-nature."

It is a mistake to suppose that a jury would not award damages for such "trifles" as Dr. Knapp points out; they certainly would be justified in doing so, and although it might sometimes be difficult for a jury, or even for a physician, to discriminate symptoms of nervous disorder or enfeeblement that were real from those that were imaginary or feigned, yet the possible existence, and, what is more, the frequency of such cases as Dr. Knapp has described, should be recognized in courts of law.

In fact, the more the subject is examined, the more clearly is it seen that hysterical affections or conditions resulting from railroad accidents are often severe and lasting. Putnam observes on this point as follows: "So marked is the influence of nervousness on the subjective symptoms that it has been even maintained that, in a large number of cases of concussion of the spine, the symptoms are of hysterical origin." . . . But, on the other hand, it is necessary to avoid the danger of overestimating the effect of mental influence, and of regarding as entirely due to this, symptoms which are real and are merely intensified by attention. The danger is especially great in cases of railway injuries, concerning which an unbiassed judgment is not easy to secure, and in which, when objective symptoms are absent, it is easy to minimize suffering and attribute too much to the mental condition."

"The sinister influence of litigation on the intellect may be traced very widely. I believe that it is rare for symptoms to be purely mental. It is often asserted, by those employed for railway companies, that subjective symptoms quickly subside when the sufferer's claims are settled, but in a good many individuals whom I have had the opportunity of observing, long after they had received their 'damages' (as the expression curiously runs), this subsidence had not occurred, and even the 'sovereign balm' of substantial compensation has appeared to do very little for the relief of the sufferer."

It is probably the case almost universally, even when the patient is not feigning, that his recovery is retarded while a settlement or trial of his suit for damages is pending. Consciously or unconsciously, he resolves to get well no faster than is necessary. The important part played by the will and by the imagination of a patient is illustrated by the following remark of a distinguished surgeon:

"Many times, when to a passing observer the state of a patient (after operation) has appeared to be in every respect satisfactory, I have seen the sister at St. Bartholomew's shake her head and heard her say, 'He would do very well if he were not so nervous; but he will never get better while he continues to persuade himself that he cannot;' and rarely has the prediction been proved to be false."

Beside those cases in which disease or injury is simulated, there are others where real symptoms or defects are falsely ascribed to railroad accidents. Page gives an instance in which the patient, a publican, advanced in years, insisted that an enlarged prostate was due to a railway collision. In another instance an impostor, who in some unexplained way had really lost all tactile sensation over the mucous surface of his nares, pretended that the injury had been sustained in an accident which happened long afterward. Sometimes the patient himself is deceived, as in the following case, also related by Page:

"A shoemaker, seventy years of age, came to St. Mary's Hospital, complaining of pain over the right side of the thorax. When he had been stripped, it was found that he had lateral curvature of the spine to an extreme degree. He said that this condition was of quite recent date, and that he had only noticed it since he felt the pain. Judged by itself alone, his story was enough to cause alarm, but it was clear, both from the ossification of his costal cartilages and from the fact that not a single cubit had been taken from his stature, that this spinal curvature was old, in all probability nearly as old as the man himself. Had it been an acute change at this time of life, and had the pain which brought him to the hospital been due to the curvature, or been a symptom of some serious malady which lay behind it, a simple liniment and a tonic would not have restored him in a short time to his usual state of health. True, in this case there was no desire to impose; but how readily, in other circumstances, might such a deformity have been used as the foundation of a fraud!"

If the experience of prison surgeons could be consulted, numerous examples of malingering would doubtless be revealed which might throw light on some railroad cases. In the Massachusetts State Prison a criminal once lay on his back for two years, asserting that his legs were paralyzed and that he was unable to move. Despite this long-continued inaction, and notwithstanding that he endured the galvanic test and the insertion of needles in his skin, the physician in charge felt convinced that the man was perfectly sound, and he resolved to try a new experiment. He directed his assistant to prepare an operating-table close to the bed of the supposed paralytic, and to get together an imposing array of knives, saws, and other surgical instruments. This was done, and the tools were then sharpened and polished with great care and elaboration in presence of the prisoner When all was ready, he was laid upon the operating board, and bound tightly to it with numerous straps and cords. Finally, the surgeon came in, and, casting a hungry look at the patient, took up a large knife, and critically examined its edge. So far the prisoner had kept silence, but he could bear the situation no longer, and feebly asked what was about to be done. "I am going to cut off one of your legs," was the calm reply, "and if the operation is successful I shall remove the other one to-morrow." This was enough. "Let me up," said this paralytic of two years, "I can walk as well as any one." And so, in fact, he could. Page relates a similar case: "A prisoner took to his bed, complaining of great pain and swelling of the abdomen. Although the belly was enormously distended and tympanitic, there was no other sign of illness about him, and there was an entire absence of any one condition on which tympanites usually depends. After a few days' observation, and having carefully weighed all the facts of the case, the surgeon came to the conclusion that the man purposely induced the distention by swallowing air. Loudly enough for the prisoner to hear him, he accordingly whispered to the warden, 'When I come to-morrow I shall bring an instrument to tap him.' On the morrow the tympanites had disappeared." The same method of imposture is said to have deceived a board of French medical officers, a citizen, who had a similar faculty of distention, having obtained relief from military service by presenting himself in an enlarged condition, with clothes made for the occasion.

At the Massachusetts State Reformatory, not long ago, there was a shrewd criminal, gifted with a strong will, who declared that he had entirely lost the use of his legs, and was unable to walk even with crutches. The keepers and his fellow-captives were convinced that the man spoke the truth, and he was conveyed about tenderly by four convicts, on one occasion being brought to chapel in this manner, and carried up to the altar, where he received the communion before the assembled prisoners. This patient also endured the usual experiments with the galvanic battery and with needles, betraying no indication of feeling in his lower limbs. Nevertheless, the surgeon to the reformatory, who had received the man in this condition from the hospital of the State Prison, became convinced by careful observation that the fellow was shamming. The reformatory authorities and the prison commissioners thought this a great injustice. Before long, however, it became apparent that the paralytic, who had now become able to get about with the aid of crutches, was making a good deal of trouble among the other prisoners, and, a specialist being called in, the reformatory surgeon's diagnosis was confirmed. It was therefore resolved to send the man to the House of Correction, where he would be put at hard work, and this decision being communicated to him, the patient, seeing that the game was over, threw away his crutches, and walked upstairs as well as anyone.

These examples show with what perseverance and even with what fortitude men will simulate paralytic or other symptoms, in order to escape hard work, or to defraud a rich defendant.

It remains only to consider whether there is anything special in the nature of a railroad accident; is there, in other words, any medico-legal presumption that its effects will be particularly severe or lasting? "Spinal concussion or shock from railway collision," says one authority, "does not differ from forms of the same injury received in other ways. It is absurd, therefore, to give a particular pathological history to so-called railway spine." This is true, of course, in a sense, but in a sense it is not true. The horror and fright produced by a railroad accident are, as a rule, much greater than similar emotions which are felt in other accidents. The spectacle of those who are mutilated or dead, the cries and groans of the wounded, the shrieks of women and [illegible] as much as often added the [illegible] of the [illegible] and the escape of steam from the locomotive—all these elements increase the effects of personal suffering and apprehension. The cases previously mentioned, and others which might be cited, show that the mental shock of a railroad accident is sometimes sufficient to cause death. Cases where mere fright has this result occur now and then, and Sir Astley Cooper mentions one instance in which sudden terror from great agony proved fatal.

If then death sometimes follows the mental emotion produced by a railroad accident, is it not reasonable to presume that nervous, hysterical, or neurasthenic states, brought about by a similar cause, are likely, other things being equal, to prove especially severe and lasting?[1]

There is another aspect of accidents on the rail which deserves more consideration than it has received, and that is their physical character. A very able and suggestive paper on this subject was published by Dr. Thomas Buzzard, of London, in the *Lancet* (vol. i., 1867, p. 389). The author divides the injuries which may be sustained from a railway collision into four classes. These are: (1) The results of constitutional shock and terror.

(2) The results of a direct blow from contact either with the body of a fellow passenger or with the framework of the carriage.

(3) The effect upon certain interior organs of the body due to their inertia when the body itself is suddenly stopped; and

(4) The jar or shock to the whole body received through the framework of the carriage.

It is with regard to classes 3 and 4 that Dr. Buzzard makes some new and valuable observations in part as follows:

(3) "When a sudden check occurs to the speed at which the train is moving and the passenger's body is prevented from advancing on account of the obstruction presented by a partition or some such obstacle, such of his viscera as are suspended in his trunk or so situated as to permit movement will, in obedience to dynamical laws, continue their acquired motion so far as their attachments permit. The brain, filling as it does the cavity of the cranium, would not probably be so much influenced by this; but the spinal cord, being disproportionate to the size of the vertebral canal, would necessarily obey this law. A certain amount of strain is therefore placed upon the structures—nerves, ligaments, etc.—by which the cord is held *in situ*. The same holds good of the heart and its larger vessels, and more or less of the abdominal viscera; the strain thus occasioned may or may not be great."

The fact that concussion of the brain has never been associated particularly with railroad accidents, notwithstanding that this organ is less heavily guarded with bone than the spinal cord, has often been advanced to show that concussion of the spine is also unlikely to result from the same cause. But in the remarks just quoted Dr. Buzzard states a reason why the spinal cord should and the brain should not be susceptible of injury from railroad accidents; and in the following passage, dealing with the effects of jar communicated by the railroad carriage to the human body, he brings forward another reason which tends to the same conclusion:

(4) ". . . . If we imagine for a moment such a degree of violence as just falls short of exhausting itself in splintering the carriage, we can conceive the existence of an extremely potent source of injury to the human frame. . . . The elasticity of the soft structures [illegible] placed where these cover the body diminishes materially [illegible] the influence of any shock received at these particular points. But there are parts of the frame—notably the spinal column—where this protection is wanting, and nothing intervenes to prevent the shock influencing the passenger's body as it does the woodwork of the carriage. [illegible] the familiar illustration of the wineglasses and the [illegible] broken [illegible]. . . . So it has not unfrequently happened that passengers have scrambled out of the wreck of a smashed railway carriage unhurt, while others occupying a carriage which has escaped destruction have been seriously damaged by shock. . . . The enormous momentum of a heavy train, even when moving at a comparatively slow pace, is very apt to be forgotten. A train of 200 tons weight moving at 4 miles an hour will have a momentum equal to that of a train of 20 tons going at 40 miles an hour. When we hear, therefore, of the very slow pace at which a certain train is stated to have been moving when an accident occurred, it is necessary to know something of the length of the train, and consequently its weight, ere we can form an estimate of its momentum."

This, the dynamic branch of the subject, as it might be called, deserves further investigation.

Upon the whole matter it is difficult to come to any conclusion much more definite than that reached by M. Taine in a certain historical inquiry. After describing the conquest of all France by the Jacobin Club, he says: "So far I have discovered but a single principle, and that is so simple that I scarcely dare to state it. It is comprised in this one remark—human society, and particularly a modern society, is a vast and complicated thing." So we may say that the subject of spinal diseases and nervous affections resulting from railroad accidents is an extensive and complicated one. Organic injuries, varying from degeneration of the spinal cord, with its terrible consequences, to a mere strain of muscles in the back soon to be recovered from, are all to be met with; and as their first symptoms are often much alike, organic disease has again to be discriminated from functional disorders, and these in turn assume a thousand forms. Finally, the part played by the imagination or by the will must be ascertained, and true conditions distinguished from those which are feigned partly or wholly. The worst that Erichsen described may happen, and the malingering which Page detected is certain to be repeated. To do justice between plaintiffs and defendants in cases that relate to this matter will almost always be difficult and often impossible, but the prejudices by which the subject was obscured have very nearly disappeared.

CHRONIC CATARRHAL INFLAMMATION OF THE NASAL PASSAGES.

ETIOLOGY.—The origin and mode of development of acute and chronic catarrhal inflammation of the upper air tract have been discussed at length elsewhere (Vol. IV. of this HANDBOOK, p. 400 *et seq.*), and the remarks found under the section Chronic Laryngitis (Vol. IV., p. 411) are equally true of chronic inflammatory disorders of the nasal passages.

Before passing to the consideration of the peculiar features of this particular form of inflammation, it may be interesting to review, as briefly as possible, some of the more important hypotheses which have been advanced concerning its essential nature.

THEORIES WHICH FROM TIME TO TIME HAVE BEEN HELD CONCERNING THE NATURE OF CATARRHAL INFLAMMATION OF THE UPPER AIR TRACT.—Reference has been already made in another portion of this work (Vol. IV., article Larynx, Catarrhal Affections of the) to the doctrines of the ancient physicians, their long continuance, and final overthrow by the labors of Van Helmont, [illegible] and Schneider. As a matter of historical interest, it may be well to give a brief résumé of the crude hypotheses which for centuries were accepted as gospel by the entire medical world.

In the earliest medical records we find catarrh, as its name indicates, regarded as a kind of falling down from the brain of a peculiar flux or rheum. According to many, during the process of "concoction" a crude distemper was generated in the stomach, by means of an inordinate heat derived from the liver, which ascended to the ventricles and pituitary gland of the brain through the veins and arteries (chiefly as clouds of vapor). According to others, the noxious material was generated primarily in the brain. The latter organ, which was supposed to be of a cold and moist nature, and therefore adapted to the formation of cold phlegm, and which was variously likened to the head of an alembic, the cover of a boiling pot, a sponge, a cupping instrument, a wild cucumber, and a mushroom, was supposed to condense the clouds of vapor and shower them down upon the parts below "like showers of rain." Some likened the head of man to the sun, as possessing an especial affinity for vapors, while others, following Galen, compared it to a smoky house. Aristotle, in his "Problems," propounded the question why man was more liable than other animals to catarrh, and assumed that the erect posture favored the descent of pituitous particles to the parts below. Schneider devotes an elaborate chapter to the refutation of this absurd idea. The method of escape of the matter thus manufactured or condensed in the brain gave rise to many varying hypotheses. While some held that it passed out from the sinuses of the corpus callosum through the mammillary processes and cribriform plate, others maintained that the cells of the sphenoid bone were the channels of exit; while still another class of observers believed that the nerves of the nose and throat, and those of the spinal cord, were the avenues through which the pituita descended from the brain.*

As was mentioned elsewhere, Van Helmont was one of the first bold enough to handle with pitiless satire the universally accepted doctrines of Hippocrates and Galen. He declared "that the large catalogue of diseases imputed to a distillation of rheum from the head to the toes and extremities, without any obstacle impeding the descent, is an old wives' fable invented by the common adversary of mankind on purpose, lest the causes of diseases being known, the remedies might at the same time be revealed," and that "the gray-haired dreams of the Grecians have drawn the whole Christian world after them into a servitude that is ridiculous, lying, and pernicious to humane society." (Those interested in the subject will not fail to be amused by the "Deliramenta Catarrhi" of Van Helmont. Describing the accumulation of the deluge of phlegm in the head, he likens it to a standing pond, "from whose oppression the brain is not able to deliver itself, neither by the aqueducts of the nostrils, nor the laborious pump of coughs. Oh, then," says Van Helmont, "instantly follows a stupid drowsiness, an inexpugnable propensity to outsleep Endymion, catoches, a lethargy, vertigo, apoplexy, loss of memory, and perdition of senses." Speaking of concoction, and the odors supposed to arise from the process, he dwells on how horribly offensive we would be, and adds: "Our very breath also, continually blasted with them, would save us the trouble of foreign poisons, disparage the fatal emissions of the basilisk, and be as dangerous to conversation as the fumes of the Lago di Tripergola," etc. As might be naturally expected, Van Helmont had many imitators, among whose works may be especially mentioned the essay of Conrad Horlacher.[1]

Before passing to the consideration of more modern views concerning the etiology and essence of catarrhal affections, it may be interesting to pass in review the various theories entertained by some of the chief directors of medical thought during the sixteenth and seventeenth centuries.

In the first half of the sixteenth century, the views which chiefly obtained were those derived from the occult medical philosophy of Paracelsus. In the quaint language of the Prince of Empirics, coryza and allied affections are due to the liberation of a salt, called "tartar," from its stronghold in the blood and its distillation to what was termed the region of Mars, or the naso-pharyngeal emunctory. This latter excretory being closed by a copious accumulation of tartar, the salt, not finding a sufficiently free exit, erodes the membrane and flows backward to the fauces. The saline liquid flowing from the veins of the "region of Mars" was supposed to irritate the membrane during its discharge, thus accounting for the inflammatory condition of the nasal passages and the frequently associated redness of the external nose. Nasal and throat hæmorrhage were ascribed by Paracelsus to a too great liquidity of the blood, by virtue of which its natural consistency was destroyed, so that it could not be contained within the vessels; and that its exit was furthermore facilitated by rupture of the vessel-walls by a volatile sulphur, which, loosed from its chemical bonds, expanded with such rapidity and force as to burst the tunics of the veins.

Toward the close of the century, and at the beginning of the following, the grotesque chemical theories of Paracelsus were supplanted by the more fantastic and curious chimerical conceptions of Van Helmont. Inflammations of the nasal passages and throat were believed to arise from the glowing or incandescence of the Archæus, a mythical demon or spirit, whose chief abode was in the stomach, and who, when the nose was irritated by any foreign matter, flux, or anything which deranged its nutrition, became so incensed that it established an inflammatory process at the area of irritation—placed, to use the metaphorical language of that period, a fiery seal upon the part as the symbol of its wrath and indignation. Nature was then supposed to send a modifying spirit, called the Latex, or source of serous humidity, to correct the anger of the Archæus and the impression made from without by the air, etc. (*influent spirit*, impetum faciens), and in this way the discharge originated.* Hæmorrhage was thought to result from the liberation of an "acor" in the blood, which so enraged the Archæus that it broke through the walls of the vessels.

Toward the middle of the seventeenth century a new doctrine was announced by Francis de la Boë, or Sylvius, as he is more commonly called, of Amsterdam, afterward the famous clinical teacher of the University of Leyden. One of the first to accept the doctrines of Harvey, he repudiated the fanciful Archæus of Van Helmont, and announced a theory based on more exact anatomical observation. Sylvius explained the phenomena of catarrhal inflammation solely by the laws of chemistry. His theory, which may be termed the chemico- or physio-pathological theory of catarrh, may be briefly stated as follows: Nasal polypus and sarcoma (hypertrophic catarrh) † result from an active determination of nutrient blood, as the case corrected by a peculiar acid generated in the glandular secretions (lymphs). The fibrous or harder structures of the membrane, eroded or ulcerated by the corroding acid, receive a greater supply of blood, which leads to [illegible], through [illegible] action, by the acid lymph into swelling and [illegible] generation. The simple inflammatory condition of the [illegible] and the redness of the external nose, from which catarrhal patients suffer, were due, he thought, to [illegible] and [illegible] of blood, brought about either by some effervescing [illegible] carried to the parts with the blood, or from the [illegible] of a [illegible] acrid [illegible] substance which [illegible] this part "as a fire." In the disease called coryza, he maintained that the external air so affected the "conglomerate glands" [illegible] of the [illegible] plexus and lateral [illegible] as to cause [illegible] of their peculiar humors, and accounted in this way for the acrid taste of the secretion in the disease. Hemorrhage from the nose and throat was due, he thought, to [illegible] rupture of the vessels from [illegible], [illegible] or [illegible] of the blood, [illegible], swelling, [illegible], etc.

---

* The above is, of course, the merest outline of the views held by the writers of antiquity. Those desirous of pursuing the subject further will find the best ancient account of it in the third book of the *De Causis Symptomatorum* of Galen. A good *résumé*, based mainly on the observations of the ancients, was published about the middle of the sixteenth century by Sebastian Paparella (*De Catarrho, Papiæ*, 1562). It is curious to note that in this book, which contains much that is good mingled with crudities and absurdities of doctrine, Paparella refers (pp. 114-115) to the debilitating effects of summer, which, he thought, "rarefies the channels of the head," and causes thereby the accumulation of much excrement, etc. A very elaborate account of the views held by his predecessors and contemporaries is also given by Schneider.

* The following passage from Van Helmont may possibly be of interest: Describing the latex, he observes: "It comes to pass not seldom, that the latex, contaminated by the admixture of some foreign salt, doth therewith infect the influent spirit, so that it becomes degenerate from its requisite simplicity and purity, not by injury from the air, etc., but from a breath or blast of *contagion* conceived in the *part affected*."

† It is only within a comparatively recent period that the hypertrophic enlargements of the turbinated tissues have been relegated to their proper anatomical place among affections of the nasal passages. The ancients probably knew of their existence, but confounded them with polypi: the Greeks under the terms "hypersarcosis" and "sarcoma," the Romans under the appellations "carnis excrescentia" and "germinatio." It is unnecessary to invoke the long list of ancient writers, from Hippocrates down, in defence of this proposition, but I will simply direct attention to the following words of Actuarius as a fair presentation of the doctrine of his day: "Polypus, est meatuum, qui a colatu ἠθμοειδεῖς (quasi dixeris colatorios) vocantur, obstructio, propter carnis excrescentiam, quæ ea parte ita inhæret, ut ægrè detrahi possit. Fiunt enim frequentes germinationes, quæ instar polyporum, naribus circumcirca adfixæ adhærent quibus inspiratio expiratioque præcluditur, et siquid superne pituitæ aut muci defluit haud facile obstante polypo delabi potest."[2]

A distinction was made by some[3] between true polypus and other "caruncles" found in the lower and more fleshy parts of the nose, and Janus[4] draws an accurate differential parallel between "ganglia" (evidently the hypertrophic turbinated tissues of the present day) and polypi in the following sentences: "Credo vero differentias posse inde hauriri: primo ganglia semper deprehenduntur in naribus in partibus inferioribus. Polypus vero frequentius adnascitur in partibus superioribus; dein circa basin semper sunt crassiora et per latera, contra polypus magis est attenuatus imo sæpissime pensilis. Tertio ganglia sunt duriora. Polypus vero mollior. Carnositas vero atque duritas distinguntur a ganglio, quod ganglium ut plurimum retineat colorem eundem cum partibus vicinis; polypus contra aut nigrescat aut colore præditus sit livide."

While Sylvius was expounding his views at Leyden, his contemporary and fellow iatro-chemist, Thomas Willis, was introducing in London a theory which, although differing essentially from that of Sylvius, nevertheless resembled it so far as it was based upon similar iatro-chemical principles. According to Willis, coryza and polypus arise from obstruction to the nervous fluid and its consequent stagnation in the nose, where evaporation of the more spirituous components takes place, and the fixed particles remain behind as a solid mass. The simple inflammatory conditions of the nose and throat result from effusion and damming up of blood from the arterioles under the surface, with retention of many saline fixed particles, especially the acid constituents of the blood. Hence arise swelling, redness, and fever. Coryza is due to a serous catarrh effused from the blood in which the "tubulated membranes" and the processus mammillares and the nasal structures are included. This copious fluid so fills the pores and meatuses that it is squeezed from them "as from a sponge," and as the result of the compression the matter either exudes into the nasal passages, or is transmitted through them to the palate and fauces. Willis's ideas of nasal hæmorrhage were considerably in advance of those of his predecessors, doubtless from his more perfect acquaintance with anatomical and physiological science. He considered that hæmorrhage arose from a vice of the blood (plethora, acrimony, etc.), blood-vessels (laxity of fibres, patency of mouths, etc.), or both, or from imperfect transfer of blood from artery to vein, as in the scorbutic and cachectic; or, finally, from spasmodic or convulsive affections of the motor fibres.

The effect which the philosophical speculations of Descartes produced on the theory of medicine are sufficiently well known; and hence it is not surprising that there were not wanting those who applied his doctrines in explanation of the phenomena of inflammation. According to the Cartesian school, coryza and allied affections are due to "acute" acid or acrid particles floating in the air, and vellicating the fibres of the membrane which invests the nares. The lymphatic vessels receiving the stimuli, pour out a liquid so sharp that it erodes the parts it flows over, and so copious that it flows to the larynx and fauces, and gives rise to hoarseness and cough. The acridity of the discharge also occasions sternutation.

The space allotted to this article does not permit an extended review of the many modifications of the hypotheses detailed above, and I shall therefore only indicate the state of medical thought on the subject at the opening of the last century. According to [illegible], who may be regarded as representative of that epoch, the humors (blood and other juices) enter into the mouths of the smaller vessels, which they dilate, and in time obstruct them [illegible]. Hence arise [illegible], swelling, redness, and pain. The constantly dilated and distended vessels do not readily return to the normal state, and therefore in winter time the blood and other contents present an obstacle to the circulation, and cause the individual suffers a return of his malady. Should the obstruction and retention of humors exist for a long period, an increase in volume of the part affected may take place and a polypus thereby result.*

At the close of the seventeenth century Michael Ettmüller looked upon catarrh as a preternatural degeneration of the lympha or blood serum, and considered the orifices of the lymph-glands, distributed by Steno in the membranes, as the seats of these diseases.†

Passing now to the middle of the next century, we have the first detailed advance made by F. Hoffmann (see article on Larynx, Catarrhal Affections of the), who declared that catarrh was the local expression of a general febrile state, and that the diseased condition of the mucous membrane was produced by the acrid character of the lymph or serum, which was eliminated as a critical discharge from the glandules. Hence arose the inflammatory catarrh or fever of the last century.

Later on Pinel (see Larynx, Catarrhal Affections of the) taught that catarrh was an inflammation or exaggeration of function of the mucous membranes. In Great Britain the inflammatory theory was supported mainly by Cheyne, while in France Laennec held that the nature of catarrh was still in doubt; that in certain cases it resembles a highly inflammatory affection, while in most others it presents the characters of a simple congestion, and in some indeed those of a passive or atonic congestion.

Passing through the era of Broussaisism we now come to the year 1791, when a curious theory was propounded by Théophile de Bordeu. Bordeu argued at great length that catarrh was an inflammation of the cellular tissue of the body, and endeavoured to reconcile this view with the doctrine of Hippocrates. The lungs, pleura, etc., were compared by him to a cellular pyramid, which formed the nidus for the diseases called catarrhal. The whole cellular tissue formed a vast, so to speak, connective or sympathetic chain, so that inflammation of one part might be felt in organs far remote, as, for example, in the pathological connection between diseases of the rectum and throat.

In the early part of the present century Erhard Schäffer maintained the thesis of an intimate relationship between catarrh, rheumatism, and the acute exanthemata. When the disease attacks a mucous membrane, it is catarrh; when a serous membrane, rheumatism.‡

Shortly after Schäffer wrote, Schönlein advanced the idea that catarrh was a true blennorrhœa, and looked upon the copious flux as the leading and essential factor. A few years later his pupil Eisenmann reverted to the old doctrine of the rheumatic origin of the affection, and held that, through atmospheric influences a disturbance of the general capillary system was produced, which resulted in an exanthematous condition of the mucous membranes—in short, an erythema. In a subsequent work [12] he thus described the mechanism of the process: The impulse produced by the temperature causes a kind of shock to the peripheral excito-motor nerves, the lungs, or the stomach. This shock is directly reflected to the origin of the nerve in the cerebro-spinal apparatus. This reflex act then oscillates through the whole spinal cord, but generally causes a molecular change or disturbance of function in the nerve-root which is in nearest relation with the afferent peripheral nerves.

† It is a curious fact that [illegible] has taken [illegible] [illegible].

‡ The close relationship or identity of catarrh and rheumatism is generally a matter of common acceptance. [illegible] Sauvages, [illegible], Hoffmann, [illegible], Lancisi, Huxham, Stoll, and others. Among these, [illegible] considered that catarrh is [illegible].

The theory which attributed catarrh solely to secretory changes in the mucous membrane was combated, among others, by Canstatt,[13] in 1843, who maintained that of hyperæmia and stasis. A few years later, a novel idea was suggested by Schönbein,[14] a distinguished chemist of Basle, who, as the result of certain experimental researches, was led to believe that the presence of ozone in the atmosphere bore a definite relationship to the periods at which catarrh of the respiratory apparatus was most prevalent, and argued from this, and its irritating effect upon his own nasal mucous membrane, that therein lay the principal causative agency of the disease. Further investigation, however, demonstrated the fact that ozone acted only as a local irritant, like chlorine and other gases; while its supposed relationship to the so-called catarrhal months was subsequently overthrown by the observations of Seitz.[15] The rôle which the nervous system plays in the mechanism of this class of affections is well known and sufficiently obvious; and quite recently Woakes,[16] of London, has pushed the neurotic theory to its utmost extreme. Woakes bases his hypothesis of the origin of catarrh on the assumption that the ganglia of the sympathetic act as subcentres, bringing various tissues into reflex relationship by virtue of an inherent correlating power, by which the afferent impressions starting in a given tissue are reflexly referred to a totally different tract. Nasal catarrh is a neurosis of the cervical sympathetic ganglia, whose essential feature consists in an inability on the part of these ganglia to transmit reflexly the afferent impressions to the efferent vaso-motor nerves. A condition of perpetual vessel-dilatation is thus kept up in the tissues where the latter are distributed, as the result of which hyperplastic changes develop. The phenomena of "taking cold" are explained according to the above, and the general inference is drawn that catarrhal symptoms spread to contiguous regions because the adjacent structures receive their *nervi vasorum* from a centre (ganglion) identical with that which innervates in a similar way the regions primarily affected.

Contagion.—That the simple catarrhal affections of the upper air-tract, and notably coryza, are communicable by contact, is an orthodox popular belief which has obtained, chiefly on the continent of Europe, less so in our own country, for many years; while the idea of contagion by floating particles of matter in the atmosphere was implied in the doctrines of the Cartesian school. Several centuries ago Crato * adverted to the superstitious belief among the Germans that a coryza could be transmitted by drinking from a glass which had been used by one suffering from the disease; and later Bonnet[17] and Schurig[18] mentioned the same subject, without however bringing forward any clinical evidence to its support. In the "Ephemerides of Natural Curiosities,"[19] Standigelius tells the story of four children of a peasant, who were taken in the same week with a very fetid catarrh or ozæna. But the evidence here of contagion is altogether presumptive, and the possibility of the direct transmission of the disease is overthrown by the fact that when the malady broke out in all its fury the children were not together.

Years ago Dr. J. K. Mitchell, and later Sir Henry Holland, of London, and Mütter, of Vienna, advanced the theory that catarrhal disease was due to the action of a micro-organism, and more recently its parasitic nature has been urged by Dr. Austin Flint.[20] While certain clinical evidences of direct transmission apparently favor this view, it has, on the other hand, been completely negatived by the failure to produce the disease by inoculation.[21] Exact evidence is also wanting to establish the *epidemic occurrence* of acute simple coryza, except under the meteorological conditions which have been described in the article on the Etiology of Catarrhal Affections.

Classification.—The classification of the stages of chronic nasal inflammation given below is based on anatomical and clinical experience, and will, I venture to think, prove of practical value in the diagnosis and rational treatment of this affection.

The leading anatomical characteristic of chronic nasal inflammation resides in certain changes which the erectile bodies undergo. In the earlier stages of catarrhal inflammation there exists a peculiar excitability of these structures which causes sudden obstruction of one or both nostrils; later on is found a permanent swollen or puffy (dilated) condition of the erectile tissue, due to a subparalytic state of the intercellular walls with consequent dilatation of the erectile spaces. As the disease advances there is a metamorphosis of the intercellular walls into dense fibrous tissue, which, in contracting, gradually obliterates these spaces, and causes, finally, atrophy of the erectile bodies.*

These changes in the erectile structures furnish the anatomical ground for the classification which I present for consideration.

Classification of the Stages of Chronic Nasal Inflammation.—I. *Simple Inflammatory* (*Rhinitis Simplex*); divisible into periods of—

α. Irritability of erectile tissue.
β. Permanent dilatation of erectile tissue.

II. *Hypertrophic* (*Rhinitis Hypertrophica*); divisible into periods of—

α. Dilatation with hypertrophy.
β. Complete hypertrophy.

III. *Atrophic* (*Rhinitis Cirrhotica*); divisible in periods of—

α. Commencing atrophy.
β. Complete atrophy.

I. The first, or simple inflammatory stage, consists of two periods, the one characterized by abnormal irritability of the cavernous tissue, the other by permanent dilatation of the same.

α. Period of irritability: Characterized by increased irritability of the mucous surfaces, expressing itself chiefly in abnormal excitability of the erectile tissue, leading to sudden obstruction of one or both nostrils in the presence of changeable atmospheric conditions, when the individual assumes the recumbent position, as at night, or when under the influence of certain forms of excitement, and in some women at the menstrual period; in fine, when the individual is exposed to any of the exciting causes of coryza.

β. Period of dilatation or permanent puffiness of the erectile tissues (chronic coryza). As the result of the repeated erection of the cavernous tissues which occurs in the first stage, a paralytic or subparalytic state of the resilient and contractile elements of the walls of the erectile cells develops, leading to their permanent dilatation, recognizable by the eye as an engorged or puffy condition of the turbinated tissues, which may be distinguished from true hypertrophy by its collapsing under the probe, by the readiness with which it can be pressed against the external wall of the nostril, and by its diminution in bulk under various measures which produce reflex contraction, or emptying, or depletion of the erectile spaces, such as the sudden application of cold, the use of cocaine, etc.

It is this subparalytic condition of the tissue, represented by the puffy character of the swelling, which is the connecting link between the simple and the hypertrophic stages.

II. The second, or hypertrophic stage, is divisible into

[*] Concil. et Epist., liber 2. p. 246, Hanov., 1595; quoted also by Hagens, Diss. de Coryza, Berolini, 1841, p. 21. Ettmüller (op. supra cit., p. 334) also alludes to contagion from nose to nose, and from the promiscuous use of cups and napkins.

[*] For further particulars concerning these changes, see article by the writer in the Philadelphia Medical News of October 4, 1884, entitled, Some Notes on the Pathology of Intranasal Inflammation.

two periods, characterized respectively by hypertrophy with dilatation, and by complete hypertrophy.

a. Period of hypertrophy with dilatation. Characterized by commencing hypertrophy of the intercellular connective-tissue walls of the erectile bodies, with uniform puffiness of the tissue not especially involved in the fibrous process.

b. Period of complete hypertrophy. Characterized by more or less complete conversion of the affected portion of the tissue into a fibrous mass; swelling generally uniform, non-shrinking. This complete hypertrophy is most commonly met with on the posterior extremity of the inferior turbinated body, while its anterior extremity is generally puffy and dilated, doubtless from collateral engorgement.

III. The third, or atrophic stage, is separable into two periods, one of commencing atrophy, and one of complete disappearance of the erectile tissue.

a. Period of commencing atrophy. Characterized by pronounced contraction of the newly formed fibrous bands, leading to an irregular, nodular condition of the tissue, most prominent in the posterior part of the inferior turbinated body and along its inferior border. This uneven appearance of the diseased portion not infrequently assumes the appearance of fibrous or papillomatous excrescences which may become detached, the process of detachment constituting one step in the future and complete atrophy of the tissue. The erectile spaces are inconspicuous, and, in some places, entirely gone.

β. Period of complete atrophy (turbinated cirrhosis). Characterized by a rudimentary condition of the turbinated bodies, due to more or less complete disappearance of the erectile tissue.*

SYMPTOMS.—The symptoms and rhinoscopic appearance of chronic inflammation of the nasal passages may be conveniently considered under three heads, corresponding to the three phases or stages of the disease—the simple inflammatory, the hypertrophic, and the atrophic.

Simple Inflammatory Stage.—The most prominent symptom of this stage is increased irritability of the nasal mucous membrane, which finds its most conspicuous expression in an abnormal excitability of the erectile tissue, which is found on the turbinated structures and septum. This irritability of the cavernous tissue constitutes the characteristic and central phenomenon around which the other symptoms of this stage are grouped, and from which many of them proceed, either from purely mechanical causes or as the results of reflex or vasomotor influences (see article on Nose, Neuroses of). The subjective expression of this condition is a more or less constant sensation of stuffiness or of a foreign body, and a tendency to temporary stoppage of one or both nostrils. This is usually most noticeable in the presence of changeable atmospheric conditions, when the individual assumes the recumbent position, as at night, or, sometimes, when under the influence of sexual or other excitement; and, in women, at the menstrual epoch. In fine, when the individual is exposed to any of the predisposing or exciting causes of the disease. In some persons the turbinated tissue is thus rendered so exquisitely sensitive to the slightest perturbation or vibration of the air that they can presage with certainty the approach of atmospheric changes by the sudden swelling of the nasal structures, as the twinges of corns can predict the coming of a storm.

Other things being equal, the tendency to stoppage is much more liable to occur in those of a pronounced neurotic temperament, but this can by no means be accepted as a universal law. There can be no doubt that direct irritation of the sensitive or olfactory nerves of the nasal mucous membrane, or an impression reflected from the eyes, or even other remote organs, leading secondarily to dilatation of the erectile cells and the filling of their cavities with blood, is the mechanism of the sudden obstruction of the nostrils, which is the leading characteristic of this stage.

The curious clinical fact that, in acute obstruction of the nasal passages, when the individual assumes the lateral position, the upper nostril becomes free, has never received satisfactory explanation. The theory usually accepted, of gravitation of blood to the most dependent portion, has always seemed to me unphysiological and absurd, and the more plausible explanation suggests itself, that it is a purely vaso-motor phenomenon, occurring possibly through a central impulse in response to the call of the respiratory sense.

The irritation and consequent swelling of the nasal membrane may be inconsiderable, and give rise to little or no inconvenience, or it may awaken phenomena of a reflex nature, such as sneezing, coughing, and various other neurotic conditions (see Nose, Neuroses of).

The result of this increased vulnerability of the mucous membrane is that the patient is constantly "catching cold," and the slightest change in the weather is often sufficient to produce stoppage of the nostrils, hoarseness, and ringing in the ears. He is unable to explain the tendency to sneeze in the morning, or the hoarseness which follows the prolonged use of the voice in speaking or singing. A more or less constant itching at the end of the nose is frequently referred to the crawling of a mythical stranger, and the mere suggestion of chronic nasal catarrh is stoutly, and sometimes indignantly, repelled.

As the result of the repeated erection or filling of the contractile tissues, a paralytic or subparalytic state of the resilient and contractile elements in the walls of the erectile cells develops, which leads to permanent dilatation, recognizable by the eye as an engorged or puffy condition, mainly of the turbinated tissues, which may be distinguished from true hypertrophy by its collapsing under the probe, by the readiness with which it can be pressed against the wall of the nostril, and by its diminution in bulk under the various means which produce reflex contraction or emptying or depletion of the erectile spaces (the sudden application of cold, cocaine, and allied drugs, etc.). It is this puffy condition which, as has been observed above, constitutes the transition period between the simple and the hypertrophic stages. Reflex phenomena are common at this period of the affection.

The *secretion* in the simple catarrhal stage varies greatly in quantity and quality. At first it is thin, inconsiderable, and inconstant, according to the condition of the surrounding atmosphere and the presence or absence of the exciting causes of the disease. Gradually it becomes more abundant, thicker, and annoying. It collects in the sinuosities of the nasal fossæ, and produces often a false sense of obstruction, which is relieved by the use of the handkerchief. At times it distils from the nostrils as a clear, almost limpid fluid; at others it collects in flaky, whitish-yellow masses, which adhere to the swollen, reddened mucous membrane beneath them, and which are most frequently observed on the anterior ends of the turbinated structures, in the middle meatus, and in the hollow of the septum; or, in other words, in those situations where they are with most difficulty removed by the expiratory forces. Occasionally, and especially in cases of long duration, the mucous membrane is covered with a multitude of little, whitish masses of secretion, which present a more or less mealy appearance. The secretion also varies in color from a dirty white to a greenish-yellow hue, and is not infrequently streaked with blood. Occasionally the discharge has a distinctly bluish coloration.

In persons in whom the neurotic element predominates, the discharge approaches the character of a true rhinorrhœa, and under these circumstances fabulous amounts of fluid are said to have distilled from the nostrils.

Impairment of the sense of smell and difficulty in respiration are unusual at this stage, their presence being determined by the location of the structures chiefly involved and the extent of swelling of the same; and this is also true of interference with the functions of audition and voice production.

The intranasal vascular changes are often shown in an unusual tendency to flushing of the apex of the nose, which in some persons becomes permanent. This redness of the external nose, which may be confined to the apex, or dorsum, or may spread from the latter across the cheeks like two crimson wings, is now and then observed in a number of members of the same family.

---

* This classification was first presented to the [illegible], on April 4, 1886.

In long-standing cases, a veritable varicose condition of the vessels of the external nose develops. This varicose condition is especially well-marked at the entrance to the vestibule, and is sometimes associated with a similar condition within the nasal chamber. The redness of the nose which is frequently met with among habitual drinkers is often due to the catarrhal condition of the naso-pharyngeal passages which is common to chronic alcoholism; and the acne rosacea of this class doubtless frequently originates in a similar manner.

As the disease progresses, the follicles at the apertures of the nostrils become diseased, the vibrissæ are loosened, and become detached. Occasionally small follicular abscesses form at this situation, which are a source of great annoyance, and which, in some instances, are due more to the treatment than to the disease. Not infrequently, and especially in children and in neglected cases, the sharp, acrid discharge produces an eczematous or inflamed condition which may invade the whole upper lip. It may even happen that a sodden condition of the mouth and gums may result, and a patient under the observation of the writer attributed the loss of her front teeth to this condition alone.

The discharge varies greatly in amount. It is usually most conspicuous on arising in the morning, and may disappear during the day, or may be always present. It is either expelled through the anterior nares, or may gravitate or be drawn voluntarily into the pharynx, from which it is expectorated. The thicker the secretion and the richer it is in solid elements, the greater the tendency to adhesion to the mucous membrane, and the subsequent production of crust-formation. If it be allowed to remain in the nasal passages, decomposition occurs, a fetid smell and taste are imparted to it, and the expired air acquires a peculiar, sickening smell. A potent factor in the reflex expulsion of the secretion is the act of sneezing, and by this means much of the inspissated discharge is loosened from parts in which its dislodgement is exceedingly difficult or impossible by the simpler expulsive force used in what is commonly termed "blowing the nose." Examined under the microscope, the secretion contains a multitude of leucocytes, the remains of the degenerated epithelium of the nasal passages, blood-cells, granular débris, micrococci of decomposition of various kinds, and various objects derived from the external air. No characteristic germ has ever been discovered, and there is no microscopical evidence to show that catarrhal inflammation of the nasal passages is in any sense a parasitic affection.

In some cases, instead of an abnormal increase in secretion, is found exactly the reverse. The membrane presents a dry, almost shiny appearance, and the expired air is generally offensive. The character of the odor varies greatly, and seems in some instances to be due to individual peculiarity. Occasionally it has a singular earthy character, difficult to describe, but whose repulsive character, if once perceived, is never forgotten. Although the mucous membrane may be only slightly swollen, there is a more or less constant sense of false obstruction present, and the individual is constantly endeavoring to clean the nostrils of imaginary secretion.

The *rhinoscopic appearances* are those of diffuse or localized congestion, with varying degrees of inflammatory swelling, with the presence of secretion of varying character and quantity (see Symptoms). True ulceration rarely, if ever, occurs in simple chronic rhinitis. On the other hand, the epithelium may be detached through chemical or mechanical irritation, and we should therefore carefully distinguish between this loss of substance and that produced by the pathological process itself. Beginners frequently mistake small, isolated areas of dried, adherent muco-purulent secretion for losses of substance, an error that only needs pointing out to be avoided. Now and then the vessels of the mucous membrane present a more or less varicose and swollen condition, and small spots of hæmorrhagic infiltration may be discovered, the most frequent seat of which is the septum on the inner wall of the nasal vestibule.

Hypertrophic Stage.—There arrives, sooner or later, a time when the symptoms of the first stage become more pronounced. The patient becomes aware of a gradually developing difficulty of breathing through the nose. Sleep is rendered unquiet by the accumulation of mucus in the throat, and the individual arises in the morning with a dry throat and coated tongue. The organic matter of the buccal secretion is deposited on the teeth and gums, and collects and dries at the corners of the mouth; the breath is often offensive, and headache is complained of. Soon the lips become fissured and cracked, and the mucous membrane peels off; the general health, especially in children, begins to suffer; the appetite becomes capricious; more or less constant ringing in the ears, followed by gradually deepening deafness, is also common. These signs indicate an increase in the thickening of the membrane;—the second stage has been reached—the rhinitis has become hypertrophic.

When the symptoms of this stage are more closely examined, it becomes evident that obstruction of the nostrils from hypertrophic enlargement of the internal structures is equivalent to interruption of its functions as an organ of respiration, olfaction, audition, and voice-modification, and the phenomena to which it gives rise will therefore depend upon the anatomical seat of the obstruction, and the physiological properties of the structures that assist in its production. The symptoms of nasal obstruction are often so intricately blended with those of the conditions which complicate it that their explication would involve a review of the clinical history of the commoner affections of the nose, throat, and ear, and I shall therefore content myself with simply indicating the pathological results of an obstructive nasal lesion.

Obliteration of the upper meatuses or malformation of the nasal roof is accompanied by interference with the sense of olfaction and the varied train of morbid impressions which follow its perversion.* Over a century ago, Morgagni called attention to deflection of the septum as a not infrequent cause of unequal distribution of the nervous power of smell, and[22] related a case in which, from obliquity of the crista galli and consequent diminution in number of the olfactory foramina, this sense was supposed to have been less acute in the nostril corresponding to the narrower side of the cribriform plate. Just here let me observe that the ability to respire with freedom through the nose by no means negatives the existence of obstruction; the upper nasal chambers may be crowded with growths and the pharyngeal vault covered with vegetations, and yet respiration go on with perfect ease. This is a fact which is systematically and persistently overlooked by many practitioners of medicine, and the absence of obstruction is too often inferred from the passage of air through the nostrils when the mouth is closed.

Should the obstruction occur in the inferior meatus, the mouth becomes the channel through which the air passes to and fro from the lungs, and nasal is transformed into buccal respiration. From this transference of physiological relations it naturally follows that the air reaches the delicate lining membrane of the lower respiratory tract in a state unfit for respiration. Hence arise hyperæmia and chronic inflammation of the pharyngo-bronchial membrane, with their associated alterations in the voice.

Besides the part which the nose plays in olfaction, respiration, and voice-production, it also serves as the channel through which air reaches the middle ear. Hence, imperfect aural ventilation often occurs, with resulting otitis media, and sometimes perforation of the drum membrane and consequent otorrhœa. This same chain of events follows the obstruction of the Eustachian tubes by growths in the pharynx or the pressure of the hypertrophied nasal turbinated structures, or by inflammatory engorgement of the orifices of the tubes themselves. This not only cuts off the air supply from the tympanum by direct continuation of its natural channel, but also by interfering with the motions of the velum, and therefore with the opening of the tube for the proper relief to drainage of the tube. The intimate and direct connection of the blood-supply of the tube and pharynx with that of the middle ear and their anatomical continuity of tissue, favor, furthermore, the extension of the inflammatory process from the one to the other. Indeed, in very many cases the aural inflammation is merely a symptom of nasal catarrh, and gradually disappears without special treatment upon the removal of its primary cause.

---

* See article on Nose, Neuroses of the.

Inflammation of the tube may result in stricture; and in long-standing cases of salpingitis fatty degeneration of the tubal muscles occurs with the consequences described above.

These are by far the most common causes of chronic catarrhal inflammation of the middle ear. There is still another way, however, in which morbid conditions of the nose may react upon the circulation and upon the nutrition of the aural chambers, viz., through the reflex agency of the vaso-motor and trophic nerves. I am led to the assumption of reflex irritation by the pain and congestion in the ear which occasionally follow the manipulation of instruments within the nasal cavities, or the application of caustics or other remedies to their lining membrane; and, furthermore, by the existence of symptoms referable to the ear (tinnitus, pain, etc.) which cannot be explained on any other hypothesis.

It is impossible to exaggerate the part which diseases of the nose play in the production of inflammatory conditions of the middle ear. Between sixty and seventy-five per cent. of all cases of ear disease originate primarily in morbid states of the naso-pharynx, and the successful treatment of middle-ear catarrh will in the vast majority of instances depend upon their recognition and removal. So important is their relationship that we may lay down the rule that *the examination of the ear should be begun, not with the inspection of the external meatus and tympanic membrane, but with the exploration of the nasal fossæ and retro-nasal space.*

The symptoms of advanced nasal obstruction from adenoid growths have been well described by Meyer and others. The pallid countenance assumes a dull, stupid expression, and the cheeks become flabby from elongation of the naso-labial sulci. The mouth is kept open, the lower jaw depressed, the gums are [illegible] and cracked, and saliva dribbles from the mouth. This often leads the parents of the child to connect the stupid countenance and the deafness which is nearly always present, with imbecility. Some writers call attention to the unusual prominence of the front teeth as a symptom of obstruction in the naso-pharynx, and Michel[20] observed in a girl aged eight years the inner canthi of the eye so depressed that her countenance wore a strange "Chinese" appearance. Deafness and tinnitus are nearly always present. Neuralgia is common. Taste is impaired; the nasal discharge is profuse, excoriating the nostrils, filling the pharynx, preventing sleep, and provoking suffocating attacks. These symptoms, together with constant snuffling, are well marked among children, and react most powerfully upon the general health. Several of my patients complained of a heavy dragging sensation in the back of the nose, which they compared to the presence of two heavy weights hanging into the throat. (The condition found was bilateral turbinated hypertrophy.) Later in life the nostrils become abnormally narrow, from arrested development or collapse of the alæ nasi. "The speech becomes nasal, the tone of the voice dull and 'dead'" (Meyer). The voice is furthermore weakened and rendered indistinct by the interference with the mobility of the soft palate from the presence of tumors and hypertrophies of the turbinated bodies. Obstruction in the nasal fossæ (deflected septum, polypi, etc.) prevents the free passage of the voice and diminishes correspondingly the force of the tone.

Rhinoscopic Appearances.—If the nasal passages be examined at this stage they will be found obstructed by enlargement of the turbinated bodies (generally the inferior) and thickening of the mucous covering of the septum.

When the hypertrophy is anterior the diagnosis can be made by inspection of the anterior nares, and in some cases the deeper regions of the nose, and even the Eustachian tubes, can be seen with the aid of a strong light and special inspection apparatus. To the practised touch the probe is often an important auxiliary in the detection of posterior hypertrophies, but all such manipulation is rendered unnecessary by the ease with which the posterior nares may be examined by reflected light. Anterior hypertrophy appears as a smooth, globular, or [illegible] sessile mass causing more or less complete obstruction of the fossa. The swelling occasionally attains a very large size, displacing the septum, or projecting even from the nares. Hypertrophy of the anterior structures does not, as a rule, reach the extreme hardness often found in the posterior enlargements, nor is the peculiar raspberry appearance as frequently met with. Care should be taken not to confound true hypertrophy with collateral congestion or mere puffiness. It is only in exceptional cases that the floor of the nostrils and the whole of the inferior edge of the lower turbinated bone can be seen in a posterior rhinoscopic examination. Generally only the upper portion of its posterior end is visible, the lower half being concealed by the veil of the palate, and this anatomical fact furnishes an excellent guide in measuring the amount of hypertrophy. When, however, the posterior part of the lower turbinated body is hypertrophied, it appears in the mirror, rising above the velum, to a height varying with the amount of enlargement. It often projects backward over the palate into the naso-pharynx, and occasionally extends across the septum to the nostril of the opposite side. The inferior meatus may be alone occluded, or the whole naris may be occupied by the hypertrophic mass. The latter is sometimes freely movable, and may readily be mistaken for polypus. It may be uniformly smooth or irregularly lobulated, or it may be studded with little protuberances giving it the appearance of a raspberry. It varies in color from a dirty grayish or yellowish-gray color to a deep red or even purplish hue. In contour it is either rounded or oval; sometimes its upper border is irregular in outline, occasionally presenting a depression at its upper inner aspect.

The hypertrophy is nearly always bilateral and associated with a swollen condition of the tissue covering the middle turbinated bone and posterior half of the septum. In some cases I have been able to demonstrate its existence even on the superior turbinated bones. After the removal of the redundant tissues small nodular growths are occasionally seen in the middle meatus which represent localized hypertrophies or polypoid growths of that region. The hypertrophic turbinated tissues have sometimes a whitish, œdematous, almost hydatid appearance due to cystic degeneration of the mucous membrane. Almost always there is a corresponding hypertrophy of the tissue covering the septum, which bulges into the fossæ on either side and assists in the occlusion of the nostril. In this situation the hypertrophied tissue sometimes presents a depression corresponding to the convex enlargement of the turbinated bone. Small localized hypertrophies of the lateral surfaces of the septum are also observed, presenting the appearance of papillary growths. Hypertrophy of the upper posterior half of the septum is common in long-standing cases and causes a bulging on either side of the median line, which, with the central depression, presents sometimes a heart-shaped appearance. The blood-vessels over the septum are often enlarged and tortuous. In the majority of cases hypertrophy of the pharyngeal tonsil exists, either as a well-defined sessile tumor or as a mass of polypoid vegetations. This hypertrophy is at times so excessive as to fill the entire naso-pharynx, occluding the nares and Eustachian tubes, and pressing the velum downward and forward. The lips of the Eustachian tubes are generally enlarged, tumefied, and reddened, their orifices dilated and patulous. This gives the tube the appearance of an enlarged cervix uteri in a state of chronic hyperplastic inflammation. Occasionally a granular condition is noticed, due to swelling of the muciparous glands of the tube (tubal tonsil of Gerlach). They are sometimes occluded from pressure of the enlarged pharyngeal tonsil and hypertrophied turbinated bodies. Mucus collects in the orifices of the tubes, in the fossæ of Rosenmüller, on the pharyngeal vault, and in the posterior nares. Usually a thick, tenacious shred extends from the vault of the pharynx to the posterior border of the septum. All secretion must be removed before a satisfactory diagnosis can be made.

Adenoid growths appear as sessile or pedunculated vegetations of varying size, number, and consistence, scattered over the vault, posterior and lateral pharyngeal walls, and upper part of the septum. They are often massed together so as to form a tumor of considerable magnitude. When removed, they present the gross appearances of papillomata. Their diagnosis can be made with the mirror, or, in small children, by means of the finger introduced behind the velum. The sensation communicated to the finger is compared to that obtained by touching a bunch of worms. They bleed readily when touched, and, as a rule, discharge profusely. In all cases of deafness in children the naso-pharynx should be examined for these growths; if present, their ablation is imperative. If thoroughly removed, the deafness and nasal discharge rapidly, often immediately, disappear; and, if the case be not complicated with hypertrophic catarrh, no further treatment will be necessary.

We now come to a form or stage of nasal inflammation which for centuries has been the subject of much dispute, which is one of the most difficult of affections to deal with, and which in ancient times excluded its possessor from the privileges of the priesthood, and in more modern days has actually sufficed for divorce. It is the affection known under a host of names, such as dysodia, rhinostenose, coryza fœtida, fetid catarrh, dry catarrh, stinknase, punaisie,[*] rhinitis atrophica, rhinitis atrophica fœtida, etc.; but the most common of all appellations is perhaps the ancient one, ozæna, which, as implied in its Greek origin, signifies a stench from the nostrils. The term ozæna is an unfortunate one, for the condition is, properly speaking, not a disease *per se*, but a symptom of a number of pathological states. Thus it occurs in all ulcerative[†] diseases of the nasal mucous membrane, whether from syphilis, cancer, glanders, rhinoliths, and other foreign bodies (in which latter case it is almost invariably unilateral), phagedenic and other ulcers, and is the usual accompaniment of caries and necrosis of the intranasal bony framework. It also is occasionally present as a symptom or complication of nasal and postnasal growths, and may be symptomatic of simple or purulent inflammation of the accessary sinuses, and particularly of the antrum of Highmore. It may occur, too, as an accidental phenomenon from simple detention and decomposition of secretion in ordinary coryza, particularly in children, from imperfect removal of the secretion; or in adults and children, either from some imperfectly defined so-called "idiosyncratic" influence or from the presence of some vice of constitution, inherited or acquired. Occasionally a simple inodorous catarrh will become offensive at the menstrual epoch, losing its disagreeable odor during the decline of the ovarian disturbance; while any existing odor is very frequently aggravated at periods corresponding to those of the menstrual flow. Sometimes a condition resembling it is produced by snuff, various foods, and the habitual use of alcohol.

In the present article the term ozæna will not be used, and attention will be solely directed to that period of nasal inflammation which I have termed in my classification *rhinitis cirrhotica*, and which is used to denote a simple atrophic or cirrhotic condition of the mucous membrane of the nasal and accessary cavities, associated or not with corresponding changes in the bony framework, and which is usually if not always the representative of the third or last stage of hypertrophic nasal inflammation (*vide* section on Pathology).

It must not be understood that every case of hypertrophic catarrh, if left to itself, will terminate necessarily in atrophy. The latter process appears earlier in some cases than in others, the rate and time of its occurrence being probably dependent upon peculiarities of constitution, modes of life, and other conditions which influence the rate of progress of simple inflammation in general. In either or any event, it is usually the sequel of an hypertrophic condition—the legacy of a neglected or, what amounts to the same thing, a badly treated catarrh.

The existence of syphilis, or other diathetic conditions (see Pathology), undoubtedly predisposes to the atrophic process, and I am of the opinion that the constant and habitual use of alcohol is a prolific source of the new formation of connective tissue, just as it leads to similar changes in other organs, notably the liver and kidney.

The two most prominent symptoms of ozæna are the horrible odor and the special tendency to crust-formation. The crusts vary in color from a dirty brownish-gray or greenish-yellow to a pronounced blackish or coal-black hue. They exhibit also varying degrees of consistency, from soft, easily friable, to tough, leathery masses, and sometimes acquire a stony hardness which may lead to their confusion with dense foreign bodies. Uniform, or distinctly laminated in structure, they adhere with great tenacity to the mucous membrane, from which they are separated at intervals varying from two or three days to several weeks, as casts of the regions which they occupy. Occasionally the posterior nares become completely occluded, and the two obstructing crusts become connected by a band over the posterior edge of the vomer, so that when detachment takes place the expectorated crust presents an appearance not unlike that of a pair of eye-glasses.

They occur in all portions of the nose and nasal pharynx, and their expulsion is often attended with great difficulty. They are sometimes detached during sleep, when they may give rise to symptoms of sudden suffocation from their presence at the entrance of the laryngeal vestibule. Their separation is effected by the accumulation beneath them of a fetid muco-purulent secretion. This exudes from the under-surface of the crust, and bathes its surface with a thick discharge, in which the hardened mass is partially macerated and expelled, leaving an abraded, bleeding surface at the points of adhesion. The stench is generally intensified during the detachment of the crusts.

This tendency to inspissation of the discharge and the formation of crusts is, in a great measure, due to abnormal increase in the capacity of the nasal chambers, but it is doubtless also, to some extent, encouraged by the atrophy of the erectile and other sensitive tissues, and the consequent diminution in the reflex excitability of the nasal apparatus.

The amount of discharge varies greatly in different cases. At times it is so profuse that it necessitates the constant use of the handkerchief, while at others it is only trifling in amount. This has led some writers to describe two varieties of the disease, a moist and a dry atrophy.

The destruction of function which atrophy of the intranasal structure involves will naturally vary according to the region principally involved by the disease. The senses of smell and taste are usually impaired, or may be entirely destroyed.

Rhinoscopic Appearances.—The external nose is either normal in appearance or presents a variety of unnatural positions. The depressed, flat, and saddle-shaped nose which is characteristic of disappearance of the cartilaginous septum is rarely met with in simple atrophic rhinitis. The changes in the external nose will depend upon the extent to which the destructive process has advanced within the nostril. The abrogation of the respiratory function of the nostrils leads to impairment of the motions of the alæ nasi, and quite often the apex of the nose is tilted upward, so that the anterior nares look more or les directly forward. This elevation of the tip of the nose is also met with in contraction of the posterior parts of the nostril, and in adenoid growths of the nasal pharynx.

---

[*] The term usually applied by the French. It is remarkable that in the Ayur Veda there is an affection described under the name *pinasa*, which is represented as occurring in an acute and chronic form, and which possibly is the disease in question.

[†] The ancients used the terms ozæna and ulcer of the nostrils as synonymous.

The mucous membrane of the dilated nostril, after the removal of the crusts, is thin and smooth, and of a pale reddish or dirty gray hue. Ulceration is not met with. According to my experience, in simple atrophy the atrophic process is most marked in the respiratory region, the lower turbinated bone being, in many instances, reduced to a mere rudiment, allowing in some cases a perfect view of the posterior nasal region. The middle turbinated structures are either atrophied or, as is often the case, simply hypertrophied, and hang in the dilated meatus like polypi. When extensive atrophy exists the posterior upper wall of the nostril (pars olfactoria) can be seen presenting the appearance of a more or less lobulated growth. In rare cases the pars nasalis and the upper turbinated bones can be distinctly seen. The changes described above are usually found in both nostrils, but cases are occasionally met with in which the atrophic process is limited to a single nostril, and this apparently independently of pre-existing or concomitant aural disease.

PATHOLOGY AND PATHOLOGICAL ANATOMY.—The following account of the pathology and pathological anatomy of intranasal inflammation is based mainly on an anatomical study, now extending over a period of over seven years, of a large number of inflammatory growths removed from different portions of the nasal chambers and at all stages of the catarrhal process. These observations were first published in the *Medical News* for October 4, 1884.*

I. The changes found in common catarrhal inflammation of the nasal passages are pathologically separable into three distinct groups, corresponding to the three clinical stages of the disease, viz., the simple inflammatory, the hypertrophic, and the atrophic.

The gross anatomical appearances of the first stage consist essentially in localized or diffuse injection, with moderate swelling of the tissues.

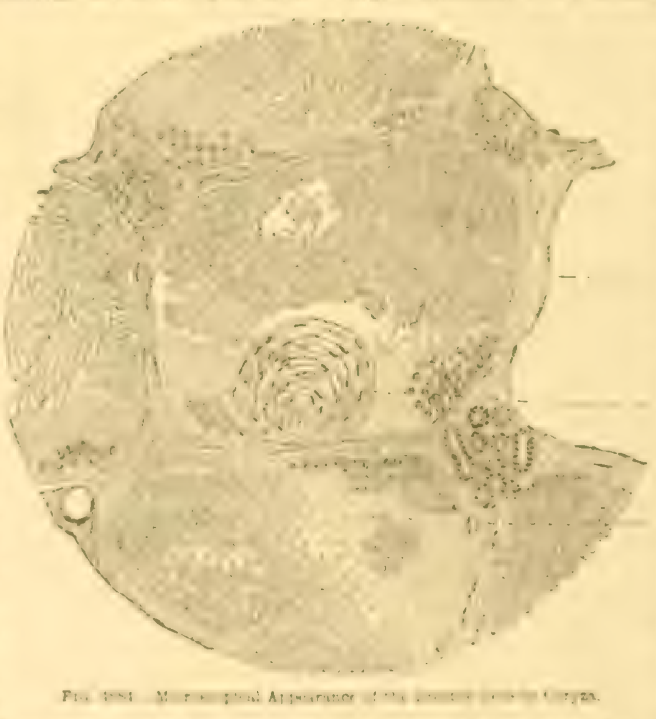

FIG. 1251.—Microscopical Appearance of the Erectile Tissue in Coryza.

There is very little, if any, swelling of the mucous membrane proper, the main condition being repeated engorgement of the erectile bodies. Portions of the mucous and underlying tissues removed with the snare bleed freely, are soft to the touch, can generally be flattened out with the finger, and, when thrown into alcohol, sink slowly to the bottom of the vessel. They are uniformly smooth in contour, and present, when first removed, a dark purplish and mottled look on the upper surface, while on the under aspect the peculiar spongy appearance of the honeycomb and dilated erectile body can be distinctly made out. Under the microscope the appearance which immediately strikes the eye is the enormously dilated and engorged condition of the erectile spaces and the extreme tenuity of their walls. The latter are often reduced to the merest shred, resembling the meshes of a delicate web. Occasionally, large, irregular spaces are observed, which doubtless result from rupture, either before or during the compression produced by the snare. In some cases small hemorrhages are discoverable in the submucous tissue. I have not met with any notable changes in the mucous membrane. The epithelial layer is usually intact, and beyond perhaps a slight amount of cellular infiltration of the submucous tissues, there is nothing to call for special remark. An excellent idea of the condition of the erectile cells in the first stage may be derived from inspection of the accompanying drawing, in which we have, too, the probable microscopical picture of coryza.* In the case from which the section was taken, the nasal passages presented the appearances commonly observed in the condition known as coryza, and in the permanent puffy condition found in more chronic inflammation, the most noticeable being intense engorgement of the cavernous tissue, especially well marked over the lower half of the middle and posterior portion of the inferior turbinated body. Upon cutting into the engorged bodies with a snare, the blood, which flowed freely, could be squeezed from them as water from a sponge. The mucous membrane of the maxillary sinuses was not in the slightest degree touched, and presented simply a more or less cyanotic appearance.

Under the microscope the condition which at once attracts the eye is the enormous dilatation of the erectile spaces and the extreme tenuity of the intercellular walls. Here and there rupture of the latter had occurred from the enormous blood pressure, and two or more spaces in this way communicated. Along the inner walls of the dilated spaces were seen congregations of lymphoid corpuscles and in some of them collections of fibrinous exudation.

The mucous membrane proper presented no noticeable pathological change. The epithelial layer was intact. At some places it seemed slightly thicker than at others, but beyond a moderate amount of cellular infiltration of the tissues beneath the basement membrane, there was nothing in the mucous layers to call for special remark.

Jutting out from and attached to the wall of the central space (n, the diagram) was a well-formed parietal thrombus, to which I would like to call particular attention.

Here, too, is illustrated the minute anatomy of the puffy condition or state of permanent dilatation of the erectile spaces which characterizes the second period of the simple inflammatory stage before hypertrophic changes have developed, and to which I have called attention elsewhere (see Classification).

Of great interest, too, is the formation of the parietal thrombus as illustrative of a mode of obliteration of the erectile spaces hereinafter alluded to.

In the second, or hypertrophic, stage, the gross appearances vary considerably. The growths, when removed, are either round or oval in contour, uniformly smooth or irregularly lobulated, or covered with little protuberances, giving them the appearance of a raspberry. Frequently, when the loop of the snare is disengaged from the hypertrophied tissue, a small shred or stem projects from the under surface of the latter, which, together with the smooth upper surface of the growth and its rounded, folded inward edges, presents a striking resemblance to a mushroom. The hypertrophies vary in color, from a dirty grayish or yellowish-gray, to a red, and even purplish hue. The color and density of the hypertrophy vary with its age. The older the growth, the paler the color and the harder the consistency.

---

* The accompanying drawing [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] Hospital, [illegible] [illegible] [illegible] [illegible].

* These observations were first brought before the American Laryngological Association in June, 1886, in a paper entitled A Contribution to the Pathological Histology of Acute and Chronic Coryza. See Transactions; and also New York Medical Journal for August 28, 1886.

Cross-section with a knife discloses often a peculiar *nutmeg appearance*, due to the interlacing fibrous bands and the dark-brownish aspect of the blood in the erectile spaces. In other cases this nutmeg appearance is not well marked, the whole tissue being converted into a dense, fibrous mass. These masses are incompressible, and sink immediately when thrown into the preserving fluid. They are sometimes covered with little granular or papillary projections.

The microscopical appearances vary. In all, the most remarkable is the conversion of the walls of the erectile spaces into dense fibrous bands, which, in contracting, obliterate more or less completely the erectile cells.[*] These latter present numerous irregularities in outline, and, in those places where the fibrous change is most marked, contain very little, or are altogether destitute of, blood. This fibrous process invades the submucous tissues, and converts them, too, into a fibrous mass in which their glandular elements disappear. The latter are apparently destroyed or obliterated, not only as the mechanical result of the contraction of the new-formed tissue, but also by cellular infiltration of the glandules themselves. The latter is of two kinds, an intra- and peri-acinal.

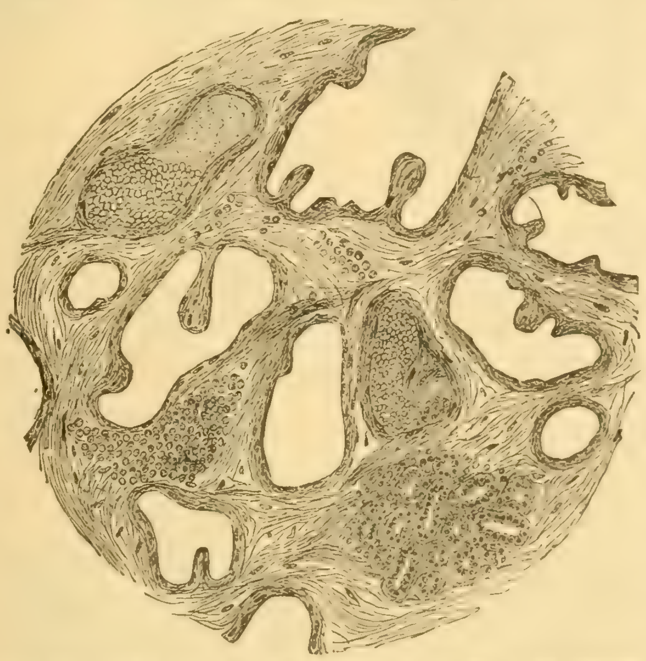

FIG. 4885.—Buds or Bulbous Processes projecting from the Walls of the Cavernous Sinuses.

When the fibrous process is confined to the deeper layers, the epithelium is usually intact. When, however, the structures immediately under the basement membrane are invaded by the round-cell infiltration, the epithelial layer is notably thickened, often in an irregular manner. This thickening is most marked in the undulations of the free surface. Occasionally the epithelial proliferation assumes the form of distinct filamentous papillary growths, which are beautifully shown under the microscope.

In some places the epithelial cells are filled with a granular detritus, or are altogether wanting. The latter occurs when the fibrous process encroaches on the superficial layers and obliterates their blood supply. When this occurs, the epithelium may be entirely gone over a considerable extent of surface, nothing being left but the basement membrane. When all the layers are involved in the shrinking of the new-formed tissue, the surface of the growth is often thrown into small, pear-shaped projections or knobs, which consist entirely of fibrous tissue. I am inclined to believe that these knobs may subsequently become detached, and that this process of detachment may be one step in the future atrophy of the membrane. For, if the histories of certain cases of atrophic rhinitis be carefully taken, it will appear that, from time to time, there are found in the discharge from the nose, during the hypertrophic stage, small nodular masses, which are described by the patients as "little pieces of flesh." They will affirm, furthermore, that, when this has occurred, the nostrils are perceptibly freer, and, encouraged by this false hope, which they take as an evidence of return to the healthy condition, they neglect treatment and allow the disease to go on to the atrophic stage. I have not met with any mention of this clinical fact in the writings of others, and am inclined to the opinion that the "pieces of flesh" are none other than these polypoid knobs of fibrous or papillomatous tissue, and that their expulsion may be regarded as an index of approaching tissue destruction.

Before leaving this brief consideration of the hypertrophic stage, I wish to call attention to an appearance which I have twice met with, viz., the obliteration of the lumen of the erectile spaces by masses of round cells which resemble the white corpuscular elements of the blood.

I also wish to call attention to certain buds or bulbous processes which in the hypertrophic stage are occasionally found jutting out from the walls of the cavernous sinuses, and which are made up of outgrowths from the newly formed connective tissue. These appearances were first pointed out to me by my friend Professor Councilman, of the Johns Hopkins University, who had taken one of my sections for examination.

Projecting inward, they form bulbous processes or septa of varying thickness, which sometimes interlace, sometimes form bands which connect one portion of the sinus-wall with another, thus constituting another factor in the division and obliteration of the cavernous spaces. Care should be taken not to confound them with the remains of a thinned and ruptured intercellular wall; in the latter case a similar projection will usually be found at a point diametrically opposite to that occupied by the projecting band.

We have, then, four modes of obliteration of the erectile spaces in nasal inflammation:

1. By the contraction of the newly formed intercellular fibrous bands.
2. By obliteration of their lumen by masses of round cells which resemble the white corpuscular elements of the blood.
3. By the formation of thrombi in certain cases.
4. By the process of septa-formation.

The transition of the first stage into the hypertrophic does not seem to me to depend necessarily upon the presence of constitutional disease, or vice of constitution, inherited or acquired. While it is true that certain diathetic diseases predispose, other things being equal, to the development of this fibrous tissue in excess, the same takes place in the perfectly healthy, and in those who are free from the slightest trace of constitutional taint. In the hypertrophic tonsillar bodies which I have removed from syphilitic patients the fibrous tissue was notably excessively developed, and that this disease predisposes to the subsequent atrophy of the tissue, I think there can be no doubt. It is, indeed, doubtless true that certain diathetic conditions, and especially the inherited form of syphilis, as well as certain imperfectly understood personal peculiarities, exert an important influence in the determination of the atrophic stage of rhinitis; but there is a form which, in the present state of our knowledge, is indicative of no particular dyscrasia, traceable to no particular vice of constitution, occurring in the healthy as well as in the badly nourished and cachectic, the clinical and histological history of which contains nothing to differentiate it from the atrophic stage of a simple catarrhal inflammation.

---

[*] This connective tissue formation has also been studied by Seiler (Diseases of the Throat, Philadelphia, 1883, p. 197) and Bosworth (New York Medical Record, June 10, 1882). Seiler found the epithelium intact, although some fatty degeneration of the cells had taken place. In Bosworth's sections the epithelial layer was greatly thickened. The myxomatous change which takes place in the fibrous tissue, and which is mentioned by Seiler, I have also observed.

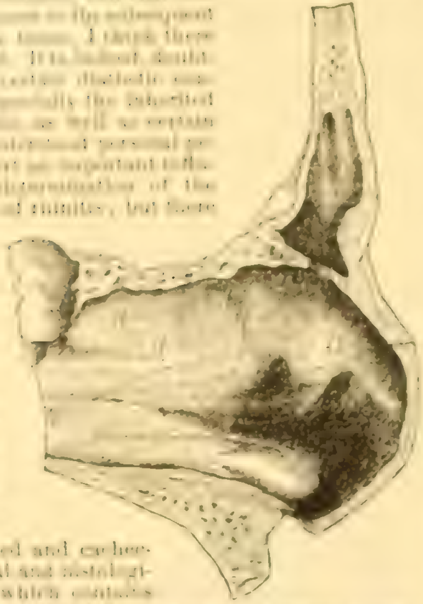

Fig. 4886.—Enormous Hypertrophy of the Mucous Membrane and Underlying Structures of the Septum Narium. (Drawn by A. C. [illegible].)

II. Is rhinitis ever *ab initio* atrophic? In the absence of direct histological proof of such an occurrence; in consideration of the rapidity with which, in some cases, the hypertrophic variety passes into the atrophic; in view of the many obvious difficulties in the way of certain historical data in its favor, and in the light of anatomical investigation, I think that, for the present, at least, this question must be answered in the negative. The strongest argument in favor of the independent origin of the atrophic form is the alleged occurrence of ozena in the newly born—that is to say, atrophic changes show themselves at a period too soon after birth to warrant the assumption of a pre-existing chronic catarrhal inflammation. It seems to me that this objection is sufficiently answered by the by no means violent assumption of the previous existence of an intrauterine catarrh.*

That atrophic rhinitis always appears as the sequel of a pre-existing catarrhal inflammation is rendered highly probable from a number of clinical and pathological facts. If the clinical history is accurately taken, it will point to a pre-existing catarrhal process. As has been indicated above, the rapidity with which the hypertrophic passes into the atrophic form of rhinitis is proportionate, in all probability, to the presence of some constitutional taint, such as the congenital or acquired form of syphilis. The early appearance of atrophy in some cases is dependent, doubtless, too, upon certain modes of life and other conditions which influence the rate of progress in simple nasal inflammation in general. I have seen it also occur with rapidity after the profound impression made upon the nutrition of the parts as the result of acute systemic disease. If the patient is not under intelligent special observation from the outset, it may be difficult to establish with certainty the chronological relationship of the two stages; but so far as my observation goes, I have never been able to satisfy myself of the independent origin of the atrophic form.

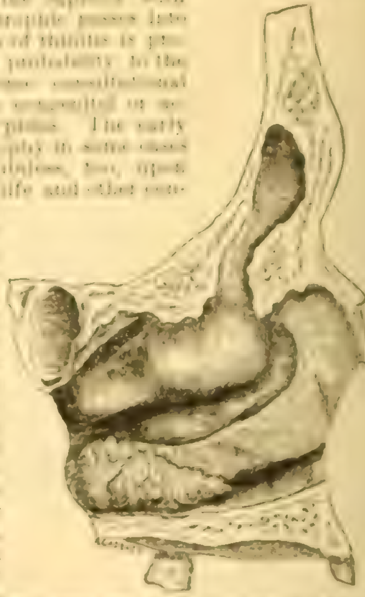

Fig. 4887.—The Hypertrophic Stage of Rhinitis Chronica.

In this connection it is worthy to note that the transition of hypertrophy into atrophy does not necessarily imply the existence of ozena. I now and then see cases in which the most widespread atrophy has occurred, and in which the capacity of the nasal chambers is greatly increased, in which no odor can be detected; and I have removed portions of membrane from the nose which showed under the microscope marked atrophic changes, in which no symptoms of ozena, strictly speaking, were present. How is the fact to be explained that in some cases in which extensive atrophy has occurred there is an absence of the characteristic odor of ozena, while in others (exclusive, of course, of pre-existing disease of the accessory sinuses) in which the destruction is less extensive, there is pronounced fetor? It is insufficient here to urge the operation of adventitious influences or the theory of simple decomposition. Does not the presence of the peculiar odor depend rather upon agencies operating within the tissues than upon those which approach from without? In other words, is not the atrophy that results from simple inflammation less liable, other things being equal, to give rise to the characteristic stench than that which depends upon constitutional causes?*

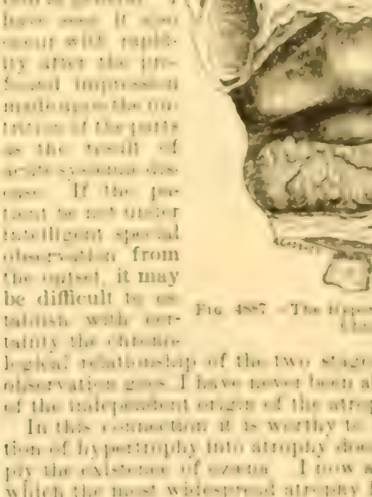

Fig. 4888.—Atrophic Rhinitis.

---

* In this case the [illegible]

* I have shown elsewhere (Congenital Syphilis of the Throat, [illegible]) that the [illegible] form of congenital syphilis [illegible] more frequently among [illegible], a fact which may perhaps explain the frequent occurrence of ozena among young girls at or about the age of puberty.

The pathological history of "ozæna" is, moreover, that of the conversion of hypertrophic changes into those of an atrophic form. In the rhinoscopic image, in the microscopic section, the processes of hypertrophy and atrophy are found side by side. More than that; the atrophic changes are more pronounced in situations in which the catarrhal inflammation originally developed. Thus, for example, if the disease originate as a catarrh of the maxillary sinus, the atrophy is more pronounced in the latter situation, the nasal mucous membrane proper presenting evidences of simple or hypertrophic catarrhal inflammation. If, on the other hand, the disease commence in the nasal fossæ, the morbid condition of the sinus, if such exist, is that of simple or hypertrophic inflammation. Finally, as the hypertrophic variety almost invariably commences in the respiratory portion of the nostril, so in the atrophic form, the region of the inferior meatus, the classical seat of atrophy, is the first to be destroyed.

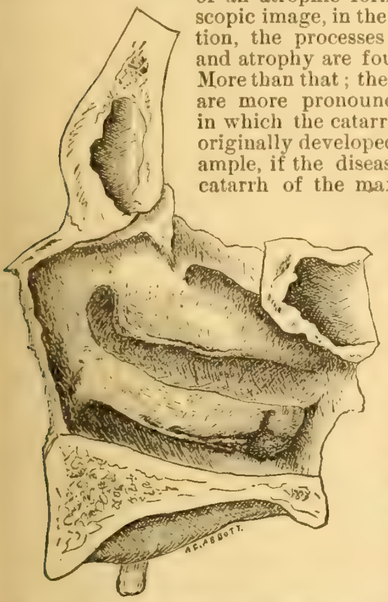

FIG. 4889.—Transition Stage from Hypertrophic to Atrophic Rhinitis.

Weighty evidence in support of the position that atrophy is always preceded by catarrhal inflammation, is furnished by the microscope. Here the processes are either found side by side in the section, or portions of the membrane show signs of atrophy, while in others, where the process is less advanced, hypertrophic changes are discovered.

I have never had the opportunity of a thorough post-mortem examination of a case of ozæna, but I have found the essential changes described by others—the process of contraction, destruction of glandulæ, etc., in the hypertrophic membrane removed with the snare—a condition of *turbinated cirrhosis*, so to speak, so that I am forced to regard this atrophy of the membrane, which may with propriety be called *rhinitis cirrhotica*, as the sequel of a pre-existing hypertrophic condition. At no stage of the catarrhal or atrophic process have I ever met with ulceration.

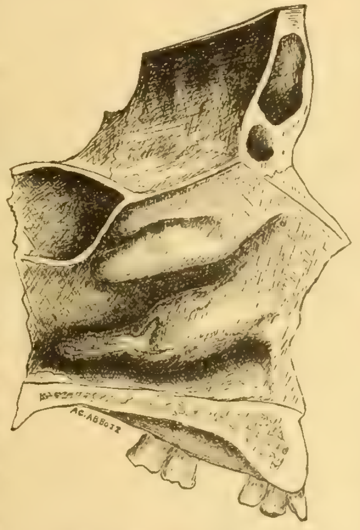

FIG. 4890.—Atrophic Rhinitis (Syphilitic). The characteristic cicatrices are seen on the posterior end of the inferior turbinated bone.

An opportunity is rarely offered for the histological study of pure uncomplicated atrophy of the nasal mucous membrane. Such chances belong to the accidental discoveries of the post-mortem table, and it is therefore only in a few isolated cases that its pathological histology has been recorded. Among these the most carefully studied are those of Eugen Fränkel[24] and Hermann Krause.[25]

When the nasal cavities are exposed, they are found filled with a dirty, discolored, foul-smelling mucus and crusts. Upon removing these, the atrophied mucous membrane is seen to be of a pale ashy-gray or dirty brownish color, its surface either smooth or glazed, or thrown into folds, giving it more the appearance of a serous than a mucous membrane (Zuckerkandl[26]). Dense in consistence, it can sometimes be stripped with ease from the underlying periosteum. Associated with this thinning of the mucous membrane is always more or less corresponding atrophy of the bony framework, and especially of the inferior and middle turbinated bones. Zuckerkandl, who has studied the different phases of atrophy of the turbinated bones in morbid specimens, finds that in the mildest grades of atrophy there is simply thinning, with rupture of continuity, or occasionally perforation of the bone. Later on, the free convex edge of the bone becomes straight, or even concave, and, as the process goes on, it is reduced to a mere ridge along the wall of the nostril. These changes are more pronounced in the respiratory region, but not infrequently invade the olfactory area.

The histological picture is simply that of a gradual atrophy or wasting away of the different layers of the mucous membrane, and the conversion of their individual elements into fibrous connective tissue, a purely cirrhotic or sclerotic process. The free surface of the mucosa is either completely deprived of its epithelium, or covered with cells of varying size and contour—round, polygonal, or spindle-shaped—with cloudy contents and illy-defined nuclei. Here and there it is covered with a fine detritus, which probably represents the remains of the epithelial cells. Fränkel found embedded, in a mass of round and spindle cells a number of small oval or rounded nodules, of a transparent, homogeneous appearance, which were found, upon examination with the higher powers of the microscope, to consist of broken-down cells and nuclei, and which were more or less completely isolated from the tissues in their vicinity (as a rule, in the neighborhood of the free surface). Fränkel regards these circumscribed nodules as the representatives of a retrograde metamorphosis of small cells and nuclei—a process presenting a certain resemblance to the infiltration of cells and nuclei of the subepithelial layer of the vocal cords in certain forms of phthisis.

The subepithelial layers are either crowded with round and spindle cells, represented by a ground substance (stroma) of fibrous tissue, or are converted into a dense structure composed of bands of fibrous connective tissue running parallel with the free surface of the membrane, and enclosing in its substance round and spindle cells, sometimes massed together, the long diameters of the latter being also parallel with the free surface. Here and there, either lying between the meshes of the fibrous tissues, or within the substance of the spindle cells themselves (Fränkel), pigment masses are found which consist of an amorphous granular matter, and which are more often met with in the upper layers of the membrane, and which disappear as the periosteum is approached. In the cases of Krause, the round and spindle cells either contained a cloudy, granular protoplasm, or had lost their contour and become converted into a fatty detritus. Krause, moreover, found everywhere, interspersed among the different layers, masses of fat granules, either assuming the form of spindle cells or arranged in rows alongside of each other. In addition to these, which should not be confounded with pigment, groups of fat-globules were discovered, which presented a light, grayish-yellow coloration, and which, together with the fatty degeneration of the cellular infiltration, are regarded by Krause as the cause of the odor in the disease (*vide infra*).

The glands either show no remarkable changes in structure and number, being simply surrounded by a round-cell infiltration in different grades of degeneration of their stroma may be so encroached on by the newly formed connective tissue as to cause their complete disappearance. This result results not only from the compression of the acini, but also from the interference with their vascular supply through the diminution in the calibre of the blood-vessels of the affected area. The changes which bring about this contraction consist in thickening of the adventitia, with corresponding narrowing of the lumen of the vessel.

In Fränkel's case the lumen of the smaller vessels of the olfactory region, and especially the arteries, was greatly diminished or completely obliterated by inflammatory changes in the tunica intima (endarteritis obliterans), while in the respiratory passages these changes in the lumina of the smaller vessels were not present.

So far the microscope has failed to reveal any noticeable change in the nerve elements.

The changes described above are much less pronounced in some places than in others. Here and there the microscopical appearances are rather those of a simple catarrhal inflammation than of an atrophic condition. These are more marked in the respiratory than in the olfactory region, and may be associated with similar processes in the accessory sinuses. The changes in the latter represent an earlier or a later stage of the inflammatory process according as the sinuses were originally the starting-point of the disease or were invaded secondarily by the inflammatory process. Thus the mucous membrane of the nasal fossa may be atrophied, while that of the sinuses shows evidence of an acute inflammation or a chronic hyperplastic process.

The changes in the periosteum and bony framework consist essentially in the gradual atrophy of the latter. The walls of the Haversian canals are gnawed away in an irregular manner, their lumen is filled with osteoblasts containing a varying number of nuclei, and in some places the space between the individual canals is so narrowed that nothing but a thin remnant of the bone is to be seen (Krause). Division of the nuclei of the bone corpuscles has been also observed (rarefying osteitis).

It is doubtful whether true ulceration ever occurs as a lesion of simple atrophy. Occasionally abrasions of the mucous membrane are seen which result from accidental causes, such as the use of the finger in the detachment of crusts, or from the separation of the latter when closely adherent to the surface; but neither abrasion nor true ulceration can be, in my experience, included in the pathological picture of the disease.

Against the theory that the atrophic process represents the later stages of hyperplastic or hypertrophic catarrh, Dr. Bosworth,[illegible] of New York, basing his view on personal observation, believes that the atrophy is "not due to connective-tissue hypertrophy encroaching on the glandular structures of the membrane, but rather to the transformation of epithelial structures into inflammatory corpuscles, together with an active epithelial desquamation from the surface of the membrane, and the lining of the acini." He believes also that the atrophy of the turbinated bones is due to pressure exercised on them "by the drying and contracting of the inspissated mucus," which process he compares to the action of a film of collodion. The latter speculation is scarcely conceivable, and in regard to the former, while it is doubtless true that round-cell and perhaps glandular infiltrations, as shown above, play a certain rôle in the atrophy of the glandulæ, there is abundant histological evidence to show that they are not constant or essential factors; while the histological observations of others and myself place the facts of connective deposit and contraction of newly formed connective tissue beyond the reach of reasonable controversy.

The horrible stench, which suggested the term ozæna, is one of the distinctive objective features of the atrophic stage. It has been compared by the French to the smell of crushed bedbugs, but even this is not sufficiently descriptive. It is penetrating, nauseous, disgusting in its sickening odor and sweetish. Its cause or origin has given rise to much discussion and speculation. To account for it, some have assumed the existence of a ferment or micro-organism, either developed in the nasal secretion or derived from the surrounding atmosphere; and that this ferment can be transferred from individual to individual is thought to be probable from the occurrence of ozæna in several members of the same family, and its disposition in certain countries, as in Galicia, Poland, and Russia. This hypothesis has, however, been overthrown by the failure to find such a ferment, and by the negative results of direct inoculation with the secretion of the atrophic nasal membrane.

According to others, ozæna, or atrophic rhinitis, originates as a chronic purulent inflammation of the accessory sinuses, especially the ethmoidal and sphenoidal, the decomposition of the secretion in these cavities furnishing the explanation of the peculiar odor. This theory, which was originally advanced by Drake,[illegible] copied by Vieusseux,[illegible] and Rouge,[illegible] and which has been resurrected in recent days by Michel,[illegible] is at variance not only with the clinical but also with the anatomical facts of the case, as demonstrated by post-mortem examinations. There is abundant clinical and anatomical evidence to show that the sinuses are, as a rule, only secondarily affected, and that a simple purulent inflammation is of itself insufficient to produce the characteristic odor of the disease.

From the stunted or atrophied condition of the turbinated bones, and especially the inferior, which usually accompanies the affection, and the consequent increase in capacity of the nasal chambers it has been thought by some that congenital atrophy of the turbinated bones, and particularly the inferior, is the essential feature in atrophic catarrh. This speculation, which has been especially insisted upon by Zaufal,[illegible] rests, however, upon the assumption of facts which in all probability do not exist, for both clinical observation and pathological anatomy alike demonstrate the fact that atrophy of these structures is invariably secondary—always the result of preexisting disease of the turbinated tissues. If congenital atrophy occur at all, it must be reckoned among the rarest of pathological curiosities; for investigations purposely directed with reference to this question have failed to discover its existence.* There is, moreover, no case on record which may be looked upon as an unequivocal example of congenital atrophy. That abnormal widening of the nasal cavities is of itself insufficient to account for the stench is shown by the fact that the odor is not infrequently altogether absent in cases in which atrophy and destruction of the turbinated tissues, resulting in a most widely opened cavity, has taken place. While it is unquestionably true that abnormal widening of the nasal passages favors and predisposes to the development of putrefactive changes within the nose, it is at the same time highly probable that it alone is not enough to account for the peculiar fetor of the disease. To explain the latter it is necessary to assume the existence of some other influence, or some alteration in the chemistry of the nasal secretions brought about either by the atrophic changes in the nasal tissues, or from some constitutional or systemic cause. Exactly what such alteration consists in, is as yet unknown. Whether it be produced by atrophy and disappearance of the glandular elements (Bowman's glands), or by the evolution of fatty acids from the disintegration of fat globules and leucocytes (Krause), are questions which have received as yet no definite solution. The existence of the former seems hardly sufficient to account for the fetor, while the presence of fat is probably accidental, and has been demonstrated microscopically only in the cases of Krause.

Putrefaction implies the presence of a micro-organism, and hence it is not surprising that the dominant pathology of the present day should inspire a vigorous [illegible] search for a possible special microbe. Many observers have seized upon the opportunity presented, among whom may be mentioned Löwenberg[illegible] and Eug. Fraenkel.[illegible] The first-named author claims to have discovered a special diplococcus, which he believes to be the essential cause of the disease. But, unfortunately, when the evidence on the subject is thoroughly sifted, there is only one conclusion possible, viz., that, in the present state of our knowledge the existence of a characteristic microbe, capable of producing the disease, has not been demonstrated, and that the investigation of the matter has as yet yielded no practical results. The constant exposure of the already fetid and decomposing nasal exudation to every vitiation of the atmosphere,* is of itself sufficient to render the problem an exceedingly complex one, and it is, therefore, very doubtful whether the discovery of a special microbe for atrophic rhinitis will be an event of the immediate future.

---

* In 378 [illegible]

In this country, the changes in the common catarrhal affections of the nose are most marked in the area covered by erectile tissue, and are more pronounced in the lower or respiratory region, in the bony nostril than in the vestibule, and occur in the posterior more frequently than the anterior portions of the nasal fossæ.

These changes have their starting-point in one or more of three different structures, the erectile tissue, the mucous membrane, and, perhaps, the periosteum. The erectile tissue is primarily involved, probably, in those cases in which catarrhal conditions are met with as the result of reflected irritation (doubtless through vasomotor influences operating, in the first instance, through the constant or repeated erection of that tissue, with subsequent development of trophic disturbances), and it is conceivable that the same result may be brought about through obstruction or other derangements in the local or systemic circulation; in fine, from any cause that does not act as a direct irritant to the mucous membrane. Even in the latter case the local irritant may, and does in some cases, bring about a similar result through reflex action. A more or less constant dilatation of the erectile cells is thus brought about, which, if kept up, will eventuate, sooner or later, in a paralytic or subparalytic state of the resilient and contractile elements of the intercellular connective-tissue walls.

In another class of cases the process starts from the superficial layers of the mucous membrane, through the irritation produced by foreign substances, the lesions of acute and chronic constitutional or systemic diseases, either through direct infection or through vitiation of the general circulation, and the consequent changes in the nutrition of the mucous membranes. Even in this class there is always more or less secondary erection of the cavernous tissue.

There is still a third class, in which it is probable that the changes in the erectile tissue are secondary to hyperplastic conditions of the perichondrium, as, for example, in the hard, dense hypertrophies met with in syphilitic subjects.

Wherever originating, the erectile bodies become sooner or later involved, and the subsequent changes which they undergo constitute the characteristic feature of acute and chronic nasal inflammation. This is the distinguishing mark between it and other inflammatory conditions of the mucous membrane of the respiratory tract, and it furnishes the rational guide to the management of these affections. I wish to emphasize this fact, for it marks an era in nasal therapeutics. That it is not fully appreciated, is evident from the fact that authority often sanctions the use of methods, the inevitable tendency of which is to bring about results directly opposite to those they are intended to accomplish.

DIAGNOSIS.—The diagnosis of the different stages of chronic nasal inflammation is generally sufficiently easy from the history and rhinoscopic appearances. These have been given above, and it now only remains to point out a few difficulties which may present themselves to the beginner, or even the experienced practitioner. Before doing so it may be well to give some practical hints concerning the early recognition of intranasal inflammation.

In the natural state the lumen of the nostril, or that space which exists between the turbinated bodies and the septum, is indicated by a slit, narrow and pointed above, and broader and more triangular below, which may be roughly compared to the slit in the sounding-board of a violin. When the turbinated tissues are made to contract artificially, obliteration of this slit occurs, the middle and inferior meatuses are represented by a broader, more pyramidal passage, and the middle and deeper portions of the nostrils come into view. The opening of the posterior nares into the retronasal cavity is then seen as a dark, clearly cut, perpendicular line. In some persons, especially in those whose nasal chambers are naturally capacious, this linear opening may be seen without artificial contraction of the turbinated bodies.

The position of the turbinated bodies also varies within certain limits in the normal condition. When the inferior turbinated bone is "depressed," its anterior end appears as a rounded, or, in some instances, bluntly pointed protuberance jutting out from the external anterior wall of the nostril, and closely in contact with the floor of the inferior meatus, from which it seemingly springs. When the bone is "elevated" there is a distinct, sometimes very broad, space between its inferior border and the nasal floor, the curve and dip of its anterior extremity is generally well defined, so that a *comma-shaped space* is left between it and the external wall. The inferior surface of the bone is not visible except in cases in which the long axis of the bone is directed upward and forward.* In some families, the inferior turbinated bone of one side is unusually developed without giving rise to serious inconvenience,† a fact which it is well to bear in mind in coming to a conclusion in diagnosis.

The rounded, bulging, middle-turbinated bone occupies the upper and outer portion of the anterior rhinoscopic picture. In the anterior portion of the nostril the space between it and the inferior varies greatly within the limits of health. Usually it presents a more or less pear-, or inverted comma-shaped appearance, with or without a comma-shaped space between it and the outer nasal wall.

It is only in very exceptional cases that the superior bone can be seen.

In the posterior rhinoscopic image the floor of the nostril is not visible in health, being hidden by the bulge of the palatal muscles, and the inferior edge of the lower turbinated bone can be seen only in exceptional cases of the "elevated" form. Generally only the upper portion of its posterior extremity is visible. The posterior border of the septum is almost invariably straight, but just anterior to it, and within the nostril, there is a slight bulging or cushion which represents the cavernous body located there.

The middle turbinated body generally projects inward as a pear-shaped protuberance, while the superior is either scarcely visible, or appears as a rudimentary-looking tubercle or projection.

Only a small portion of the inferior meatus is visible as a small, dark, and three-cornered space. That portion of the middle meatus which is included between the turbinated bones is seen in the mirror as either a half-moon or an imperfectly defined S-shaped slit. The irregular spaces between the bones are continuous with the space common to the three meatuses, and which appears as a dark chamber in the rhinoscopic image.

The color of the mucous membrane in different individuals and in the same individual, at different periods, varies within the limits of perfect health. It may be said, in general, that it is of a pale reddish hue, more pronounced in the area covered by erectile tissue. In the posterior rhinoscopic picture the color of the membrane appears of a darker hue, the parts being thrown more or less into shadow.

The mucous membrane is closely adherent to the an-lower portion of the septum and walls of the vestibule, while over the posterior part of the septum and turbinated bodies it is loosely and separated from the periosteum by the erectile body, which becomes a thin layer as the anterior extremity of the bone is reached.

---

* A German investigator (Thost) claims to have found the so-called coccus of pneumonia in the nasal secretion of ozæna patients.

* In a patient suffering from mental [illegible], I observed the inferior turbinated bone so elevated that it occupied the position usually occupied by the middle, and its obliquity was such that more than half of its inferior surface was distinctly visible.

† I have observed this condition twice.

In the anterior portions of the nostril, therefore, the turbinated bodies are more compact and closely adherent than in the posterior segments of the nasal chamber.

I have dwelt upon the above anatomical considerations because I have found them invaluable guides to diagnosis. In anterior rhinoscopy the amount of swelling may be very conveniently measured by the changes in breadth and direction of the S-shaped slit and the degree of obliteration of the turbinated-septal space; while the amount of posterior hypertrophy is most accurately determined by the anatomical facts detailed above. The amount of swelling on the septum may also be determined in a similar manner.

The amount of swelling or hypertrophy, and the implication of the bone in the process, may furthermore be measured by the hard and incompressible, or the soft and yielding character communicated to the finger by the probe; while hypertrophy may be differentiated from mere puffiness by the ease with which the erectile bodies may be emptied or compressed by mechanical causes or artificial contraction. In the latter case the rapidity of contraction is often a measure of the amount of mere puffiness. In using cocaine, for example, if the swelling be due to mere puffiness or to transitory engorgement, it subsides very rapidly, almost instantly; while if hypertrophy exists the tissues collapse much more slowly and less completely.

In making the diagnosis of incipient rhinitis it should be borne in mind that the disease not infrequently has its starting point in the erectile bodies, and occasionally in the periosteum. In such cases the first evidence of its existence is a more or less engorged state of the area occupied by cavernous tissue. A stimulus, too, which in the normal state would exert little or no impression, is usually sufficient to provoke more or less erection of this tissue with, it may be, the evocation of reflex phenomena. In all cases the cavernous structure becomes sooner or later involved. Abnormal irritability of the area covered by this tissue, and slight puffiness of the same, are, therefore, invaluable guides in the early recognition of chronic intranasal inflammation. It should be borne in mind, at the same time, that this condition of the erectile bodies is not always the forerunner of rhinitis, but may be due to other and physiological causes. The swelling of the mucous membrane of the vestibule and anterior portion of the septum (cartilaginous portion) is always inconsiderable, except in the latter portion of the hypertrophic stage, when it is often excessive.

In their perfect physiological condition, the nasal passages are moistened by a scarcely perceptible halitus which varies in amount according to the condition of the surrounding atmosphere and other external and internal causes. The existence of mucus must be regarded as pathological, and therefore incompatible with a perfectly healthy condition of the nasal passages. While the secretion of mucus may be due to temporary causes (local or systemic irritation), it is always present in greater or less amount in the earlier stages of rhinitis. The more or less constant presence of mucous secretion within the nostril is therefore indicative of commencing inflammation.

The hypertrophied nasal membrane may be mistaken for a polypus, or, if situated on the septum, may be confounded with a deflection or outgrowth of that structure. The ordinary gelatinous polypus is much paler in color than the hypertrophied membrane, and presents usually a peculiarly brilliant reflection of light, which often leads to its detection in the upper and deeper portions of the nostril when no distinct growth is visible or suspected. Occasionally a somewhat similar reflection is observed in the hypertrophied, or even normal, membrane of the central portions of the cartilaginous structures, and may be mistaken for a growth. The red color of the hypertrophied membrane is usually uniformly distributed, while in the gelatinous polypus the enlarged vessels are thrown out in bold relief against a dull white or pale pinkish background. The vessels of the polypus, moreover, are seen to run from above downward, while on the turbinated bodies the direction is more commonly horizontal. The gelatinous mucous polypus is distinctly pedunculated, and its mobility may readily be determined by the probe or nasal sound; or, if firmly impacted between the walls of the nostril, its pedunculated character may be brought into view, and its mobility may be demonstrated, by the artificial contraction of the turbinated tissues by means of cocaine. The application of this drug to the membrane will cause mere puffiness of that structure to disappear, while it only partially affects the color of a polypus. By closing the mouth and forcibly expelling the air through the nose, displacement and forward movement of a distinctly pedunculated polypus will occur, while an hypertrophied membrane remains unmoved.

The gelatinous polypus is intensely hygroscopic, while the same amount of moisture will not necessarily affect the nasal membrane. Pressure on a polypus with the probe communicates to the hand the sensation of a soft fleshy body, and when some force is used, it bleeds readily, and also imparts a sort of crackling sensation to the finger of the operator. The hypertrophied membrane, on the other hand, though often yielding and resilient, has a hard bony foundation, which is readily detected upon pressure. Nasal polypus—and this is especially true of the fibrous or fibro-cellular variety—is often, though by no means always, confined to one nostril; while in the hypertrophic stage of catarrh both cavities are, in different degrees it may be, usually obstructed.

In hypertrophy the difficulty in respiration is principally in inspiration, while in polypus expiration is the act most commonly interfered with, the growth often acting as a ball-valve. A large polypus, or numerous small polypi, usually produce complete obstruction to both inspiration and expiration; in hypertrophy, the air way is rarely completely occluded. Unless the hypertrophy be very great, the voice is less distinctly nasal than when the nasal fossa is filled by a polypus. Polypi generally develop or spring from some portion of the middle meatus, while the most common seat of hypertrophy is the lower turbinated bone, and principally its posterior portion. Hæmorrhage from one nostril was formerly considered diagnostic of polypi; but in our present knowledge of nasal hæmorrhage in its relation to intranasal inflammation (see article on Nose, Hæmorrhage of the), this test can no longer be relied upon in the differential diagnosis.

In the posterior rhinoscopic image a mucous polypus can generally be distinguished, not only by its glistening appearance, but also by its position, filling or obstructing the dark spaces of the meatuses described above.

The confusion of a hard, sessile, fibrous polypus situated in the deeper portions of the nostril, with an hypertrophied condition of the turbinated bodies, is sometimes a difficult matter to avoid; and this becomes more easily intelligible when we consider the anatomical mode of origin of many of these growths. The differential diagnosis between a posterior hypertrophy and a fibrous polypus, either originating in the nasal cavity or springing from the posterior ends of the turbinated bones and septum, is occasionally perplexing, and some confusion has arisen in the separation of the two conditions. Indeed, my examinations show that a not small proportion of the so-called fibrous polypi of this locality are nothing more nor less than enormously hypertrophied and pendulous turbinated bodies. It should also be remembered that now and then true fibromata, with sessile bases on the anterior naso-pharyngeal wall, may, instead of going downward, send one or more prolongations into the nasal fossæ, and thus further complicate the diagnosis. A mistake may, however, be prevented by keeping the diagnostic appearances of the hypertrophied tissue carefully in mind, and by attending to the fact that a fibrous polypus presents either a smooth or a distinctly lobulated appearance. Surgeons of wide experience in these matters will doubtless recall cases in which the fibrous polypus, originating by one or more pedicles in the nasal and accessory cavities, has sought the direction of least resistance, and presented at the posterior nares as a hard, immovable mass, easily mistaken for an hypertrophied turbinated body. When we consider the mode of origin and growth of nasal polypi, and the manner in which they often fill the meatuses and destroy the normal anatomical relations of the parts, it is not surprising that, in the limited rhinoscopic picture and in the case of subjects difficult to examine, mistakes of this kind now and then arise.

On either side of the septum posteriorly are found, in the normal condition, two bulging hemispherical bodies, which are composed of erectile or contractile tissue, and care should be taken not to confound them with either polypi or true hypertrophy. In this climate it is rare to find the posterior nares in a condition which altogether meets the requirements of absolute anatomical and physiological perfection. The posterior ends of the inferior turbinated bodies are very frequently of an unnatural color and uneven shape, and this apart from any inconvenience to the individual. The novice, therefore, should hesitate before operating on all such cases, simply because the posterior nares do not present the appearances seen in diagrams and anatomical plates.

Cystic tumors of the posterior nares are exceedingly rare, but it would be well to bear their possible existence in mind in a doubtful case. Exostoses and hypertrophic enlargement of the turbinated bones themselves, and various malformations of the bony framework of the nasal fossæ, either congenital or acquired—as, for example, in the altered anatomical relations of the nasal chamber left after necrosis and the expulsion of diseased bone—so alter the normal appearance and position of the parts that it is well to call the attention of the beginner to their possible presence.

To the careful observer the confusion of hypertrophic inflammation of the septum with deflection or enchondrosis of that area ought not to happen; but, at the same time, it should be remembered that distinguished surgeons have made this mistake, and subjected patients to needless pain by bungling attempts at removal.

It may perhaps be safely said that perforation of the septum never occurs as the result of a simple catarrhal inflammation. It may occur from traumatic causes, as the constant injury by the finger in picking the nose, but the most common cause is syphilis. At the same time it should be remembered that it may result from lupus, malignant disease, and certain blood affections such as typhoid fever, diphtheria, and other acute infectious diseases, and that it may be due to the corrosive action of chemical agents. It is a familiar accident among the workers in chrome,* arsenic, mercury, and other similar agents. It may also have resulted from the incautious use of caustics, and in rare instances it is congenital.

An enormously engorged condition of the turbinated structure may possibly be confounded with an angiomatous tumor. Indeed, certain cases of so-called angiomatous tumors may probably be referred to vascular changes in the turbinated bodies. There is also another condition, which I have described elsewhere,[41] which rarely occurs, it is true, but which may possibly be confounded with both angioma and turbinated hypertrophy. It is a peculiar condition of enlargement of the turbinated structures, associated with prolapse, and forming a dense, dark reddish, hard, fleshy mass or tumor, which may hang free in the nostrils, or may rest on the floor of the inferior meatus. Such tumors or masses may constitute, in some cases, the initial stage of the future angioma.

The diagnosis of atrophic rhinitis is sufficiently easy, and will depend upon the exclusion of the affections causing "ozæna," and on the history of a pre-existing

---

* Among the many inconveniences from which those directly engaged in the manufacture of chrome suffer, the most prominent, perhaps, consist of a group of symptoms referable to the respiratory tract, and especially the nasal cavities and their dividing septum. In the chrome factory of Baltimore the workmen employed in the chambers where the bichromate is made, almost invariably acquire perforation of the cartilaginous portion of the septum from the irritating and corrosive action of the fumes and floating dust evolved during the chemistry of its manufacture. This destruction of the cartilaginous septum appears to be the most prominent anatomical lesion, and occurs with such striking frequency that it may be looked upon as a characteristic and constant sign of this particular form of chrome poisoning. Perforation occurs, as a rule, with great rapidity: generally in a few days after exposure to its exciting cause. I am told by one of the workmen, who has been engaged in the factory for over fifteen years, that extensive destruction of the cartilage sometimes takes place within twenty-four to forty-eight hours. It is commonly preceded by general congestion of the mucous membrane, with more or less epistaxis, or by the symptoms of a well-defined coryza, such as obstruction of the nares, heaviness of the head, discharge of limpid fluid, sensation of foreign body in the nasal passages, reflex acts, etc. The mucous covering of the septum is quickly destroyed and the cartilage laid bare. Necrosis of the latter soon follows, and a communication between the nostrils is established by a gradual corrosion and breaking down of the septum, which produces finally a round or oval perforation. Or, the same result may be accomplished by the exfoliation of necrotic plates or layers of the cartilage, presenting the appearance as if they had been punched out by instrumental aid.

When the mucous membrane is destroyed a crust forms, which becomes closely adherent, and beneath which the corrosion of the septum proper goes on. After perforation takes place there is also a tendency to crust formation about the edges of the artificial opening. It is possible that the crusts may act to a certain extent as protective agents, thereby preserving the edges of the cartilage against the invasion of the floating particles, and hence limiting the further progress of the corrosive action. The latter process seems, in the vast majority of cases, to be confined to the cartilage, and very extensive destruction of the latter may occur without change in the external appearance of the nose. The most frequent seat of perforation is the antero-inferior portion of the cartilage—or, in other words, that portion which is most directly exposed to the action of the irritant particles. The perforation itself varies greatly in size. I have seen almost complete destruction of the cartilaginous septum, nothing remaining but the merest rim of tissue to support the fleshy structures of the external nose.

Although this is its most frequent seat, the ulcerative process is not confined to the septum, but is occasionally met with in other portions of the nose, as the turbinated bodies and nasal pharynx. It is more likely to occur in the latter situation, as the voluntary removal of foreign substances from this cavity is more difficult than their expulsion from the nasal chambers. Ulceration, moreover, is also more likely to persist in the former than in the latter situation. The lower pharynx is also sometimes the seat of more or less clearly defined ulceration, and the same is probably true of the larynx, although I am unaware of its occurrence in the latter. The condition of the lower respiratory tract generally found is that of inflammation, characterized by intense redness, moderate swelling, with tendency to inspissation of secretion. These appearances are found as far down the trachea as the laryngoscopic view extends. In fact, the mucous membrane of the entire naso-bronchial tract is intensely hyperæmic, more or less swollen, and presents at various points evidences of capillary hæmorrhages and small extravasations of blood. These appearances are more pronounced in the respiratory region of the nose. Ulceration also attacks the hair follicles in the nasal vestibule, causing a dryness and itching, with falling out of the vibrissæ.

As the ulcerative process in the nose and retronasal space advances, the secretion becomes muco-purulent, and portions of the necrotic tissues are expelled either in shreds or as a fine detritus mingled with the greenish-yellow discharge. In some the nasal flux is inconsiderable, and perforation of the cartilage may occur without the knowledge of the individual. There is often a great tendency to the formation of hard, laminated, or tough, leathery crusts, which adhere to the structures with great tenacity, and whose expulsion is attended with considerable difficulty. They may be expelled through the anterior nares, or may fall into the lower pharynx and be expectorated. Occasionally detachment occurs during sleep, the crust entering the laryngeal vestibule and giving rise to suffocative paroxysms.

Accompanying the catarrhal symptoms there is a sensation of heat or burning in the nose and throat, and sometimes intense headache, which is referred to various portions of the cranium. The sensation experienced is sometimes described as that of a bubbling or boiling, as of water in a caldron, in the vertex, and constitutes one of the most annoying features of the case.

Attention has already been called to the inspissation of the secretion and its tendency to crust formation. Notwithstanding such disposition, however, and the profuse and purulent character of the discharge, there is little, if any, tendency to the development of a condition of ozæna. Fetor is, so far as my experience goes, always absent, or at least is never a prominent symptom. This I consider a point of especial interest. The absence of odor here is certainly in a measure due to the fact that the agent which excites the discharge at the same time destroys the forms of life upon the presence of which the fetor of such conditions is supposed to depend.

The corrosive action is not always limited to the mucous membrane of the nose and throat. Purulent inflammation of the drum cavities also occurs, with perforation of the tympanic membrane and the consequent development of otorrhœa. This is in part, doubtless, due to extension through the Eustachian tubes, but it is conceivable that the membrane may become corroded by direct contact of the bichromate dust.

There appears to be a decided limit, however, to the destructive action of the corrosive agent on the cartilage and mucous membranes, a certain self limitation of its corrosive power which agrees with the known comportment of the poison in the presence of organic matter. For, as is well known, every molecule of matter with which each molecule of chromic acid comes in contact, is not only immediately destroyed, but the acid, in accomplishing such destruction, is itself rendered innocuous by its conversion into an insoluble oxide of chromium.

Experimental chemistry has closely concerned itself with the investi hypertrophic catarrh. The disgusting peculiar odor should be carefully distinguished from that which occurs in the presence of bone disintegration from caries and necrosis. Each is separate and distinct, and the resemblance of the two baffles all the powers of description. By alternately closing the patient's mouth and nostrils, the source of the odor may be determined.

Finally, it should be borne in mind that unilateral catarrh may be symptomatic of various neuralgias of the fifth nerve, syphilis, foreign bodies, tumors, empyema of the antrum or accessory cavities, or may occur as a complication of acute and chronic middle-ear catarrh from peritonsal inflammation or other causes. I have seen it associated with parenchymatous conjunctivitis as the result of exposure to a high wind. Unilateral swelling of the turbinated bodies, with other evidences of catarrh, occur during the [illegible] excitement of the menstrual period. It occasionally occurs, too, as a reflex phenomenon, from a carious tooth, cerumen in the ear, or other forms of irritation of the auditory meatus. It may also result from injudicious instrumental or chemical irritation of the nasal cavity.

When called, then, to a case of unilateral discharge from the nose, or excess, the practitioner should search for some such cause as those just mentioned, and should direct his treatment accordingly.

COMPLICATIONS AND SEQUELÆ.—The possible complications and sequelæ of chronic nasal inflammation are of the most manifold character, and may be extended to almost every organ of the body. So important is a proper discharge of the nasal functions not only to the structures directly involved, but also to the general welfare of the individual, that the abrogation or suspension of the vital properties of the intranasal tissues may be looked upon as one of the most serious obstacles to the enjoyment of normal physiological life. This is especially true in early childhood, when growth and development are going on with rapidity, and when the demand for healthy respiration is accordingly all the more imperative. It is a remarkable fact that congenital occlusion of the nares seems to be incompatible with the viability of the fetus, and the bad health and stunted growth of children suffering from nasal obstruction is a matter of every-day occurrence, unfortunately too frequently overlooked.

Inflammatory affections of the nasal passages derive much of their importance from their influence on the functions of respiration, olfaction, audition, and voice production, as the starting-point of diseased conditions of the nasal pharynx and other accessory cavities, and the nasal duct. The affections of those organs to which it gives rise have been fully discussed in other portions of this work. The most common is inflammation of the nasal pharynx (see article on this subject in Vol. V.). The extension of the inflammatory process into the ethmoidal, or even sphenoidal, cells, is also met with, and is often a most difficult sequel to deal with. Obstruction of the nasal duct and dacryocystitis are occasional complications; but both these affections and the extension of inflammation to the frontal sinus are comparatively seldom met with, although popular belief would seem to indicate that catarrh of the latter cavity is the prolific source of all the headache of catarrhal rhinitis. In regard to the relation of inflammatory conditions of the antrum maxillare to intranasal processes, I would like to offer some suggestions.

While I am convinced that the chronicity of certain forms of nasal disease, the persistency of a fair proportion of neuralgic affections (and other reflex neuroses) of the head and face, are traceable to latent or unsuspected chronic antral inflammation, while it is doubtless true that affections of the maxillary sinus often run their course unrecognized during life, the secondary implication of that cavity in acute and chronic inflammatory processes originating in the nasal passages is, comparatively speaking, rare.

Inflammation of the maxillary sinus may result from congenital or acquired defect of the naso-antral aperture, or from its closure by the swollen and hypertrophied nasal tissue, polypi, cysts, etc., conditions which may favor the retention and decomposition of the antral secretion. Inflammation from this cause, however, occurs less frequently than is universally taught by inference from purely theoretical considerations. I base this assertion not only on clinical observation, but also on the results of post-mortem investigation. Those who choose to investigate the anatomical aspect of this question will be amazed to find how infrequently the mucous covering of the sinus participates in the inflammatory conditions of the nasal fossa. It is the rule to find the most marked hypertrophy of the nasal tissues, and even complete atrophy, associated with a normal condition of the sinus. What is the explanation of this fact?

On the nasal aspect of the naso-antral opening is a continuation of the erectile tissue of the turbinated bodies, which in all probability serves the useful purpose of excluding from the cavity of the sinus, by means of the vascular barrier involved in its erection, various irritants derived from the external world and nasal passages. This tissue ceases abruptly at the antral aperture. On the other side of the opening lies the peculiar, loose vas-

---

[illegible]

cular membrane of the sinus. In the majority of cases this zone of erectile tissue constitutes the extreme anatomical limit of the nasal inflammation. The thin, loose, serous-looking membrane of the sinus differs essentially from the nasal mucous membrane, and especially that portion which surrounds the entrance into the maxillary sinus, and the abrupt transition of the one tissue into the other would therefore militate, on theoretical grounds, against extension of the inflammatory process into the antrum. In other words, I believe that the so-called extension of inflammatory action from the nasal passages to the antrum—the secondary inflammatory implication of that cavity—is of comparatively infrequent occurrence; and that, when inflammation of the sinus from extension is assumed, the condition will be found, on post-mortem examination, to be one of simple congestion, with possibly some accumulation and retention of the antral secretion from mechanical causes. Even if the amount of secretion be temporarily increased, the great power of absorption possessed by the membrane of the sinus will usually suffice to make it a matter of secondary importance.

I am inclined to believe that too much stress is laid upon the decomposition of antral secretion as a factor in the production of inflammation. Take, for example, a simple coryza. With the general erection of the turbinated tissues the orifice of the antrum is completely closed, congestion follows, with possibly an increased secretion of the antral fluid. Whether this secretion, thus hermetically sealed, so to speak, in the antrum, undergoes decomposition before the patency of the opening is restored and the air gains admittance, is questionable; but, on the other hand, that decomposition does occur is beyond dispute, for, when the swelling from the acute rhinitis subsides, the aperture becomes free, and, in some instances, the fetid antral secretion is discharged into the nasal passages, a fact which accounts for the peculiar fetor of the expired air from the nostrils which is sometimes observed at the close of a severe coryza.

One of the most familiar sequels of chronic nasal inflammation is the common myxomatous, and even fibrous, polypus. In some cases the membrane is studded with small papillomatous or fibrous growths. I have also met with a veritable *trachomatous* condition of the nasal membrane similar to that found in the conjunctiva. Occasionally cystic degeneration of the membrane is seen, and, in very rare cases, perichondritis and abscess of the septum, and even rhinoliths, have been observed. In long-standing cases hypertrophic changes in the turbinated bones themselves and septum may develop, and deflection or malposition of the latter is now and then due to this cause. Nasal obstruction may even lead, in very young subjects, to asymmetrical conditions or imperfect development of the nasal and accessory chambers, and other portions of the skull on the side corresponding to the seat of obstruction. Indeed Ziem[42] has shown experimentally that in certain cases nasal obstruction may be an important factor in the production of asymmetrical conditions of the cranium.

Perforation of the septum rarely, if ever, occurs as the result of simple inflammation (*vide infra*). Thickening and slight flattening of the bridge of the nose, with sometimes pain on pressure, is not infrequently met with in simple chronic catarrh, and is probably the result of a localized nasal perichondritis. This should not be confounded with the very conspicuous flattening and consequent separation of the eyes which occurs in long-standing post-nasal obstruction.

Hæmorrhage is a common complication, and has been fully considered in the article on Hæmorrhage of the Nose (Vol. V.). The host of interesting neurotic phenomena which complicate this class of affections have also been elaborately discussed in another portion of this work (Vol. V., article, Nose, Neuroses of the).

Osteitis is rarely, and necrosis probably never, the result of a simple catarrh. It is a matter of common experience that various forms of excoriated mouth depend upon a disordered stomach, the so-called herpetic diathesis, etc., but occasionally cases occur which cannot be referred to these conditions, whose dependence on hypertrophic nasal catarrh must be inferred from their disappearance with the cure of the nasal affection. Several factors are probably concerned in their production, among which mouth-breathing plays an important part, and, possibly, the disordered condition of the stomach occasioned by the nasal discharge. The inflammation of the conjunctivæ, which is so often observed in connection with nasal catarrh, is generally explained by the extension of the inflammatory process through the nasal duct; but I am inclined to regard it in the majority of instances as a reflex vaso-motor phenomenon, the vessel dilatation being kept up by the constant irritation of the sensitive nasal area. In like manner I would explain the recurrent herpes and keratitis which have been observed in connection with this disease, the phenomena in these cases being called forth by trophic disturbances. Zaufal[43] has found trachoma a frequent complication of ozæna.

In nasal obstruction of long standing, chronic inflammatory changes are sometimes induced in the bronchial and pulmonary mucous membrane, which are exceedingly difficult to deal with even after the original cause is removed, and this has doubtless given rise to the popular idea that "catarrh" is the forerunner of consumption. Certain it is that nasal obstruction predisposes, other things being equal, to inflammatory conditions of the respiratory tract, and that the practical physician cannot afford to overlook the influence which it exerts in their production. In this country the vast majority of the cases of chronic laryngitis originate primarily in disease of the nose, and many a winter cough is allowed to go on from bad to worse because of failure to recognize this relationship. I am furthermore convinced that nasal obstruction may and does awaken diseased states of the lungs, and *in an individual so predisposed may favor* the development of pulmonary consumption. Fränkel states that emphysema frequently coexists with nasal stenosis, and Kussmaul believes that acute hyperæmia of the lung may be produced by the forced inspiration of the air. The vesicular murmur is weakened, feeble and shortened in inspiration, and only approaches the normal when deep inspiratory efforts are made. Frequently mucous and subcrepitant râles can be heard in different portions of the chest. Attention has been called to certain deformities of the chest-walls consisting chiefly in malposition of the bones and loss of power in the muscular covering. I believe these deformities to be rare, except in very young children.

The influence of nasal obstruction in such cases is of course purely accidental and mechanical. Although the theory of the direct pathological relationship between simple nasal disease and tuberculosis of the lungs has been gravely advanced by more than one observer, it seems scarcely necessary to remark that we must accept observations of this kind with the utmost caution, and require more abundant proof of the alleged facts than those already in our possession.

There is one symptom of nasal obstruction to which especial importance must be attached, and for which alone the physician is often consulted. *Dyspnœa on exertion* is one of the most annoying features of the case. Such patients complain that in talking they must frequently pause for breath; that in going upstairs walking rapidly, or running—in fine, in all bodily operations which require unusual exertion, they get very readily out of breath. Difficult breathing is also present when the mouth is occupied or closed, as in swallowing, smoking, etc. They are accordingly constantly haunted by the dread of heart disease and consumption. Physical examination, however, fails to detect any cause for the dyspnœa. At times the breathing is perfectly normal and vesicular; at others a few small mucous râles may be heard posteriorly in the inferior lobes, or in the infrascapular and mammary regions.[44]

PROGNOSIS.—The prognosis of a disease is one of the most difficult chapters of its history to write. Assertion must be followed by indefinite qualification, and there are so many things to take into account, that the study of each case on its individual merits becomes the only rational way to reach a satisfactory and intelligent opinion.

There are two great influences which particularly affect the prognosis in chronic catarrhal diseases of the upper air tract: climate and individual environment. Pronounced nasal inflammation of long standing, in any of its stages, is a difficult affection to deal with in a climate such as that described elsewhere (see Vol. IV., Article on Larynx, Catarrhal Affections of) as most productive of the disease, and especially is this true if the individual, either from compulsion or design, does not live under the guidance of the common law of health.

The prognosis, in general, will depend in many cases upon the constitution, surroundings, habits, occupation, and a host of other influences pertaining to the individual, and will accordingly be determined by an indefinite number of agencies. This will be the more clearly understood upon reference to the remarks in Vol. IV. of this Handbook, on the Etiology of Catarrhal Affections of the Upper Air Passages. In this section we shall speak of the prognosis in uncomplicated cases living under fairly good hygienic conditions.

In its incipient stages the affection is always amenable to treatment, but in the vast majority of instances the patient either is unaware of the insidious approach of his disease or is disposed to make light of it, and therefore only consults a physician when the inflammatory process is firmly entrenched in the nasal membrane, and permanent tissue-structural changes have taken place.

In the first stage the prognosis may be written down as good. It is, however, often a very difficult and rebellious affection to cope with, even under the most favorable circumstances, and relapses frequently occur after the disease has been apparently effectually eradicated. In this as in all other forms of catarrh of the upper air-tract, different individuals present the most varying degrees of susceptibility to treatment and recuperative power. In some the disease will yield with great rapidity, a few weeks sufficing to produce a cure, while in others months, and even years, are necessary to bring about a like result.

In the second stage the outlook is also generally good, and it is at this period that some of the most brilliant results of nasal surgery have been achieved. Relief can always be obtained, and permanent cure is often the result. Indeed, the prognosis in nasal disease very often depends upon the amount of surgery in the case.

In the early stage of atrophy the prognosis is much less favorable, while in advanced cases it is unquestionably bad. Under favorable circumstances it is possible to arrest its progress, and in every case relief can be obtained and the nose kept under control, but it is naturally impossible to restore the functions of an organ whose physiological properties have been hopelessly destroyed, and the atrophied structures must therefore be placed, with the contracted liver and kidney, in the list of incurable affections.* When "cure" of atrophic rhinitis is spoken of, it almost invariably refers to a condition of comparative comfort.

It may be well to state here that it occasionally happens that extensive atrophy of the nasal structures exists with little or no marked discomfort to the individual. Whether the structures be congenitally small, whether the condition present is the legacy of a former syphilitic or other local affection, or the remains of the destruction left by chronic or other corrosive chemical agents, are sometimes difficult to determine; but the fact remains the same.

Coexisting atrophy of the fauces makes the prognosis proportionately more grave.

GENERAL RULES OF TREATMENT.—The general principles governing the rational treatment of the different stages may be summed up briefly in the following propositions:

In the early part of the first stage the treatment is mainly hygienic (bathing the skin, ventilating the nasal passages, attention to general health, protection of nasal passages from direct or indirect sources of irritation, removal, if possible, to an equable climate, etc.), and consists in many cases simply in the search for and removal of the cause (local or reflex irritation, general systemic disease, lowered constitution from various causes, excesses, surroundings of patient, etc.). At this period local treatment is often unnecessary, and in some cases harmful. In other cases great benefit is derived from the judicious use of detergent, alterative, and astringent preparations, applied as far as possible to the diseased surfaces alone, in the form of solution or mixture with some such substance as cosmoline, glycerine, vaseline, etc.; or these substances may be advantageously used unmedicated. In a certain proportion of subjects the administration of remedies to control reflex excitability of the nerve centres is productive of good.

The treatment of the second period of this stage must be carried out on the same general principles as above. Remembering the condition of the contractile elements of the intercellular walls, the physician should take measures to restore their loss of power (strychnine and electricity are occasionally useful). If the simpler means fail, resort may be had to the galvano-cautery or to electrolysis.

In the above periods, medicines in solid form (e.g., powders) are absolutely contraindicated as tending to increase the irritation and to hasten the coming of the hypertrophic stage.

The management of the first period of the hypertrophic stage consists in a combination of the above methods. Here surgical procedures are more justifiable. In the second period of this stage the treatment is essentially surgical, and consists in the removal of the obstruction, in procuring thorough cleanliness of the nasal passages, and in attention to the general principles indicated above. Solid remedies are contraindicated. The general treatment of the third stage is tonic and hygienic; the local treatment is palliative, and consists in keeping the parts scrupulously clean and lubricated.

The methods of cleansing the nasal passages are the spray, the nasal douche, irrigation by the anterior and posterior nasal syringe, the nasal bath (pouring the liquid from a spoon into the nares), direct inspiration of the liquid through the nose (the so-called "drinking" through the nose), or, finally, regurgitation through the nasal pharynx into the posterior nares. When the mucus is very tenacious, the physiological act of sneezing may be provoked in order to assist in its expulsion.

Of these methods the most effective and least objectionable is the spray, except when hot liquids are employed; for, in the separation of the liquid into finely divided spray particles, the temperature is so lowered that it practically amounts to a cold injection. For ordinary purposes a fine spray is sufficient, but when the secretion is inspissated or closely adherent, a coarse spray is often necessary.

The nasal douche is too dangerous a remedy to be extensively employed, for it often subjects the patient to inflammation of the middle ear. Since Roosa first called attention to this fact, there has been an almost daily accumulation of evidence to warrant the condemnation of its indiscriminate use. Acute inflammation and abscess of the middle ear have repeatedly followed its use, and in one case death was the result.

My experience agrees with that of Beverley Robinson, that chronic inflammatory infiltration of the turbinated tissues results sometimes from its employment, and I have known cases in which there could be no reasonable doubt that chronic middle-ear disease was caused by its use.

When the nasal pharynx is filled with secretion, gargles are sometimes of benefit, but the sphere of their usefulness is limited. Even by Trœltsch's method very little of the fluid reaches the posterior part of the pharynx, and as all communication is shut off between the upper and lower pharynx in the act, the remedy never reaches the spot it is designed to medicate. The medicament may act, however, mechanically by producing muscular contraction and thereby dislodging mucus from the naso-pharynx. A gargle of water will accomplish the same result.

---

* [illegible]

Regurgitation of the fluid into the naso-pharynx is an unphysiological procedure and a roundabout way of accomplishing a great deal of possible harm with considerable difficulty and personal inconvenience. A better method is to lie flat on the back, with the head inclined slightly downward, and allow the fluid to gravitate into the pharynx.[*]

Whatever method be employed, it should be remembered that the constant use of too much water in the nose if often productive of evil, for the reason that it produces a constant saturation of the intranasal tissues, with consequent disease and destruction of function. Sprays are not to be employed indiscriminately, nor for too long a period of time. By the spray method water may also gain access to the middle ear, and I have known in several cases the use of the post-nasal syringe to give rise to acute inflammation and even abscess of that cavity.[†]

The indications in the treatment of hypertrophic nasal inflammation may be considered under the following heads:

1. *Removal of the Obstruction.*—If the catarrh be dependent upon a deflected or dislocated septum, or upon other irregularities in the nasal chambers, these must, of course, be rectified before we can proceed with the treatment of the case. If adhesions, from syphilis, the essential fevers, misuse of caustics, etc., exist, they must be divided. If the pharyngeal tonsil be hypertrophied, or if growths exist in the nose or the retronasal space, they should be removed. If, as is often the case, the faucial tonsils be enlarged and indurated, they should be excised. It is useless to temporize with sprays, caustic applications, and other palliative measures.
2. The nasal and retronasal chambers should be thoroughly cleansed and *kept clean.*
3. The congested or inflammatory condition of the naso-pharyngeal membrane which remains should be treated on the general principles which govern the management of simple inflammation of this structure, and the patient should be put under the hygienic conditions which favor a return to the normal state.

To remove the element of obstruction a number of methods have been suggested—caustics, dilatation with bougies, sponge-tents, etc., galvano-cautery, thermo-cautery, electrolysis, injections, the knife, forceps, and cold-wire snare.

Caustics.—The caustics chiefly employed are chromic, glacial acetic, and nitric acids. Of these, chromic acid is probably the best. Various forms of applicators of more or less ingenious mechanism, are sold in the market, but a small pointed glass rod, as recommended by Dr. Donaldson, of Baltimore, answers for all ordinary purposes. Before applying the acid the parts should be thoroughly cleansed, and the healthy portion of the membrane protected from the possible inroads of the acid. A number of devices have been suggested, such as applying the caustic through a speculum resembling the Gruber ear speculum, or some similar contrivance, anointing the nares beforehand with glycerine, vaseline, etc.; various forms of applicators, etc.; but with a well-dilated nostril and a steady hand this paraphernalia may be in the majority of cases disregarded. The contour of the nasal vestibule varies so much in different individuals that it becomes necessary for the specialist to have quite a variety of dilating apparatus at hand. The speculum which I have found most generally useful is the one shown in Fig. 4891.

The simple principle upon which this instrument acts is that involved in the ingenious eye speculum[45] and gag[46] devised by Dr. Russell Murdoch, of Baltimore.

Into the nasal extremity of each blade is fitted an ivory shield, which may be replaced, if necessary, by other dilating apparatus. At right angles to the distal end of one blade is a rectangular bar, upon which a well-fitting square sleeve, attached to the distal extremity of the other, slides with ease. This sliding motion is accomplished by means of slight pressure on the button or handle which juts out from the sleeve. In using the speculum, the ivory shields are brought together, introduced closed into the nostril, and separated by pressure on the button with the forefinger, counter-pressure being brought to bear on the free extremity of the bar with the thumb, or *vice versa*, according to the position in which the blades are introduced.

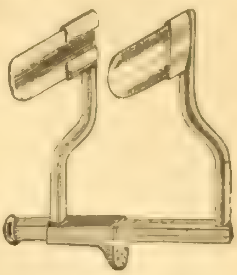

Fig. 4891.

The pressure of the sides of the nostrils arrests the sleeve at any desired point, thus furnishing the simplest possible principle of self-retention. A touch upon the button releases the blades from their fixed position, thus permitting instantaneous removal of the instrument. The upper and under surfaces of the rectangular bar are roughened to increase the amount of friction.[*]

If the glass rod be slightly warmed and plunged into a bottle of the crystals of chromic acid, a few will adhere and be immediately deposited on the diseased surface. The acid is so deliquescent that, when exposed to the air, the crystals rapidly liquefy, and this solution is frequently employed in the place of the crystals themselves. When the acid is applied, lachrymation, sneezing, cough, and various other reflex phenomena appear, and considerable pain may or may not be complained of. The pain is, however, very fugitive, and in the course of a few moments is generally gone. The nostril feels "stuffy" for a day or two, as in a common cold in the head, and after the lapse of from three to seven days the diseased tissues come away, either as well-defined sloughs or finely divided particles, in the discharge. The sudden application of the acid causes at first collapse of the normal turbinated structures, and temporary freedom of breathing through the nostril, but the subsequent effect is to cause obstruction until the sloughing process is over. A curious reflex that is often met with in the application of an acid to the nasal mucous membrane, is the sudden and immediate impression made by it upon the sense of taste. When a drop of the acid is applied to the turbinated bodies, the patient will often exclaim suddenly that he tastes the medicament. In the vast majority of instances the application of caustics to the nasal membrane is productive of no evil result. The sloughing process is sometimes disagreeable, and in some persons an annoying conjunctivitis with œdema of the lids may complicate the case, but with this exception I have never seen any serious after-effects.

Dilatation with graduated sounds (Clinton Wagner), *bougies, sponge-tents* (J. Solis Cohen), etc., has been employed to cause absorption of the indurated tissues, and is doubtless often of at least temporary good; but so much more success can be attained by other less painful, more expeditious, and more certain measures, that I am inclined to regard dilatation as contra-indicated except in very exceptional cases.

Galvano-cautery.—The galvano cautery in the hands of a careful operator is one of the most generally useful procedures for the removal of nasal obstruction. Whatever form of instrument be used, the most important point to be looked to is the temperature of the knife or snare—the condition known as cherry heat being the least painful and dangerous, and more generally efficacious than the higher or lower degrees of temperature.

The method of operating will depend upon the nature of the obstruction and the judgment of the operator. A common and very good method is to make linear, parallel incisions along the antero-posterior axis of the turbinated knife or a number of lateral incisions converging at a common point in the interior of the hypertrophy. In many cases I prefer a median incision of the turbinated body after the method described elsewhere (Vol. V. of this Handbook, p. 341). Sufficient patency of the nostril is secured, the erectility or contractility of the tissues is brought under control, and the patient escapes with very small loss of function.

---

[*] The method of regurgitation of wines and whiskeys into the nasal pharynx employed by wine-tasters, is not infrequently the source of post-nasal inflammation.

[†] See also article on the Treatment of Chronic Laryngitis, Vol. IV., for further rules of treatment.

[*] The speculum is made by Wilson & Co., of Baltimore. See Medical News, Philadelphia, December 6, 1884.

It will often be found sufficient simply to make a small number of punctures with a fine-pointed electrode in the swelling, especially in the condition of chronic puffiness described above. Or, if the nature of the obstructing portion [illegible], the loop or snare may be employed. This latter operation may be followed by considerable hemorrhage, if the tissue be not slowly severed. Finally, various other methods may be employed according to the peculiarities of the case and the ingenuity of the surgeon.

The electrode should be introduced unheated into the nostril, and the current turned on only when the incisions are to be made. Before its introduction the nasal fossa should be thoroughly cleansed of all secretions, in order not only to facilitate accuracy in placing the knife, but also to avoid the sudden reduction of the temperature of the electrode by the nasal secretions.

The amount of pain varies greatly with the susceptibility of the individual. Some bear it without experiencing any disagreeable sensation, while others complain seriously. Cocaine annuls the pain, but does not destroy the temperature sense.

My attention was first called to the isolation of the temperature sense by means of cocaine through an observation of Dr. William Warfield, of this city, who noticed, during an operation on the eye under the anæsthetic influence of this drug performed by Dr. Russell Murdoch, that, while the sensibility of the conjunctiva and cornea was abolished, the contact of the instruments was felt as a distinctly cold sensation. Subsequently Mr. H. H. Donaldson, of the Johns Hopkins University, acting upon this hint, examined the eyes of two patients with reference to this singular fact, and discovered that, although the eye was rendered completely insensitive, the sensations of heat and cold were readily distinguished.

Struck with the original observation of Dr. Warfield, I experimented with regard to the isolation of the temperature sense in the nasal and oro-pharyngeal cavities. Six persons (hospital patients) were taken for the experiments. Having thoroughly anæsthetized the mucous surfaces of the soft palate, uvula, and nasal passages with a four per cent. solution of cocaine, a probe, which had been previously immersed in a mixture of ice and salt, was made to impinge upon the parts rendered insensible to contact and pain. A distinct sensation of cold was complained of in each instance. The opposite extremity of the same probe was then heated over the burner of a lamp used for laryngoscopic purposes, and its heated extremity carried over the anæsthetized area. While absolutely no pain was felt by any of those experimented upon, there was a marked unanimity of the answers given voluntarily in regard to the sensation of heat. In three of the cases a vesicle followed the application of the heated probe, and in one an acute pharyngitis developed, yet at the time of application no pain was felt, though the temperature sense remained intact. These observations are of interest in view of the fact that, while recent physiological research has rendered it probable that the sensations of heat and cold are distinct from those of pure contact and pain, it has heretofore been impossible to demonstrate the fact by the complete isolation of the temperature sense. It is accordingly obvious that its separation from the other senses may lead the way to some interesting physiological discoveries.

The electrode should be withdrawn unheated from the nostril, and the wound treated on ordinary surgical principles. After a period varying from five to fifteen days the sloughing tissues are eliminated, and cicatrization takes place. An excavated surface thus results which resembles somewhat the under surface of a mushroom, and this becomes gradually filled with cicatricial tissue. Scars in the turbinated bodies are often invisible to the inspector during life, from the fact that their surrounding engorged walls of erectile tissue hide them from direct inspection.

Many accidents have followed the too vigorous use of the electro-cautery, among which may be mentioned hemorrhage, acute inflammation and abscess of the nose, otitis, conjunctivitis, erysipelas, high fever, septicæmia, meningitis, and other serious affections. These complications would be less frequently met with if the galvano-cautery were employed less in the posterior portion of the nares, and its use confined to simpler operations. Apart from a temporary prolongation of the sloughing process, and an occasional rise of temperature after the operation, I have never met with any serious sequel, and can only re-echo the words of Clinton Wagner, that, "with a well-dilated nostril, proper illumination of the parts, a battery in thorough working order—care being taken that the platinum be not too thick to become raised to white heat instantly—and then with a steady hand and not keeping the contact [illegible] for more than a second or two at a time, accidents, as above described, need not be feared."

Thermo-cautery.—The method by thermo-cautery is rarely employed. Dr. Goodwillie, of New York, by whom the method was introduced, uses a modified Paquelin instrument with a glass speculum, and claims good results.

Electrolysis is inferior to, and less certain than, the electro-cautery in the treatment of the hypertrophic stage. In conditions, however, in which the cautery is contra-indicated, and in the state of chronic puffiness which represents the transition of the first into the second stage, it may be employed with advantage.

The number of cells used will, of course, depend upon the density of the tissue and the closeness of the circuit. It should be undertaken with caution, and the requisite number of cells be determined by tentative experiment. The battery which has given the most satisfaction is the dry chloride of silver apparatus of Mr. Barrett, of New York.

Injections of ergotine have been used with some success by Dr. T. Amory De Blois, of Boston, but the method has not passed into general use. It is, moreover, probable, in view of the structure of the turbinated bodies and their anatomical relations, that its indiscriminate use may lead to dangerous results.

Knife.—The use of the knife for the removal of the hypertrophic membrane is now scarcely ever resorted to, for the reason that, in addition to the risk from hemorrhage, a much more successful result may be obtained by other less dangerous methods.

Forceps.—Various forms of cutting and serrated forceps have been devised for the removal of the indurated tissues. So eminent a practitioner as Dr. Beverley Robinson, of New York, still recommends evulsion with forceps, but the general sentiment of authority regards this method simply as a matter of purely historical interest. The operation is intensely severe, and is easily replaced by simpler, more efficient, and less painful procedures.

Cold-Wire Snare.—Although these masses were probably again and again removed by the wire, as anyone can convince himself by referring to the standard surgical works of the last two centuries, their true anatomical significance and relation to nasal inflammation was not properly appreciated until Bigelow demonstrated the erectility of the tissues concerned in their development. The credit of urging the necessity of the removal of the hypertrophic mass with the cold-wire snare belongs to Dr. Jarvis, of New York. Prior to the introduction of the wire the galvano-cautery had been used both in this country and in Germany. In the latter country it was extensively adopted, and it is a noteworthy fact that Zaufal, who is an enthusiastic advocate of the snare for the removal of polypi, recommends the cautery for the hypertrophic masses of the turbinated bodies.

The use of the snare in the removal of intranasal growths dates from the time when Robertson published the account of his instrument in the *Edinburgh Medical Journal* for 1805. This was one step, and an important one, in the evolution from the ligature of the ancients to the apparatus in use at the present day. The Greeks and Arabs applied the ligature by means of a peculiar kind of forceps which is described and figured by Dionis, but it was not until centuries later that the cannula was introduced by Fallopius. This was variously modified by the surgeons of the eighteenth century, prominently by Levret, who, among other contrivances, used a double cannula with retention rings, and also, in common with Palucci and others, a single cannula divided at its distal extremity by a small partition. Various methods have, from the time of Riolanus, been suggested for the tightening of the wire, the most interesting of which is perhaps the knot-tightener of Graefe, which consisted of an outer piece sliding on the cannula, and thereby producing compression of the tumor. This was subsequently modified by Dupuytren, the ligature or wire being attached by several turns to a retention nut at the proximal extremity of the instrument, and compression of the mass secured by means of a quick screw, after the method in use at the present day. It was probably these instruments that suggested the snares of Robertson and Wilde, and led to the modifications of Hilton, Blake, Zaufal, Jarvis, and others.[55]

Whatever form of snare be used, the most important thing to be looked to is the character of the wire employed. Steel piano-wire, as recommended by Zaufal,[56] Jarvis,[57] and Bosworth,[58] is the one commonly employed, as it possesses considerable resistance and resiliency, and retains its original direction to a great extent when projected from the mouth of the cannula.

In performing the operation with the aid of the rhinoscope, the nostril is first dilated with the speculum, and the wire loop passed, under the guidance of a strong light, through the slit between the turbinated bones and septum, into the naso-pharynx. The nasal speculum is then removed, and the tongue depressed, either by an assistant or the patient himself, with a Türck or similar depressor. The mirror is then introduced with the left hand, the loop directed over the hypertrophy with the right, and the wire pulled home. The mirror and spatula are then removed, and the operation completed by slowly tightening the screw. When the pharynx is unusually small or narrow, the soft palate may be tied up, prior to the operation, by means of a rubber cord, whose ends are passed through the nostrils, brought out through the mouth, carried over the ears, and tied under the chin, after the method described by Wales,[59] or the uvula may be elevated by one of the combination tongue depressors in use among specialists. These latter accessories are, however, rarely necessary; the latter instrument, although theoretically an excellent auxiliary, will too often be found an embarrassing impediment, and the elevation of the palate will sometimes interfere with rhinoscopic examination by the involuntary salivation and gagging which it every now and then occasions. Although the rhinoscope facilitates the operation and renders it impossible to damage any of the tissues adjacent to that to be removed, it is in the majority of cases unnecessary, *provided* the changed relations of the parts be known and mapped out beforehand, and the touch be sufficiently educated to recognize the various parts with which the instrument comes in contact, and, therefore, to avoid needless injury to the sensitive structures that it traverses. The mode of operation which I generally adopt is as follows: The patient is seated in a tall, straight-backed, narrow-seated chair, with the head thrown slightly back against the head-rest (or supported by the arm of the operator). The surgeon, standing at the side of the patient to be operated on, and elevating the tip of the nose with the thumb of the left hand, passes the wire loop, having the requisite diameter and curve, into the nostril. In this position the cannula of the instrument will form an angle with the floor of the nostril, varying with the curve of the loop, and its subsequent passage into the nasal fossa will throw the shank of the instrument toward the median line. It should then be pushed slowly and gently backward and slightly downward, until the loop enters the naso-pharynx. Bearing in mind the distribution of the fifth nerve in the nostril, the snare should be kept as close as possible to the floor, hugging the inferior border of the septum, and avoiding as much as possible contact with the external wall. This not only facilitates its introduction, but lessens the tendency to reflex phenomena and painful sensation. The wire, being pliable, will adapt itself to the sinuosities of the nostril and pass the obstruction without difficulty. No force should be used; but if the cannula be arrested, firm and gentle pressure will nearly always cause it to glide past the obstruction. The patient should be directed to keep his eyes open, and avoid facial contortions, which militate against the painless passage of the instrument. In cases where the fossa is more or less completely blocked, gradual dilatation with rubber bougies will materially aid the subsequent passage of the instrument. As the loop passes through the posterior nares over the bulge of the muscular palate, the contraction of the latter can sometimes be felt as it elevates the distal extremity of the wire. The wire should be pushed back until it reaches the posterior pharyngeal wall, and then gently withdrawn, care being taken to avoid the swollen lips of the Eustachian tube. The handle is then pressed slightly inward toward the septum as it is withdrawn. This will usually bring the loop over the hypertrophied mass. The distal extremity of the cannula should now be pressed firmly against the turbinated bone, and the wire tightened by means of the screw. As the loop passes over the base of the palate, involuntary acts of deglutition sometimes occur, interfering with the adjustment of the wire. When the latter is properly placed, the presence of the growth within its grasp is easily recognized by the sense of resistance imparted to the finger in turning the screw. By this method the hypertrophied tissue may be removed without difficulty, and often with a very slight amount of pain. Where, from the extreme narrowness of the passage, the introduction of the curved wire gives rise to pain, it may be introduced straight, bending it subsequently with the forefinger introduced into the naso pharynx. In several instances I have facilitated its adjustment by the following device: A fine rubber cord is tied by one of its extremities to the wire loop; the other end is then passed through the nostril and carried out through the mouth. The snare is then introduced into the pharynx. By pulling the cord downward and outward, the wire is bent and carried over the growth. The subsequent steps of the operation consist simply in division of the mass. When, from anæmia or certain diathetic conditions, loss of blood is to be deprecated, the mass may be slowly severed, a half hour or more being consumed in the écrasement. In ordinary cases I have never occupied more than ten minutes in the operation, and although I have operated a great many times, have never seen a hæmorrhage which gave me cause for alarm. Indeed, a moderate flow of blood seems to act beneficially, by relieving the engorged condition of the remaining portions of the mucous membrane. When the hypertrophy is seated anteriorly on the bones or septum it can be snared by previously transfixing with a glover's needle, as suggested by Jarvis,[60] or, better, by using the electric cautery. The hypertrophies over the posterior half of the septum are more difficult to deal with, and in these cases I believe the galvano-cautery preferable to the snare. In a tractable patient the mass may be transfixed and snared; but I generally resort to one of the other methods which have been given above.*

---

* In one case permanent relief was obtained by linear [illegible] sions of the mass with a bistoury, followed by dilatation with [illegible] gies, which act not only as dilators but also [illegible] hæmorrhage which follows the incisions. In this connection I [illegible] that I have resorted *to incision of the turbinated [illegible]*, and invariably with great and immediate relief. A [illegible] of the erectile cells is thus effected and the [illegible] that affection is diminished. This method of [illegible] ies for the relief of coryza, headache, etc., [illegible] in the Transactions of the Medico-Chirurgical Faculty of Maryland for 1883. It has since been used with success by [illegible] (Nasal Catarrh, etc., Philadelphia, 1884), and Glasgow (Trans. American Laryngological Association, 1888).

The after-treatment consists in spraying the nostrils with a soothing, disinfectant, and detergent spray. The one I commonly employ is a weak solution of carbolic acid in oil of sweet almonds. A cotton respirator should be worn in the nostrils for a day or two after the operation to avoid the irritation of the floating particles of dust in the atmosphere. The patient may be directed to saturate a plug of absorbent cotton with the solution and pass it into the nostril once or twice a day until cicatrization is complete.

I have never seen the disagreeable after-effects here apply follow the operation with the galvano-cautery. One patient complained of pain in the infraorbital region for one or two days after the removal of an anterior hypertrophy; but it was very questionable whether this was due to the operation, as he had been for a long time subject to neuralgic pains in the course of the trifacial nerve. Rapid cicatrization and disappearance of complications has been the invariable rule in all cases where I have performed the operation.

The amount of hæmorrhage will vary with the time occupied in the ecrasement, with the age and vascularity of the mass. The slower the traction, the less profuse the hæmorrhage. As a rule, the cleaner, whiter, and older the hypertrophy, the less abundant the bleeding. To avoid hæmorrhage, it has been advised (Bosworth) to tighten the loop slowly, giving one-half turn of the screw every five or ten minutes, consuming at least two, or better, three hours in the operation. I have never found such a procedure necessary. When the operation is quickly performed, a gush of blood follows the removal of the mass, and the nose continues to bleed until the engorged vascular spaces of the erectile tissue have been depleted. The hæmorrhage then ceases in many cases spontaneously. Secondary *hæmorrhage* sometimes occurs, and generally takes place from six to twelve hours after the operation. It is never profuse, and can be readily checked by the patient himself.

In many instances, if the instrument be gently and skilfully introduced, and the facial contortion and straining of the patient be controlled, the snaring of the hypertrophy is quite painless. If the mass be slowly severed, very little pain is felt—sometimes none at all. I have several times removed the growth without the patient's being aware of the performance of the operation. When the nostril is very tortuous, or when hypertrophy of the turbinated bodies coexists with a deflected or irregularly thickened septum, the introduction of the snare is sometimes painful, the amount of pain depending upon the altered relations of the parts, the degree of hyperæsthesia of the mucous membrane, and the curve and diameter of the wire loop. The pain may be diminished, however, by hypodermatic injections of morphine or an anæsthetic spray. In the compression of the mass, pain is occasionally referred to various points in the distribution of the fifth nerve. Various other reflex phenomena sometimes occur during the operation, such as cough, pain in the ear and larynx, movements of deglutition, etc.

The advantages which may be claimed for this operation, apart from its comparative painlessness and simplicity, may be briefly summed up as follows:

(1) It fulfils in the simplest and most radical manner the chief and absolute indication in the treatment of hypertrophic nasal catarrh, viz., the removal of the obstruction.

(2) It restores the respiratory current to its normal channels, thereby avoiding the irreparable injury with which the organs of respiration, vocalization, audition, and olfaction are necessarily threatened.

(3) It removes one of the most prolific sources of the discharge in nasal catarrh, and favors the return of the mucous membrane to its normal state.

(4) In the majority of instances it causes the various complications, and especially those of reflex character, to disappear.

(5) By the depletion of the cavernous cells of the turbinated bodies it exercises a beneficial effect upon the whole area occupied by the erectile tissue.

The second indication is best accomplished with a detergent alkaline spray. Carbolic acid, borax, benzoic acid, the bicarbonate, phosphate, and sulpho-carbolate of soda, alone or in combination, are the medicaments commonly employed. By means of the compressed-air cylinder the nasal cavities can be thoroughly cleansed and the crusts removed with facility. If a sufficiently powerful spray be not available, the latter should be carefully brought away, a probe wrapped with absorbent cotton and dipped into vaseline, cosmoline, or some such substance being used for the purpose. Sometimes thick shreds of mucus are found in the Eustachian tubes and the fossæ of Rosenmüller, which cannot be dislodged by the spray, and which must be removed with the cotton-carrier or forceps. The cleansing of the nose is of the utmost importance. It should be ascertained by inspection that the parts are clean before applying alteratives or other remedies to the nose. It is useless to apply them to inspissated mucus. The continuous use of alkaline and sulphur waters is sometimes productive of decided benefit in diminishing the secretion.

The astringent or alterative to be used will depend upon the character of the inflammation and upon the susceptibilities of the patient. It is better, as a rule, to change the remedy from time to time until one is found which accomplishes the maximum of good. One of the simplest and best is common alcohol, diluted according to circumstances. Weak solutions of bichloride of mercury, as recommended by me elsewhere,[11] are often of decided benefit. For post-nasal and pharyngeal inflammation I have also used the *tincture of galanga* with excellent results. Galanga is an Indian remedy for catarrh, whose powdered root has been recommended (Bosworth) in the form of snuff. It will be found, however, exceedingly difficult to reduce the root to an impalpable powder, and even when mixed with other powders it is irritating and often produces attacks of acute coryza. To obviate this, I have had an alcoholic tincture of the root, diluted according to circumstances, prepared for use as a spray behind the soft palate. This has an aromatic, not unpleasant odor, and produces a sharp, pungent, peppery sensation, which subsides, however, almost instantaneously, and generally affords immediate relief. The application leaves an agreeable astringent sensation in the throat, which lasts for some time, and is not open to the evil results which follow the use of nitrate of silver and similar substances in that locality.

The use of powders in the nose will often do more harm than good, unless the substance be reduced to an impalpable state. Their indiscriminate use is to be discouraged, especially where the parts cannot be thoroughly and repeatedly inspected. Otherwise they will form a thick paste with the discharge, whose removal they mechanically impede, or, collecting in the crevices of the nasal chamber, lay the foundation for crust formation, or act as foreign bodies. It is much better to apply the remedy to the mucous membrane in some such vehicle as glycerine, gelatine, cosmoline, vaseline, etc. This should not be thrust blindly into the nose, but the nostril should be dilated and the application made directly to the diseased surface. Where excoriations or ulcerations of the nostril exist, I have found that the powder of calendula dusted over the raw surfaces, or applied as a glycerole, will cause rapid healing and diminution of the discharge. I have also found the combination of this drug with boracic acid, as recommended by Dr. Sexton,[12] of New York, as ointment, of considerable value in purulent cases of catarrh of the nose.

During inclement weather, and when exposed to a vitiated atmosphere, the nasal chambers should be protected by means of a respirator. Those in common use are ungainly objects, against which personal vanity and æsthetic taste alike rebel. Few patients, especially ladies, will submit to being muzzled with these unsightly appliances, which, besides detracting to a great extent their personal charms, are in the eyes of their fellow-man the outward and visible suggestion of chronic nasal catarrh. When the discharge is not very profuse, absorbent cotton, medicated or not according to circumstances, may be substituted for the ordinary respirator. A small piece of cotton is taken and its fibres teazed gently apart with the fingers. It is then folded lightly upon itself and introduced into the nostril just beyond the orifice of the anterior nares. If care be taken to separate the fibres sufficiently loosely, respiration can take place with ease. This simple expedient will be found of considerable value to mitigate the severity of the atmosphere and to equalize the temperature within the nasal chamber.

The cotton respirator should not be confounded with the plugs in common use to medicate and give support to the inflamed nasal membrane. The use of tents of various kinds as a means of conveying remedies to the cavities of the nose is of very ancient origin, and it is therefore amusing to read the altercations in which some surgeons of the present day have indulged as to the priority of their introduction in the treatment of nasal inflammation. Where the discharge is profuse, or when caries or necrosis of the bones is present, I can strongly recommend *oakum* as a substitute for the cotton tents commonly employed.

In addition to local applications, attention should be given to the general health, which is often seriously impaired. The existence of diathetic diseases should be carefully sought for, and the different organs and their functions systematically interrogated.

The principal measures for the treatment of the third stage of chronic catarrhal inflammation of the nasal passages, have already been given in detail in the article on Ozæna. The principal points to be attended to are (1) the utmost cleanliness of the nasal passages, (2) the dissipation of the odor, and (3) the stimulation of the healthy mucous membrane to vicarious activity. As a disinfectant I have found nothing better than the bichloride of mercury. This may be used topically in solution, or the local application may be assisted by the administration of small tonic doses of mercury internally.

It would carry me far beyond the limits of the space allotted to this article to consider the hygiene of the upper respiratory organs ; but a few general remarks upon certain all-important subjects may, perhaps, be not out of place. A catarrhal patient should not be deprived of all the luxuries of life, severed from all legitimate pleasures, or driven to the verge of inquisitorial torture by an enforced system of coddling and a perpetual dread of the variations of the thermometer, nor be taught to rush indoors whenever a cloud passes over the sun. He should live as much as possible in the open air and indulge in systematic exercise, according to his individual endurance. The skin should be kept in a healthy and active condition by daily cold baths, frictions, etc. As little liquid nourishment should be taken as is compatible with the comfort of the individual. The ingestion of large quantities of liquid, especially in the form of alcohol, is greatly to be deprecated. It is surprising what an effect the combination of exercise and abstention from a superabundance of fluid often has upon the course of a catarrhal inflammation. I have known it to check the secretion when all other means had failed. To sum up, the patient should exercise a sufficient amount of common sense and discretion in matters included under the commonly recognized conception of "taking care of one's self," and live as much as possible under the guidance of the common law of health.

In the preceding pages, and in the article on Chronic Laryngitis, in Vol. IV. of this HANDBOOK, I have endeavored to give a general idea of the principles which should govern the physician in the treatment of chronic catarrhal inflammation of the upper respiratory tract. To enter into detail either in the matter of methods or the comparative merits of drugs would be impossible within the contracted sphere of the present communication. Each case must be studied by itself. Indeed, in all cases, the search for the cause should be the study of the individual and the complex forces by which he is influenced and surrounded ; and upon the correct interpretation of these, more than upon mere inspection of the local malady, will often rest a rational diagnosis and a successful mode of treatment.

John Noland Mackenzie.

EAR, SYPHILITIC AFFECTIONS OF THE. I. ACQUIRED SYPHILIS.—AURICLE.—*Primary syphilitic chancres* have been but very seldom seen on the auricle and the adjacent parts. Desprès[1] found among twelve hundred syphilitic patients one with a chancre (?) on the auricle. Pellizzari[2] reports having seen a primary sore on the lobule, and thinks that it was caused by the use of a razor, which the son of this patient had previously used in shaving a sore on his penis. Hepner[3] saw a chancre on the lobule of a woman's ear, which resulted from a kiss by her infected husband. The same author[4] saw also, in the clinic of Dr. Fournier, in Paris, a phagedænic hard chancre on the lobe and the posterior part of the lower third of the auricle, caused by the bite from an infected individual. A similar case due to a bite has been observed also by Hutchison.[5] Hulot[6] saw a chancre on the base of the tragus, the origin of which was problematical. Zucker[7] has described at length the history of a case of chancre on the outer surface of the tragus. A chancre on the mastoid process in a man, due to the kiss of a prostitute, has been observed by Mracek,[8] and another in the same place in a child, caused by infection from the nurse, has been described by Hulot.[9] Finally, Lancereaux,[10] speaking of otitis syphilitica externa, says that it attacks sometimes the auricle, at other times the external canal, or it may attack both parts simultaneously, and that it manifests itself usually in the form of a chancre.

As far as can be seen from the description of the cases here cited, the chancres presented the usual appearance; the lymphatic glands in the vicinity were enlarged and indurated. In Zucker's case the tragus was of a livid red color, of twice the normal thickness, and on its anterior surface was a pigmented radiating cicatrix. The entire parotid region was involved in the process; it was greatly swollen, felt as hard as a board, but was not at all painful. There was no secretion from the external canal, and the hearing was but slightly diminished in acuteness. In this case the diagnosis of primary syphilitic infection was facilitated by the recent appearance on the surface of each hand of three or four small, round, slightly scaly efflorescences. The genitals were intact, and the inguinal glands were not swollen. A course of inunctions produced a perfect and rapid cure.

A primary sore on the auricle may be mistaken for cancer, from which it differs, however, in that it presents a clean surface and secretes but little. The nearest lymphatic glands usually enlarge with the development of induration in the primary sore.

Secondary and Tertiary Forms.—Manifestations of constitutional syphilis are not very rarely observed in the auricle. Squamous, pustular, and papular eruptions, usually in connection with the same affection on the integument of adjacent parts, but sometimes limited to the auricle and external canal, have been seen by many writers. According to Gruber[11] papular eruptions are most frequently seated at the point of insertion of the auricle, while exanthematous eruptions appear mostly on the other parts of the auricle. Broad condylomata have been often seen by Desprès on the lobule, and usually in the hole for the earring. Wilde,[12] as far as I know, is the only author who maintains that syphilitic ulceration is by no means uncommon, and that rupia is frequently seated on the external ear.

Tubercular syphilides* and gummata of the auricle have been observed by Zeissl,[13] Burnett,[14] Buck,[15] Field,[16] Hessler,[17] Politzer,[18] Sexton,[19] Pierce,[20] Ravogli,[21] Weekes,[22] Barclay,[23] Bumstead and Taylor,[24] and McBride.[25] In all of the cases reported the affection appeared in the so-called tertiary stage of syphilis. In almost all only one ear was affected, and in the majority of the cases no other symptom of syphilis was present at the time the patient came under observation. The seat of the tubercle or gumma was in the anterior part of the auricle in all the cases, except Burnett's, in which it occupied the posterior surface. A case with symmetrical patches of lupus erythematosus in the concha of each ear, probably syphilitic, was seen by Hutchinson (l. c., page 148). According to Zeissl, the auricle may be the seat of both the dry (non-ulcerating) and the ulcerating forms of gummata, and the latter frequently shows a tendency to the lupoid character in this situation (Fournier). In Burnett's case, which is about the only one recorded in which the disease was seen in its earliest stages, there first appeared a circumscribed infiltrated lump on the posterior surface of the auricle, and this gradually extended until it had diffused itself throughout the tissue of the pinna. It was slightly elevated above the general surface of the auricle, of a deep reddish color, painless, and was not attended with itching; it was inclined to run a slow course. In the space of a month or six weeks the infiltration had diffused itself throughout the greater part of the auricle, and somewhat over the mastoid portion. The thickening and deformity of the auricle had become considerable, the groove behind the auricle was obliterated, and the appendages assumed a firm, thick feeling. This condition lasted for some weeks, then softening and ulceration ensued, the latter beginning in some natural groove or depression. The ulceration formed by the breaking down of the gumma may assume any shape, and if not properly treated, soon increases in size and depth. The floor of the ulcer is usually ragged and covered with dirty grayish matter which cannot be readily removed. The discharge from the ulcer is often excessively offensive. In several of the reported cases, necrosis of parts of the auricular cartilage, and exfoliation of the sequestra occurred, and in Field's case two-thirds of the auricle was destroyed. As a rule, comparatively little deformity seems to result from this affection, sometimes even when the infiltration is extensive and the ulcer large and deep; very often an indelible, depressed white scar is in after-years the only evidence remaining of the gumma. In Barclay's case, in which the cartilage of the concha, tragus, and canal was exfoliated, the general outline of the ear remained normal. The first abnormality to strike the attention was the peculiar deformity of the concha, the upper and lower limits of which were preserved, while the tragus and meatus were absent. The beginning of the helix above was at an oval pit in the concha, and the intertragal notch below was a circular pit. There was a shining, bulging, yellowish spot—resembling somewhat a sebaceous cyst—right over the site of the normal meatus, upon a strong band of cicatricial tissue, extending downward and backward from a spot above and in front of the site of the normal tragus, which band completely closed the meatus. Except a slight tightening of the skin, a seeming loss of subcutaneous tissue on the anterior side, and a slight drawing outward and forward of the auricle, it was otherwise apparently normal. Above and anterior to the site of the normal tragus, and near that of the temporo-maxillary articulation, was a stellate cicatrix.

The diagnosis of the diseases under consideration, as well as of those which I shall treat farther on, must rest largely on the previous history of the case. If syphilitic infection is denied, and nodes of or gummata on the bones are absent, careful search should be made for scars and marks left by secondary affections of the skin and mucous membranes. An ulcerated tubercle may possibly be confounded with lupus vulgaris and scrofulous ulcer. In both of the last-named affections there is, however, very frequently considerable redness and œdema of the skin around the ulcer, while the syphilitic ulcer is, in most instances, sharply bounded by healthy tissue skin. Lupus vulgaris begins, moreover, usually before puberty; its course is much more chronic, and there is but little discharge from the ulcer.

---

* The tuberculo-syphilide is a [illegible]

From an ulcerating epithelioma * the syphilitic ulcer can generally be distinguished by the absence of enlarged glands in the neighborhood, and by the more offensive odor of the discharge.

The *treatment* of these affections does not differ from that of tertiary manifestations in other parts of the body. Iodide of potassium, alone or combined with mercury, will cure these cases.

Local treatment alone was of no avail in any one of the cases reported.

External Auditory Canal.—This part of the ear is not very rarely the seat of *Broad Condylomata* (*Mucous Warts*) and of ulcers in persons suffering from constitutional syphilis. The occurrence of the condylomata of the external canal is mentioned by Moos and by Troeltsch; but for the first full description of this affection and its treatment we are indebted to Stöhr,[25] who had the opportunity of seeing fourteen cases of this disease in about three years. Wilde's (loc. cit., 222) case, published nearly twenty years before Stöhr's paper appeared, may, as Knapp suggests, have been also one of syphilitic origin; but Wilde who, throughout his book, shows that he was familiar with the manifestations of syphilis in the ear, says expressly that the patient was otherwise healthy, and attributed her affection to cold.

Since Stöhr's publication broad condylomata have been observed and described by Buck,[15] Knapp,[26] Christinneck,[27] Noquet,[28] Zucker,[7] Purjesz,[29] Felici,[30] Trautmann,[31] Kochner.[32] Desprès[1] found among 1,200 syphilitic patients (980 of whom had condylomata in various places), 5 cases of condylomata of the external canal; while Ravogli was unable to find a single case of condylomata of the external canal in 144 syphilitic individuals (77 of these had condylomata in other parts of the body) whose ears he had examined. Buck saw but 2 cases in 3,976 ear patients; Knapp met with only 1 case in from 9,000 to 10,000 ear cases; and the writer of this has seen but 2 cases out of about sixteen thousand ear patients. Analyzed with regard to the sex, the published cases show a preponderance among the females. In most cases but one ear was affected. As a rule, condylomata of the external canal appear early in constitutional syphilis, while other skin eruptions, ulcerated papulæ on the fauces, and glandular swellings are present. In most cases purulent inflammation of the middle ear, sometimes of long standing, precedes the development of the growth. Condylomata begin as broad, slightly raised papulæ, the surface of which at first is dry, but soon becomes moist. The papulæ gradually grow in size, and when situated close to each other they coalesce into large patches. These are often subdivided by rhagades. In most cases the upper surface of the excrescence, which is at first smooth and somewhat convex, becomes ulcerated and secretes a sero-purulent fluid, which often causes inflammation and ulceration of the adjacent parts free from these growths. If ulceration does not occur, the epidermis covering the excrescence becomes thickened, whitish, and granular. These growths often occur in great numbers in all parts of the canal, and may even be seated on the drum-membrane. Sometimes they not only fill the canal, but also protrude out of the external meatus. The excrescences are at first painless, but after ulceration has occurred they often cause severe pain, which is increased by movement of the jaw. More or less impairment of hearing and tinnitus usually result from the obstruction of the canal, and occasionally a purulent inflammation of the middle ear is developed subsequent to the appearance of the warts. In one of Buck's cases (*American Journal of Otology*, i., page 26), a man, aged twenty-eight, who had had otorrhœa for seven months before, but whose hearing was not impaired, the orifice of the meatus was found almost completely obliterated by the presence of an elevated patch of what seemed at first granulating tissue. The dividing line between this patch, which completely encircled the orifice and the healthy skin of the auricle, was sharply drawn, the edges of the elevated portion being quite abrupt. In Knapp's case, the condylomata developed a few months after infection, and when the patient came under his observation, six months after he had contracted syphilis, he found the ear canals filled, and the external orifice of the meatus and the adjacent parts of the concha occupied all around, by reddish, wart-like excrescences resembling the syphilitic condylomatous growths so often seen at the anus. Some of these were ulcerated at their apices and discharged a thin, watery fluid. A papular syphilide covered the whole body, and was very marked on the forehead. In the soft palate there were ulcers with unclean bottom and raised concave edges. The glands of the neck were swollen, and the patient was very pale and weak. During the first weeks of treatment, however, there was an aggravation of the affection of the pharynx. She suffered intense pain in the ears, and was relieved when profuse purulent discharge from the ear set in. The walls of the ear canals were so much swollen that no speculum could be introduced; yet the characteristic whistling sound on inflation showed that both drum-heads were broken. The case recovered fully under antisyphilitic treatment.

The diagnosis of broad condylomata of the external canal can usually be made without difficulty, as manifestations of secondary syphilis are almost always present in other parts of the body at the same time.

The prognosis is favorable. Under constitutional antisyphilitic treatment and the local applications to be mentioned, the excrescences usually shrink rapidly, and eventually disappear entirely. Depressed cicatrices, destitute of hair, sometimes remain, but permanent contraction of the canal very rarely follows this affection.

Constitutional treatment alone will in most cases cause the condylomata to disappear. But if they occlude the canal and cause retention of the discharge from the tympanic cavity, they may be abscised or carefully cauterized with nitrate of silver in substance. Thorough cleansing of the canal with warm salt water, and inflation of the middle ear should also be practised if suppuration of the middle ear is present. In some cases benefit was apparently derived from dusting iodoform or calomel on the excrescence, or washing the same with a one per cent. solution of nitrate of silver.

Syphilitic ulcers of the external canal seem to have been observed by some of the older writers, as Bell, in his work on Lues, speaks of deafness produced by a "scruffy" eruption, and sometimes ulceration of the external auditory passage, occurring as a consequence of that disease. Referring to these Wilde says: "But the description is not sufficiently accurate to be depended upon, and has not been confirmed by subsequent observers. No doubt, cutaneous syphilitic disease will extend by ordinary continuity of surface into the meatus, but as a special form I am unacquainted with it" (loc. cit., p. 198). Since Wilde's time such ulcers have, however, been frequently observed, and have been studied especially by [illegible]. According to this author they are usually circular in form and covered by a dirty, grayish-white exudation. Their edges are usually greatly swollen, and may thus cause considerable diminution of the calibre of the canal. They were seated in the outer part of the canal up to the point of union of the cartilaginous and osseous portions, and were found in one or both ears. He saw these ulcers in ears with normal membranæ and healthy middle ears, but in most cases they were associated with chronic purulent inflammation of the middle ear and perforation of the drum-membrane. The glands in the vicinity of the ear were always much swollen in these cases, and other manifestations of constitutional disease were never wanting. The treatment recommended by this author is energetic cauterization with nitrate of silver in substance, which, though painful, may be relied upon to heal the ulcer. Hinton has also seen secondary syphilitic ulceration of the meatus, mostly in the form of a narrow, [illegible] ulcer at the orifice, attended with an [illegible] discharge and general inflammation and swelling of the passage. The appearance and history sufficiently mark its character, and in the cases Hinton saw, iodide of potassium and black wash brought about a cure. A case of this kind has been described by Buck. The patient had acute purulent inflammation of the middle ear, with perforation of the drum-membrane. The ulcer occupied the lower wall of the outer half of the canal and extended outward upon the auricle. The limits of the ulcer were well defined. The chancre had appeared one year before, and there was also syphilitic pharyngitis.

---

* *Differential Diagnosis between Ulcer, Tubercle, and Cancer.*—Hutchison (loc. cit., p. 511), speaking of the differential diagnosis between cancer and syphilis, says: "I am most anxious to insist on its extreme difficulty. The surgeon who trusts to rules, or who ventures to rely with confidence on his own powers of observation as regards minute differences of appearance between cancerous and syphilitic ulcers, will often make serious mistakes. Cancerous processes may be simulated by syphilis in the closest possible manner. As a general rule, it may be said that we distinguish between a cancerous ulcer and one that is syphilitic by observing that in the former a process of growth precedes that of ulceration, whereas in syphilis it is at best only one of chronic inflammation. Without doubt this is a most important distinction. In syphilis the edges of an ulcer may be greatly indurated and its base may be firm, but there are seldom any sprouting masses on the surface, or any well-defined margins to the induration, such as we encounter in cancer. Exceptions, however, occur even to this statement, and now and then even a syphilitic sore may be covered with bossy masses of firm granulation structure which closely resemble epithelioma. I possess more than one drawing in which the ordinary features of rodent ulcer, its clean surface, and its sinuous, rolled edge of induration, were so exactly imitated by tertiary syphilitic sores that we had to appeal to treatment for diagnosis. I have not attached much importance, for diagnostic purposes, between syphilis and cancer, on the presence or absence of implication of lymphatic glands. Nothing can be more illusory than to teach that enlargement of the lymphatic glands is one of the *features* by which cancer can be distinguished from other local disease. There is, no doubt, however, that in any case which comes under observation late, and with enlargement of the glands already existing, we may take this part as important evidence in support of the diagnosis of cancer. Neither in secondary nor tertiary syphilitic lesion is it at all common for there to be any implication of lymphatics." "In very obscure cases the aid of the microscope should be invoked, and if this should fail to give positive evidence one way or the other, the patient should be given the benefit of the doubt and be put under antisyphilitic treatment. In cases in which it is desired to use treatment as a means of diagnosis, the best plan will usually be to rub in mercury pretty freely, and to give iodide of potassium by the mouth at the same time. Under this plan any growth or ulcer of syphilitic origin ought within a week or ten days to change its features in an unmistakable manner."

Politzer has observed two cases of this description. In one, with chronic purulent inflammation of the middle ear, the ulcer occupied the lower lateral wall of the cartilaginous portion. Syphilitic ulcers of the pharynx were present at the same time. In the other, the ulcer extended along the entire length of the cartilaginous portion, and a second ulcer with everted edges occupied the concha.

In a case reported by Jacobson the patient had been affected, up to within a few months before he came under observation, with chronic suppuration of the middle ear. He was suffering intense pain in the head, and had other symptoms of cerebral irritation. He had contracted syphilis six months before and had ulcers on the [illegible] at the time. The ulcer, which was seated at the entrance of the right external canal, was of the form of a ring; its floor was covered with an adherent, dirty, whitish-gray exudation, and its margin was much swollen. It was very sensitive to the slightest touch, and the tragus and mastoid process were tender on pressure.

Diagnosis.—Non-specific ulcers of the external canal are very rarely seen, except in children with neglected purulent inflammation of the middle ear, and in eczema of the canal in adults, and the presence of an ulcer should therefore always arouse suspicion as to the existence of constitutional syphilis. It seems hardly possible that the opening of a furuncle can be mistaken for ulcer by any one at all familiar with ear affections. In cases of syphilitic ulcer the glands near the ear are always swollen, and other signs of syphilis are never absent.

Diffuse inflammation of the external canal due to syphilis is said by Lancereaux de Lanchère to be of frequent occurrence in the secondary stage. According to this author both auricles are usually attacked simultaneously; there is only moderate swelling, the skin is red and swollen, and the discharge is very offensive. But McBride appears to be the only other author who has seen such a case, and in his there was no disagreeable odor. If we exclude the cases in which papules or condylomata are present, the secretion from which causes inflammation of the lining of the parts of the external canal free from them, instances of diffuse inflammation of this part are doubtless very rare in syphilitic persons. The writer of this article has seen but a single case of this kind, and this occurred many years after infection, and was associated with non-purulent inflammation of the middle ear, and caries of the superior maxillary and palate bones of the same side. In this case the walls of the osseous part of the canal were very red and somewhat swollen. The pain was very great, and not much relieved by repeated deep and long incisions, which at no time liberated pus. The walls were at no time covered by exudation, and there was but little secretion from them. The drum-membrane was but little inflamed, and although it was repeatedly freely incised in the hope of giving exit to supposed pent-up secretion in the tympanic cavity, none escaped. The Eustachian tube was almost impermeable. After much and long-continued suffering the pain subsided eventually while the patient was taking iodide of potassium; complete deafness remained.

The characteristic symptom of syphilitic inflammation of the external canal is said to be very severe pain, even when the swelling is not very great, which is not relieved by the usual remedies, but yields at once to constitutional treatment (Schwabach).

Exostoses of the external canal may, according to Gruber, be caused by syphilis, but nearly all other writers deny that syphilis has anything whatever to do with the production of these growths.

THE DRUM-MEMBRANE.—This part of the ear appears to be but rarely the seat of syphilitic infiltrations and growths. Lang observed a case in which there was a large, pale, glistening papule at the place of the short process of the hammer on a drum-membrane; the membrane itself was very red in its anterior upper quadrant, and slightly opaque throughout. The patient was a woman, with early symptoms of constitutional syphilis.

Condylomata, as we have seen, have been found here in a few cases in which these growths existed also on the walls of the canal.

Baratoux has recorded the case of a woman in whom he found five small gummata on the cheek, in front of the ear; a sixth on the mastoid process; three in the concha and outer part of the external canal; a small, egg-shaped, prominent, faintly opalescent, gummatous tumor on the lower posterior part of the drum-membrane; and a small, round ulcer, covered with a yellowish-white, adherent substance, in front of the handle of the malleus. The gumma on the drum-membrane became ulcerated at its summit in a few days, while the ulcer was cicatrizing.

MIDDLE EAR.—The diseases of the middle ear observed in individuals afflicted with constitutional syphilis do not differ essentially, in their objective and subjective symptoms, from the same diseases occurring in non-syphilitic subjects. Most writers are agreed, however, that the syphilitic forms are characterized by a marked tendency to implication of the labyrinth, or to speak more precisely, by the appearance of symptoms commonly regarded as indicative of disease of the auditory nerve at an unusually early period. The middle-ear disease may present itself in the form of an acute catarrhal inflammation, a chronic catarrhal inflammation, a purulent inflammation, or as a neuralgia of the tympanic cavity.

Acute Catarrhal Inflammation.—This disease is usually, but by no means always, associated with syphilitic disease of the naso-pharyngeal cavity. Frequently but one ear is affected, and in such cases the disease of the pharynx is usually found to be confined to that side. Sometimes this consists of only a superficial erosion. In many cases the ulceration is confined to the posterior wall of the pharynx, behind the velum palati, and, as in this location it rarely causes the patient much inconvenience, it may be overlooked if an examination with the rhinoscopic mirror is omitted.

The subjective and objective symptoms, and the course of syphilitic acute catarrhal inflammation, resemble so closely the idiopathic form that a description of the same seems unnecessary in this place. Schwartze (op. cit., p. 134) asserts that an impairment in the conduction of sound through the bones occurs regularly at an early period in this disease, and adds that it is not known to what this is due. The present writer has, however, seen a number of cases of this affection in which the bone-conduction remained unimpaired throughout.

With regard to the *treatment*, it is only necessary to state that, in addition to the local measures usually employed in the idiopathic form, a course of antisyphilitic remedies will be found necessary to cure the disease of the ear and the pharynx. In this connection it may be well to point out the danger arising from using, on healthy persons, catheters and other instruments that have been employed on syphilitic individuals. Boiling the instruments in a five per cent. solution of carbolic acid may possibly be sufficient to destroy the virus, but in the opinion of the writer it would be far safer to provide each patient with instruments for his exclusive use.

Chronic Aural Catarrh.—With regard to this disease, Wilde (op. cit., p. 254), says: "All the cases I have seen of this affection occurred in young men, and generally those of fair complexion and blue eyes, who had had primary sores upon the genitals from six to twelve months previously, which sores were rather of a deceptive character, so that mercury was seldom given, in the first instance at least, in a legitimate form. Sore throat, papular eruptions, copper-colored blotches, fissures and ulcers of tongue, with loss of strength and slight nocturnal pains, existed previous to the aural affections, which should, I think, be ranked as tertiary symptoms. In almost every case I have witnessed the disease appeared suddenly as an eruption was fading off; in two it came on at a later period and was accompanied by loss of hair; in most it appeared in the upper and middle ranks of life. In some cases there is at first a sensation of fulness in the head, and often vertigo upon stooping or rising up suddenly, but in no instance have I seen it accompanied by acute pain. Tinnitus is not always present." In all of the cases observed by Schwartze, except two, in which the patients positively stated that the disease began with lancinating pain, and in all seen by the writer of this article, the disease was insidious in its approach, and pain in the ear was absent throughout its course. Pain in the bones of the head was, however, occasionally complained of. Tinnitus was present in nearly all the cases, though it was not always very annoying.

As regards the appearance of the drum-membrane Wilde says: "Upon inspection the amount of redness and vascularity will be found much greater than in subacute myringitis, and in this consists one of the chief characteristics of this disease, that while it is unaccompanied by local pain, the membrana tympani will be found to present an amount of redness equal to, and sometimes exceeding, that seen in acute myringitis.* The redness has generally, however, a brownish hue in the syphilitic form. There is not at first much loss of polish, but in a short time the membrane assumes a fuzzy appearance. Both ears are usually attacked at the same time." Schwartze (op. cit., p. 264), Roosa, and most of the more recent writers on this subject, on the other hand, have been unable to find in the appearance of the drum-membrane in this disease anything that could be regarded as pathognomonic of its syphilitic character. Pomeroy[61] believes that it very frequently does not differ in appearance from that in non-syphilitic disease, but that signs of infiltration of the membrane, giving it a greater degree of opacity than would result from a non-specific inflammation, will cause one to suspect constitutional disease. In his opinion the most important aid, however, to diagnosis is the history. Sturgis (*Boston Med. and Surg. Journal*, June 3, 1880) regards the infiltration of the tympanum, conjoined with the absence of vascular congestion, as characteristic of syphilitic catarrh of the middle ear.

The Eustachian tube is usually easily permeable at least by the aid of the catheter. The sounds heard on auscultation are usually dry and broad, but sometimes moist râles are heard. The inflation rarely improves the hearing even for a short time, though it sometimes temporarily arrests the tinnitus. The lining membrane of the pharynx is nearly always hyperæmic, and very often superficial ulcers are found on the arches of the palate and the tonsils. The nose is usually not markedly diseased. The impairment of hearing, which is commonly already well advanced when the patient comes under treatment, in the majority of cases goes rapidly from bad to worse, so that in the course of a few months only loud speech can be heard close to the ear. In the remainder the progress is much slower, and instead of months, years may pass before this state is reached. In a case seen by Schwartze a sudden and great increase in the hardness of hearing followed a blow on the head. In many of the cases, even in persons under thirty years of age, an impairment or loss of bone-conduction occurs at an early stage of the disease, when the tick of the watch is still heard at some distance from the ear. In several of Schwartze's cases even the large tuning-fork C was heard indistinctly or very faintly when placed on the vertex.

Our knowledge of the pathological anatomy of syphilitic catarrhal inflammation is very imperfect, as it must be of all diseases which are not fatal. Moos[38] found in a case of deafness, supposed to have been due to syphilis, beside adhesive inflammation of the labyrinth and the deposit of chalky concretions on the membranous semicircular canals and sacs, inflammatory changes in the drum-membrane, thickening of the pale mucous membrane of the middle ear, and anchylosis of the malleo-incudal joint and of the stapedio-vestibular articulation, all of which have been seen often enough in non-syphilitic cases. In Toynbee's case ("Catalogue of the Museum," No. 512), which occurred in a man about forty-eight years of age, the deafness began five years before death. Right ear: loud voice close to the ear. Left ear: total deafness. The deafness commenced while he had a severe ulceration of the fauces from syphilis. Post mortem.—Right ear: anchylosis of the stapes; the articular surface of os Sylvii much flatter than usual; adhesion between the anvil and hammer; tensor tympani atrophic; membrane of round window thickened; cochlea of a deep-red color. Left ear: anchylosis of stirrup; thickening of membranous vestibule. Schwartze (op. cit., page 135) surmises that the pathological change in the syphilitic cases is a periostitis, and Roosa[39] thinks that this view is correct. The last-named author is also of the opinion that there may be also, in the course of the later periods of the disease, a syphilitic exudation into the tympanum and about the ossicles; and that it may be said, in general, that the syphilitic diathesis seems to cause a more rapid proliferation of tissue, and one that is less amenable to treatment. Sexton,[40] who believes that in the sudden deafness from syphilis (which most other writers on otology of the present day regard as due to disease of some part of the acoustic nerve) the principal lesion is confined to the transmitting structures of the middle ear, says: "As regards the pathology of the syphilitic invasion of the ear, it may be surmised that granuloma, or circumscribed, small, round-cell infiltration, takes place within the tympanum; that the invasion is rapid, and that the conductive apparatus is prevented performing its movements by the particular manner of fixation that occurs. It is doubtful if our present means of pathological study could definitely determine its seat in all cases."

Woakes[41] claims to have seen through the drum-membrane a gummatous exudation in the tympanic cavity.

From what has been said with regard to the symptoms, it must be evident that there is none by which we can positively distinguish chronic catarrhal inflammation of the middle ear, due to syphilis, from that arising from other causes. The supervention of symptoms indicative of disease of some part of the acoustic nerve (impairment or loss of bone-conduction, etc.) in the earlier stages of the disease, occurs unquestionably much more frequently in the syphilitic cases than in others, but is by no means a positive sign of the specific character of the disease. Such symptoms, when present, especially in young and middle-aged persons, should, however, arouse our suspicion as to the presence of syphilis and lead us to make a more careful search for other symptoms of this disease. Only when such are found, or a clear history of constitutional syphilis can be obtained, are we justified in making the diagnosis of syphilitic ear disease.

---

* Wilde applies the term myringitis to the disease now generally called acute catarrhal inflammation of the middle ear.

The prognosis of the syphilitic chronic middle-ear catarrh is, on the whole, even less favorable than that of the non-syphilitic form. Nearly every writer has met with some cases in which, under judicious local applications and a thorough course of antisyphilitic remedies, the hearing was improved and even restored. But such cases are, after all, according to the writer's experience, rarely encountered outside of the books. To arrest the progress of the disease is about the most we can hope for.

In the treatment of this disease it will be found necessary, in addition to the usual remedial measures for the ordinary chronic catarrhal inflammation, to resort to constitutional remedies. In all cases in which no doubt exists as to the diagnosis, the patient should be brought rapidly under the influence of mercury by inunctions or injections under the skin, and this should be kept up for a considerable period. Iodide of potassium may be given at the same time. The muriate of pilocarpine, in doses of one-sixth to one-third grain, administered hypodermically, once daily for several weeks, has been of some service in the hands of Politzer, Lucae, and others, in cases complicated with disease of the inner ear.

Purulent Inflammation.—Among the writers on otology much diversity of opinion has always existed as to the occurrence of a syphilitic purulent inflammation of the middle ear. Thus, Frank[44] and Lincke[45] describe an otitis interna, the result of lues. In this form, they say, the inflammation and ulceration extend from the throat and nose to the ear, are accompanied by great pain, and often terminate in suppuration of the middle ear, destruction of the tympanal membrane, and caries of the temporal bone. Wilde (op. cit., p. 252), on the other hand, says that under certain circumstances such a disease may, no doubt, occur, although he himself has never seen such a case and has not met with a well-authenticated instance of it recorded. Kramer[46] doubts that syphilis can cause a specific disease of the ear, and adds that he has never in his own practice, or in that of others, observed such cases, and Erhard[47] is of the same opinion. Virchow[48] mentions, as the result of syphilis, primary purulent inflammation of the tympanic cavity; stricture of the Eustachian tube resulting from cicatricial closure of its pharyngeal mouth, and caries of the temporal bone. In the treatises on diseases of the ear, of more recent date, but little can be found relating to this disease. Politzer (op. cit., p. 530) devotes less than a page to it, and Gruber (op. cit.) merely mentions syphilis as one of the causes of otitis media purulenta. Pritchard,[49] in speaking of the affections of the middle ear caused by syphilis, says that they are of comparatively rare occurrence, and that in some cases suppurative catarrh is set up with perforation, etc. Politzer (op. cit., p. 530) thinks that syphilis may interrupt the progress of the disease toward recovery, and Schwartze (op. cit., p. 176) only says, with regard to this disease, that under the influence of constitutional syphilis the suppuration may become chronic. Troeltsch, Roosa, Burnett, and others make no mention of it whatever. It may also be stated here that the number of cases of this disease reported in the medical journals within the last twenty years is exceedingly small.

Of our present knowledge of this form of otitis media purulenta, it cannot be said that it is much more definite than it was in Kramer's time. Schwartze has seen cases in which syphilitic disease of the bones was absent, but most other writers, including the present, have found such an affection existing in nearly every case. The disease of the naso-pharyngeal cavity may be any one of the various manifestations of constitutional syphilis met with in this locality, or may be a primary chancre due to the accidental inoculation of this part during catheterization of the Eustachian tube. Fortunately such accidents have but very rarely occurred.

With regard to the symptomatology and course of the purulent otitis media, most authors are agreed that they do not differ essentially from the non-syphilitic form. Buck,[50] while not regarding this statement with any great degree of positiveness, owing to the smallness of material which has come under his observation, cannot help feeling that, with increased experience and a closer study of this particular class of cases, we shall in time learn to recognize in these parts textural lesions as distinctly characteristic of syphilis as are most of its external manifestations. In one of the cases reported by him (Case XII.), a second perforation developed in the drum-membrane more than two months after the first, through a melting process similar to that observed so frequently in the velum palati, and he regards this occurrence as totally different from anything that he has ever observed in any case of non-syphilitic inflammation of the middle ear. Probably a similar melting away of a limited area of the drum-membrane took place in another of his cases (Case XI.). In neither of these cases was there any evidence of pressure from within. In the first-mentioned case caries and facial paralysis were subsequently developed, while there was no evidence of interference with the free escape of the pus formed, and this he regards as certainly not in harmony with the ordinary course of non-syphilitic otitis media purulenta. Politzer and others frequently noticed a high degree of deafness in these cases, caused by the frequent simultaneous occurrence of syphilitic disease of the labyrinth. Of the occasional occurrence of condylomata and ulcers in the external canal, in connection with this disease, mention was made in the first part of this article. In the cases observed by the present writer the symptoms were precisely those of the non-syphilitic form, and the course and termination of the disease differed in no way from the other. Ulceration of the mucous membrane, with caries and necrosis of the walls of the tympanic cavity, the mastoid process, and the petrous portion, and facial paralysis, may, according to Politzer, occur under unfavorable circumstances or inappropriate treatment, and end fatally through intracranial affections. Caries has been observed in this form probably no more frequently than in the non-syphilitic forms.

Fatal hæmorrhage from erosion of the internal carotid artery, caused by caries of the canal of the vessel, has been observed in syphilitic as well as in non-syphilitic subjects. Thus we find in the nineteen cases of fatal hæmorrhage collected by Hessler,[51] two in which syphilis was present. One of these cases (reported in full by Jungle in the *Deutsche Klinik*, No. 25, p. 250) occurred in a patient suffering from tertiary syphilis. Two years after he had come under observation he had a sudden profuse hæmorrhage from the left deaf ear, and four months later, after repeated hæmorrhages, the patient died. An autopsy revealed a complete destruction of the interior of the petrous portion of the left temporal bone. The membrana tympani and ossicles were wanting. Of the other case (described by Pilz in his dissertation, "De Arteriæ Carotidis utriusque Ligatura," Berlin, 1868) it is only known that, after severe pain in the region of the right ear, without objective symptoms, a sudden and copious hæmorrhage occurred from this ear; subsequently the blood was mixed with pus. The patient had syphilis, and a fistula on the posterior wall of the pharynx from which pus escaped. After repeated hæmorrhages Billroth first ligated the right and then the left carotid. The patient died under symptoms of anæmia. The autopsy showed extensive caries of the lower wall of the carotid canal, exposing the vessel. The erosion seen in the artery measured 8 mm. in length and 6 mm. in breadth.

Meningitis, iridochoroiditis of the eye on the same side as the purulent middle-ear disease, developed in a syphilitic subject, observed by the writer of this article.[49] In this case the ear disease was arrested and the hearing restored under general treatment alone.

As regards *the diagnosis*, the writer must confess that he knows of no aural symptoms by which the syphilitic form of this disease can be distinguished from the ordinary form. Woakes[41] thinks that the caries due to syphilitic purulent inflammation of the middle ear frequently has this distinguishing feature: the caries is symmetrical, that is, there is a corresponding lesion in both ears. In this disease, as in the diseases previously described, the presence of other symptoms of syphilis can alone decide the diagnosis.

Of *the pathological anatomy* of syphilitic suppuration of the middle ear we know but little. Quite recently Moos and Steinbrügge[50] have had the opportunity to examine both temporal bones of a case of tertiary syphilis. Moos first saw the patient fourteen years before his death. At that time the faucial orifices of the Eustachian tubes were closed by numerous thick, radiating, fibrous bands, so that the ventilation of the drum cavity must have been almost impossible; notwithstanding, there was no demonstrable deviation in the plane of the drum-membrane, in the position of the handle of the hammer, or in the cone of light. Strange to say, the patient never complained of subjective noises nor of dizziness. Bone-conduction was always sufficiently preserved to detect the loud tick of a watch, and the tuning-fork; the capacity for hearing speech was, however, so much reduced that ordinary conversation was not heard beyond one metre. The patient remained under Moos's treatment for about two years, and then passed from under his observation till a week before his death. At this time he was examined by Steinbrügge, who found that he was now only able to hear spoken words in close proximity to the ears; watch of 12 m. normal hearing distance was heard merely on contact in the right ear, and not at all in the left. Tuning-fork A' applied to the forehead was not perceived, applied to the teeth it was heard in the left ear. The otoscopic examination of the right ear revealed a cicatrix in the inferior posterior quadrant of the membrane; the external canal of the left ear contained pus, and there was a round, medium-sized perforation directly under the handle of the malleus. Post mortem, the following conditions were found: Syphilitic caries of the skull and hard palate. Chronic pneumonia. Amyloid degeneration of the spleen, kidneys, and liver. *Right temporal bone:* The greater part of the mastoid process was sclerosed. The mucous lining of the remaining cells was slightly injected. The Eustachian tube (a portion of the pharyngeal orifice was missing) was patent throughout. The tympanum contained a quantity of pus. The mucous membrane was thickened. The drum-membrane was in an atrophic state. The bony roof of the labyrinth was hæmorrhagically infiltrated. *Left temporal bone:* Greasy pus in external canal. Membrana tympani perforated. The mastoid process was sclerosed and of ivory-like hardness. The mucous membrane of the tympanum was very much thickened, and enveloped all structures contained therein. The cavity was filled with a secretion composed of pus-cells and giant-cells. The Eustachian tube (also here a portion of the pharyngeal orifice was wanting) was pervious. *Carotid artery and osseous portion of Eustachian tube:* There was no noticeable change in the outer and inner coats of the artery on either side, not even in that part where the bony partition between the artery and the Eustachian tube measured but 0.087 mm. in thickness. The mucous membrane of the Eustachian canal was normal, but the periosteum of the osseous portion in a medial direction was changed and thickened in a manner to be described below. *Periosteum and bones of middle and internal ear:* In the bony floor of the tympanum and below the cochlea, as well as in the roof of the tympanum, in the bone over the semicircular canals, and in the lateral wall of the osseous portion of the tube, were found markedly dilated medullary spaces, not only enclosing the usual normal contents, but also invariably filled—sometimes more, sometimes less—with larger or smaller groups of cells, enclosing blood-corpuscles, and also with a conglomeration of yellow or yellow brownish pigment. Evidently we had to deal here with the products of a metamorphosis of blood extravasation, the result of rupture of the thin-walled vessels contained in the medullary spaces. In the anterior wall of the bony vestibule, and in the osseous tissue anterior and posterior to the second curve of the Fallopian canal, were noticed several spaces in the bone, varying in size up to 3 mm. in length and 2 mm. in width on the left side, and 2 mm. in length and 1½ mm. in width on the right side. A similar condition was observed in the bone tissue below the first turn of the cochlea on the right side. The cavity here was circular; its diameter measured 2 mm. The contents of these spaces clearly demonstrated two separate stages in the pathological process. In the early stage these spaces were filled with a fibrous net-work, which in several sections showed unmistakable connection with the periosteum of the labyrinthine wall. The meshes of this net-work were filled with vessels more or less numerous, and a small-celled infiltration. The condition demonstrating a later stage, however, mostly predominated. Here the meshes were filled with yellowish coagulated masses, composed to a limited extent of blood-corpuscles and larger round cells, and mainly of fat globules and fatty degenerated cells stained black by the osmic acid. In addition, there were seen in many places, as indications of the earlier stage, the remains of fibres of this net-work in connection with the periosteum of the labyrinth mentioned above.

The condition of the periosteal covering of the promontory on both sides is worthy of special notice. Very much thickened, at places to 0.7 mm., the presence of numerous cavities imparted to it a cavernous appearance. The spaces were here and there lined with a low cylindrical epithelium, and in some places were filled with a tissue composed of fine fibres enclosing coagulated fibrin and fatty-degenerated cells. At first glance these spaces gave the impression of gland tissue; closer examination, however, proved them to be numerous circumscribed foci of inflammatory products undergoing retrogressive changes. The presence of smaller and larger portions of bone, cut off from the main bony mass of the promontory by strangulation of the proliferating periosteum, deserves additional notice. In some portions of the sections these spicula of bone were arranged in rows separated from each other by narrow bands of periosteal tissue. In other parts the proliferating periosteum produced deep indentations in the bone. The periosteum of the canalis pro tensore tympani, and that lining the delicate canaliculi of the plexus tympanicus, presented a similar pathological appearance.

In their comments on the above the authors say that, taking into account the fact that in their case they had to deal not with a fresh gummous neoplasm, but with the later consequences of periosteal proliferation, the above-described changes in the periosteum, with their consequences, would show a close correspondence with the description given by Rindfleisch of syphiloma ossium. Several hæmorrhagic extravasations were found in the perineurium of the tympanic plexus, and these, as well as the proliferation of the periosteum, explained, they thought, the genesis of many of the so-called pure nervous otalgiæ, occurring without objective signs of ear disease in the course of constitutional syphilis. They are also of the opinion that in cases of aural trouble without objective symptoms, occurring in syphilitic subjects, in which the functional examinations pointed to a peripheral disease of the ear, the diagnosis of periostitis of the labyrinthine wall might thereafter be made with a great degree of probability. The attacks of otalgia would serve as an adjunct in making the diagnosis.

The penetration of the proliferating periosteum into the thin, long septum dividing the osseous portion of the tube from the carotid canal, will afford an explanation for those fatal hæmorrhages which occasionally occur in syphilitic subjects, and which are attributable to caries. The observed changes in the floor of the right tympanic cavity invite attention to the possible involvement of the hollow canal [illegible] similar to that of the carotid in the dangerous hemorrhages occurring in tertiary syphilis.

Among other changes found may be mentioned the absence of a not inconsiderable number of fibres of the [illegible] nerve, and [illegible] homogeneous deposits between the fibres of the acoustic nerve; destruction of [illegible] and [illegible] in Rosenthal's canal in the first turn of the cochlea, and hemorrhagic extravasations between the nerves of the membrane of the same; [illegible] of the outer cells of Corti, which may, however, have been due as well to senile retrogression as to a pathological process.

In marked contrast with the great changes found in the above cases was the condition of the structures of the ears in a case observed by Hess, upon which v. Tröltsch made the autopsy. A man thirty-six years of age. Continuous and moderate hardness of hearing since infancy. Eight years before death he contracted syphilis, of which symptoms were still present two years before he died. A few years after infection there was a great increase in the hardness of hearing. During three years of his life he was totally deaf.

Autopsy.—The right ear was free from caries. The left ear revealed otitis media purulenta with kidney-shaped perforation of the drum membrane. The mucous membrane of the tympanic cavity was much thickened and injected. Ulceration of mucous membrane or exposure of bone could not be discovered. The anvil and stirrup were completely preserved and freely movable. There was no caries anywhere. With the exception of a slight thickening of the contents of the vestibule, and unevenness [illegible] of cochlea, the inner ear seemed normal. In his comments on the autopsy v. Tröltsch points out that it does not in the least explain the total deafness, the cause of which must therefore be sought for in the brain.

In the other cases examined after death only such alterations were found as are seen in purulent inflammation of the middle ear in non-syphilitic subjects.

The prognosis is favorable only in the beginning of the ear disease, in the milder cases, and in persons of strong constitution; but when the disease occurs in cachectic individuals, or is complicated with polypi and caries, or the hearing is totally destroyed, the prognosis is very bad. Yet recovery has been observed under antisyphilitic general treatment in cases which seemed hopeless.

The local treatment usually adopted for the non-syphilitic form—thorough and frequent cleansing with warm salt water when the discharge is at all copious; instillation of warm nitrate of silver solution or of alcoholic and watery solutions of corrosive sublimate (as recommended by Burnett), after all pain has ceased; the removal of granulations with the wire snare or with the sharp spoon, etc.—will be found of service as well in the syphilitic form. That in this, as in all syphilitic ear affections, a thorough course of antisyphilitic remedies, perhaps combined with tonics and a generous diet, is as necessary as the local treatment for the ear affection, is the experience of all who have written on the subject.

Neuralgia of the middle ear, due to constitutional syphilis, is an extremely rare disease. Usually syphilitic disease of the [illegible] of the Eustachian tube or of some part of the pharynx or larynx is present at the same time, and is probably the starting-point of the pain in the ear. The entire absence of objective symptoms of disease of the tympanic cavity, and the paroxysmal character of the pain, will establish the diagnosis. Moos, as we have seen, thinks that the hemorrhages in the tensor tympani, the [illegible] of the plexus tympanicus, as well as the [illegible] of the periosteum which he found in one of the cases examined by him, explain to us the grounds of many cases of so-called pure "nervous otalgia," occurring without objective signs of ear disease in the course of constitutional syphilis. The treatment must be directed against the constitutional disease, and if disease of the pharynx or larynx is present, applications to these parts will also be of benefit. Of these, cocaine will probably give greater temporary relief than any other remedy. Schwartze has found of especial use gargles of a solution of the bromide of potassium in such cases.

THE EUSTACHIAN TUBE.—Instances of primary syphilitic sores at or near to the pharyngeal orifice of the Eustachian tube have been observed, according to Politzer, by Ricord, Lancereaux, Desprès, Fournier, Bumstead, Lebouillon, Burnett, and others. J. Solis-Cohen ("Diseases of the Throat," p. 110) says that he has seen a few [illegible] cases of [illegible] from a chancre [illegible] not specially communicated by the infectious use of the Eustachian catheter. Chancres of the naso-pharyngeal cavity are, however, according to all writers, of extremely rare occurrence. The contagion is probably always conveyed through the Eustachian catheter. The sores present no characteristic features. The floor of the chancre is usually indurated, and the lymphatic glands at the angle of the lower jaw are commonly much enlarged. The sore as a rule causes but little pain. Primary chancres of the pharynx, like chancres occurring in other parts, are usually single. The treatment must consist of mercury administered internally or by inunction, and local application of iodoform or iodol; but if the sores prove intractable, they should be touched with the acid nitrate of mercury or other caustics.

Constitutional syphilis rarely causes isolated affections of the Eustachian tube. As a rule, the adjacent mucous membrane is the seat of the same morbid process. The earlier manifestations of syphilis met with in this locality are erythema, mucous patches, and superficial ulceration. The erythema may be generally diffused over the whole mucous membrane, or distributed in irregular patches between which the mucous membrane is of normal color. While not infrequently the syphilitic erythema presents no feature by which it can be positively distinguished from the simple catarrhal inflammation of the mucous membrane, a symmetrical distribution of the erythematous patches is regarded by many authors as strong evidence of the syphilitic nature of the disease. Mucous patches may occur in any part of the naso-pharynx, and have been occasionally observed on the tubal prominence. They present themselves as small, round, slightly elevated patches of a grayish white color, surrounded by a zone of more or less inflamed mucous membrane. Ulcers are comparatively seldom found in the naso-pharyngeal cavity in the early part of the secondary stage. They are usually quite shallow, and are nearly always the result of the breaking down of mucous patches. Usually the ulceration begins in the middle of the mucous patch and gradually spreads to its periphery.

Excrescences resembling pointed condylomata have been observed on the pharyngeal mucous membrane in two cases by Schwartze. In connection with the morbid states above briefly described, we very often find redness and more or less [illegible] swelling and thickening of mucous membrane of the greater part of the cartilaginous portion of the Eustachian tube. Frequently there is also a great increase in the secretion from the mucous membrane, so that then on inspection the upper portion of the pharynx is found covered by or filled with it.

The subjective symptoms are those of ordinary catarrhal inflammation of the Eustachian tube, e.g., slight pain in the throat extending to the ear, especially on swallowing; pressure and a sense of fulness in the ear; more or less impairment of hearing, and subjective noises. Vertigo and headache are rarely complained of. Auscultation during inflation of the Eustachian tube through the catheter commonly reveals distant moist râles, which cease after the secretion has been forced into the pharynx. The drum-membrane shows changes here, as in simple catarrh of the tube, only after the ventilation of the tympanic cavity has been interfered with for some time, and these consist chiefly in a retraction and dulness of this structure.

The prognosis is always favorable under proper management of the case.

The treatment of the diseases of the Eustachian tube occurring in the secondary stage consists in the administration of mercury, the cleansing of the naso-pharyngeal space by means of the posterior nasal syringe or an atomizer; topical applications of weak solutions of corrosive sublimate or nitrate of silver to the mucous membrane of the naso-pharynx, and frequent inflation of the Eustachian tube through a catheter, or by Politzer's method.

In the tertiary stage, gummy tumors and deep ulcers, sometimes involving the cartilage of the tube, are occasionally met with at, or within, the faucial orifice. According to Zaufal,[52] the plica salpingo-pharyngia is most frequently the seat of gummata. They present themselves as round tumors of a yellowish-red or red color, smooth surface, and a broad base, varying in size from a pea to a hazel-nut. The deep ulcerations found in this stage of the disease are probably always the result of the breaking down of gummatous deposit. Such ulcers are, according to Schwartze, not infrequently found on the tubal prominence and at the entrance to the faucial orifice, together with similar ulcers on the septum narium, choanæ, fornix, posterior surface of the velum palati, etc., in cases in which the usual inspection without the rhinoscopic mirror fails to arouse a suspicion as to their presence. They have, however, been seldom found beyond the mouth of the tube. These ulcers frequently spread with great rapidity and cause extensive destruction. If seated on or near the mouth of the tube, a complete growing together of its walls may occur during cicatrization of the ulcer. The aural symptoms caused by an ulcer on or near the mouth of the tube, do not differ from those described under the head of diseases of the secondary stage. Pain referred to the ear is, however, more frequently complained of in connection with ulceration than with erythema and mucous patches on or near the mouth of the passage.

In the treatment of the tertiary symptoms our chief reliance must be placed on iodide of potassium alone or in combination with mercury. Locally, nitrate of silver, in substance or in solution, the acid nitrate of mercury, iodoform, or iodol, may be applied daily or less often. Thorough cleansing of the ulceration should precede the application of the remedies named.

Hyperostosis and exostosis of the osseous part of the Eustachian tube are, according to Gruber,[53] sometimes caused by syphilis. This is, however, denied by other writers.

MASTOID PROCESS.—*Osteo-sclerosis* and *hyperostosis* of the mastoid process are, according to Schwartze, sometimes caused by syphilis. We know of no signs by which a differential diagnosis can be made between the idiopathic and syphilitic forms of these diseases. A course of antisyphilitic treatment will, however, soon decide which form we have to deal with. Gummata of the mastoid cells are extremely rare. Superficial and extensive caries of the outer cortex of the mastoid process, without disease of the middle ear, occurs, according to Schwartze, only as the result of syphilitic or scrofulous periostitis. The syphiloma or gumma may develop under the picture of a periostitis of the mastoid process. It may break down in parts and simulate the feeling of fluctuation. Its development may be very rapid, and it may disappear as quickly under antisyphilitic treatment.[54]

THE INNER EAR.—Of the affections of the organ of hearing caused by syphilis, diseases of the inner ear are probably least frequently met with. These diseases usually make their appearance toward the latter part of the secondary stage, or at a still later period. According to Politzer, they are sometimes developed simultaneously with secondary skin or throat affections, and in one case observed by him, a disease of the inner ear appeared as early as the seventh day after the primary infection. The same author has also recorded a case in which labyrinthine disease was developed; simultaneously with a gumma of the skull, twenty-one years after infection; and the present writer has notes of a case in which sudden and absolute deafness of one ear, in connection with naso-cranial osteitis, occurred twenty-six years after the primary disease, and after an interval of more than twenty-five years of complete freedom from symptoms of constitutional syphilis. Hutchinson ("Syphilis," p. 32), on the other hand, has no knowledge of any form of deafness due to syphilis which occurs in the tertiary stage of the acquired form.

The diseases of the labyrinth may be developed alone or in association with tympanic diseases. Frequently they supervene on pre-existing catarrhal or purulent inflammation of the middle ear.

The *symptoms* of syphilitic disease of the labyrinth do not differ essentially from those of the affection of this part due to other causes. In this form, as in diseases of the labyrinth in general, a marked diminution or total loss of the hearing power in one or both ears occurs, usually more or less suddenly. Subjective noises, of a variable nature, often of great intensity, sometimes precede the onset of the deafness, but more commonly are developed at the same time. They are rarely entirely absent. Vertigo and unsteadiness of gait sometimes usher in the attack, but more frequently these symptoms follow the deafness. Nausea, vomiting, headache, and weakness in the limbs are also early symptoms in many cases. Pain in the ear very rarely accompanies the attack. Inspection of the drum-membrane will, in many cases, give a negative result, while in others it will reveal the changes usually found in connection with chronic catarrhal disease of the middle ear. Evidences of acute inflammation of the tympanic cavity are usually wanting. The air douche through the catheter commonly shows a pervious Eustachian tube, and the sounds heard on auscultation are generally broad and dry.

A closer examination of the hearing power in these cases shows that besides the impairment of hearing for the voice, the perception of sounds through the bones of the skull is either greatly diminished or entirely wanting. In cases in which both ears are deaf, vibrating tuning-forks placed on the vertex or between the teeth are usually not heard at all, and in cases in which only one ear is diseased, the tuning-forks are heard most distinctly in the healthy ear and never only in the affected ear. Placed on the mastoid process of the affected side, the tuning-fork (the writer usually employs for this purpose a small C^2 fork of 212 vibrations a second), if heard at all, is heard from this part less long than normally in persons of the same age. In cases of great impairment of hearing for the voice the employment of Rinne's test nearly always shows the predominance of aërial over bone conduction; while in total deafness for the voice small tuning-forks are not perceived at all, but very large ones, when struck with much force, are heard when placed on the mastoid process. The examination with the piano or tuning-forks of different pitch, not infrequently shows that the perception of certain tones of the scale, usually the highest, is diminished or destroyed, or that whole groups of tones are not perceived. In a case observed by Knapp,[55] tuning-forks of high and low pitch were not heard, while those of medium pitch were perceived; neither the highest four (e'''' – a) nor the lowest four tones (A^2 — D^1) were heard; the octave next to the highest was heard, and that above the lowest tones only feebly. The power of appreciating low tones is the last to suffer and the first to recover in most cases, so that these will be heard when the high ones are not heard at all, or false, or doubled.[49] In a case reported by Blake and Walton,[56] a tuning-fork (562 v. s.) was heard in the left ear one-fifth higher than in the right, and sixteen days later, tuning-forks (560 v. s. and 1,200 v. s.) which were heard through the air, and the tone reproduced by the patient's singing, normally in the right ear, were heard and reproduced below their pitch in the left ear; otherwise the hearing was equally good in both ears.

The course of this disease is not always the same in all cases. While the clinical picture usually presented is that of a very rapid decline of the hearing power, till complete deafness is reached, the progress in the impairment is in some cases comparatively slow. In cases observed by Politzer, nearly total deafness was present three days after the onset of the disease. Concussion of the head, sometimes of slight degree, will occasionally cause a rapid increase in the deafness in these cases (Politzer, Troeltsch, Urbantschitsch, Gruber). Fluctuation as the deafness so less often observed in the disease than in affections of the middle ears. The vertigo, unsteadiness of gait, and tendency to [illegible] generally continue for a few weeks or months and then gradually disappear. The hardness of hearing unfortunately very frequently remains, and in the few cases which recover the improvement takes place very slowly.

Syphilitic disease of the labyrinth cannot be distinguished from disease of this part due to other causes, by the special symptoms or the hearing tests employed. The sudden onset of the disease and the rapid progress of the deafness for the most part, together with the absence of bone-conduction, are regarded by many authors as peculiar to the syphilitic form of this disease. The present writer has, however, seen quite a number of cases presenting such a history in which syphilis was entirely out of the question, and therefore cannot regard the above-mentioned symptoms as characteristic of syphilis of the inner ear. If, however, the train of symptoms described occurs in connection with unmistakable evidences—in the skin, throat, or other parts of the body—of constitutional syphilis, or in an individual with a clear history of syphilis, we may assume with much confidence that the labyrinth disease is due to the invasion of syphilis. In the absence of a history or of other symptoms of syphilis, our suspicion as to its presence should be aroused, nevertheless, and we should make a searching examination for its presence in all cases of sudden loss of hearing, unaccompanied by pain, occurring in vigorous young or middle-aged persons whose nervous system was in a healthy condition previous to the attack, and in whom traumatism or other plausible causes of the deafness can be excluded (Schwartze). In several of such cases in which syphilis was absolutely denied, Politzer was enabled by a rigorous search to prove conclusively that constitutional syphilis was the basis of the ear disease. In this connection it should also not be forgotten that an outbreak of tertiary symptoms may occur after a long period of apparently good health.

The differential diagnosis between this disease and affections of the middle ear involves no great difficulty in recent cases. The absence of objective symptoms of middle-ear disease and the results of tests with tuning-forks and the piano will decide the diagnosis. The case is, however, entirely different if well-marked signs of middle-ear disease are present, and more particularly if both ears are diseased and the loss of hearing has developed gradually. Under these circumstances the results of even the most patient examination with tuning-forks and the piano will often leave it undecided whether one or the other or both parts are diseased. The supervention of syphilitic disease of the labyrinth upon middle-ear disease may be inferred from the history of the case, the suddenness of the increase in the hardness of hearing, and the result of the hearing tests previously mentioned.

So far as is known to the present writer, Roosa (op. cit., p. 613) is the only author who thinks that we are justified in going a little farther in our classification than merely to state this is a disease of the labyrinth. We may perhaps, he says, diagnosticate disease of the cochlea, or at least say that the affection of the cochlea is predominant in certain cases (great impairment of hearing, inability to hear certain tones, and the production of false tones), just as we may speak of disease of the semicircular canals, when vertigo and staggering gait are the predominant symptoms. To such cases he applies the name of syphilitic cochleitis.

With regard to the pathological anatomy of syphilitic disease of the labyrinth, it must be admitted that our knowledge is still in a very unsatisfactory state. Indeed Schwartze, than whom no one is better qualified to express an opinion on this subject, does not hesitate to say that we have no anatomical knowledge whatever of this disease, and that the pathological changes in the labyrinth found by Toynbee, Gruber, Moos, Politzer, and others, of which a brief account will be given farther on, cannot be regarded as specific, since the same alterations occur in non-syphilitic cases. The condition of the organ of hearing found post mortem in individuals in whom syphilis and ear disease were known to have existed, was as follows. In a case of secondary syphilis with catarrh of the middle ear, described by Voltolini, there was found hyperaemia of the vestibule, of the commencement of the cochlea, and of the horizontal semicircular canal, and hyperostosis confined to the parts surrounding the fenestra ovalis. Gruber found in a syphilitic subject who had become suddenly totally deaf, and who died from typhus fever, considerable hyperaemia of the mucous membrane of the tympanic cavity and of the membranous labyrinth, which appeared much thickened. The fluid in the labyrinth was abundant in quantity and bloody in color. It is not stated that a microscopic examination was made. Whether the changes found in this case were the result of syphilis or of the typhus must remain undecided.

Moos made an examination of the right petrous bone of a woman, forty-nine years of age, who had been very deaf on this side and blind in her right eye since her seventeenth year. The deafness and blindness were attributed by her to washing her head while in a state of perspiration. In the history of the case it is said that she had been treated for syphilis, but whether the infection occurred before or after the development of the deafness is not stated. She died from intracranial disease. At the autopsy, made by Professor Arnold, parts of the right parietal bone were found to be atrophied in consequence of gummy tumors. There were gelatinous oedema of the pia mater and hydrocephalus internus. In the right corpus striatum was found a fresh, diffuse haemorrhage. Old syphilitic scars were seen in the liver. The examination of the petrous bone, made by Moos, showed, besides alterations in the drum membrane and in the tympanic cavity, productive ostitis in the posterior semicircular canal. The stapes was firmly united with the oval window. The membranous structures of the vestibule and the membranous semicircular canals were in part intimately attached to the periosteum by connective-tissue bands, with the exception of the posterior membranous semicircular canal, which was much thickened but not adherent to the periosteum. In those parts of the semicircular canals which could still be isolated, the epithelium and the connective-tissue membrane were no longer distinguishable. They were covered partly by innumerable large and small cells lying close together. The bands of newly formed connective tissue between the periosteum and the connective-tissue membrane were also infiltrated with cells. The form and structure of the membranous portion of the vestibule were obliterated by a thick layer of hyperplastic connective tissue which covered the membrane almost everywhere. In some central places of the membrane, where the tissue was less opaque and more reticulate, the described infiltration of cells could, however, be observed. Where the newly formed connective tissue was most abundant there were seen numerous isolated, and in some places aggregated, globular concretions of phosphate of lime. The lamina spiralis was of a brown color; it was much thickened and appeared under the microscope very opaque, very vascular, and infiltrated with numerous cells; of its several zones only the denticulate region could be made out.

Commenting on the above Moos says: "The above described anatomical lesions of the organ of hearing furnish a sufficient explanation of the total deafness during life. Leaving out of account the myringitis which supervened toward the end of life, the deafness was due to the anchylosis of the stapes and the chronic inflammation of the labyrinth. Very probably this condition resulted from secondary syphilis, although the microscopic data would not of themselves point to it as a specific cause. As far as I know, we have not as yet reliable anatomical signs of syphilitic inflammation of the labyrinth. We know too little of the pathological anatomy of the labyrinth to be able to decide this question."
